The principle of conductivity detection is the measurement of conductivity variation of the analyte solution with respect to the background solution. The basic configuration of conductivity detection involves two electrodes which can either be placed in direct contact with the analyte solution, namely contact mode, or can remain external and are capacitively coupled to the solution, namely contactless mode. Usually, An AC voltage is applied across the two electrodes, and the electrical conductivity signal is measured. When the analyte flows in and replaces the background electrolyte, a change in the conductivity of the solution is induced. The concentration of the analyte is directly related to the change in conductivity, which is given by [4]

$$C = \frac{A}{L}\sum_{i=1}^{N}\lambda_i c_i \tag{8}$$

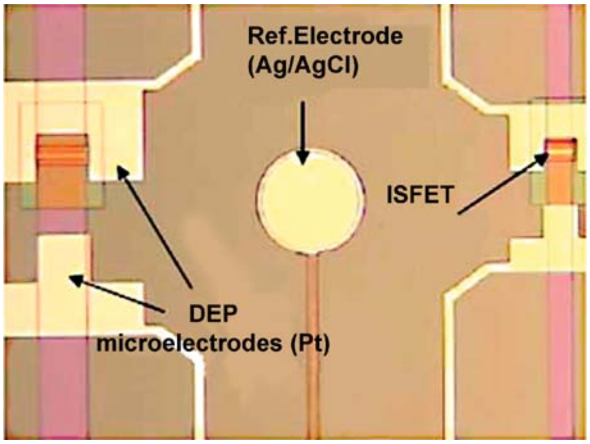
where C is the conductivity of the analyte solution, A is the electrode surface area, L is the distance between two electrodes, N is the number of ions, c_i is the concentration of the ion i and λ_i is its molar conductivity.

Amperometric detection refers to a detection method in which the current is proportional to the concentration of the species generating the current. It consists of two electrodes, a working electrode and a reference electrode, across which a DC voltage is applied. A redox reaction is induced at the working electrode when analyte solution flows in between two electrodes and the current change is monitored. The current response is directly proportional to the number of moles of analyte oxidized or reduced at the working electrode surface as described by Faraday's law:

$$i(t) = \frac{\mathrm{d}Q}{\mathrm{d}t} = nF\frac{\mathrm{d}N}{\mathrm{d}t} \tag{9}$$

where $i(t)$ is the current generated at time t, Q is the charge induced at the electrode surface, n is the number of moles of electrons transferred per mole of analyte, F is the Faraday constant and N is the number of moles of analyte oxidized or reduced.

Potentiometric detection is based on the induced potential on a membrane which is semipermeable and ion-selective. When certain ions pass through the semipermeable membrane while others do not, different ion activities at both sides of the membrane result in the buildup of a potential difference which is measured and monitored against a fixed potential of a reference electrode. A unique feature of potentiometric detection is that the detection signal does not scale down when the size of the electrode decreases.



Lab-on-Chip Devices for Separation-Based Detection, Figure 2 Photomicrograph of the central part of a microchip incorporating DEP positioning and EC detection, showing the central Ag reference electrode and two sets of ISFET and DEP microelectrodes [7]

The potential response of the membrane electrode is given by the Nicolsky–Eisenman equation:

$$E = E^o + \frac{GT}{F}\ln\left(\sum_{i=1}^{N} K_i^{\mathrm{pot}} c_i^{1/z_i}\right) \tag{10}$$

where E is the electrode potential, E^o is a constant, G is the universal gas constant, T is the temperature, F is the Faraday constant, K_i^{pot} the selectivity coefficient of the species i, c_i is its concentration and z_i is its charge.

Key Research Findings

There are many good review papers discussing Lab-on-Chip devices for separation-based detection [5, 6]. Only four representative examples are selected to illustrate separation and detection principles, and to identify challenges in this rapidly emerging research area.

Integrated Microchip Incorporating DEP Positioning and Potentiometric Detection

Castellarnau et al. [7] demonstrated a miniaturized microsystem integrating DEP-based positioning and EC detection together. The chip included ion-sensitive field effect transistors (ISFETs), a single pair of castellated microelectrodes and a reference Ag/AgCl microelectrode. An ISFET is a type of EC sensor based on potentiometry, where the gate area is sensitive to ions and is open to contact with the liquid while the source and drain leads are carefully encapsulated. The current flowing through the transistor will change as the ion concentration of the solution changes. The ISFET sensing membrane was

positioned at the minimum electric field region where cells were directed to by nDEP force. Figure 2 shows the central part of the chip. Cell position can be manipulated by adjusting the amplitude and frequency of the applied AC voltage across DEP microelectrodes. In their experiments, yeast cells were detected when a voltage of 8 V peak to peak at 20 kHz was applied and *E. coli* cells were detected when a voltage of 10 V peak to peak at 500 kHz was applied. The width and length of the ISFET sensing area are 60 and 10 μm respectively. The dimension of the internal U-shaped area of the positioning microelectrodes is 70 μm × 70 μm. Although the researchers only demonstrated the positioning and detection of one type of cells at one time, the microsystem has potential for the separation and detection of viable and non-viable cells based on pDEP and nDEP force experienced by the two types of cells.

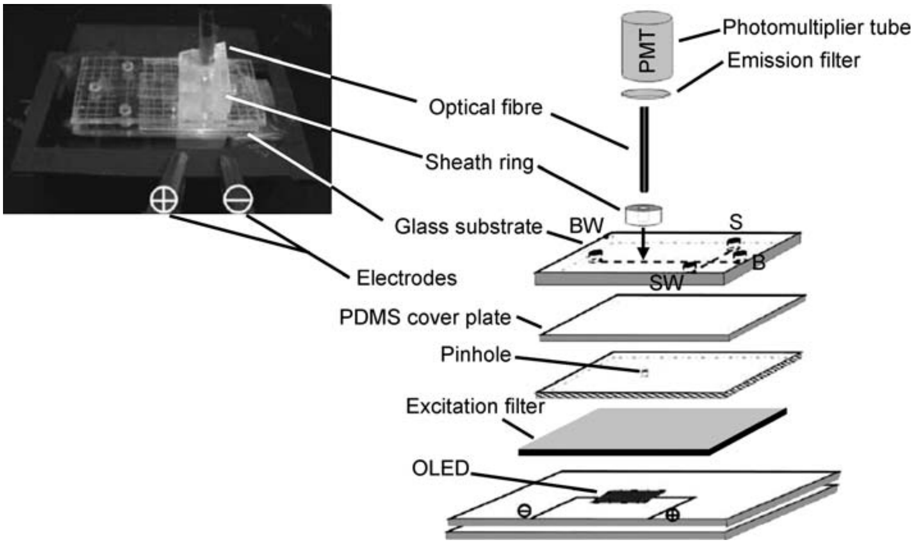
Integrated Microchip Incorporating CE Separation and Contactless Conductivity Detection

Kubáň et al. [8] provided a comprehensive report evaluating the effects of electrode geometry and operating parameters on the performance of capacitively coupled contactless conductivity detection (C^4D) for microchip CE. Unlike the contact conductivity EC detection, the sensing electrodes in C^4D were not in direct contact with the analyte solution but were placed on the surface of the separation device. A schematic representation of the assembly is shown in Fig. 3(a). The current reflecting the change of ion concentrations in the analyte was measured when a voltage was applied across the two sensing electrodes. The researchers fabricated several microchips to investigate the seven major factors that could affect the performance of C^4D. The seven factors are:

- the configuration of the electrodes;
- the electrode length;
- the electrode width;
- the size of the gap between the electrodes;
- the stray capacitance which resulted from direct capacitive coupling between two electrodes;
- the distance of the electrodes from the capillary channel; and
- the excitation voltage and feedback resistor which was used to convert the induced current to the output voltage.

The researchers successfully demonstrated the separation and detection of six ions (NH_4^+, K^+, Ca^{2+}, Na^+, Mg^{2+}, Li^+) in real water samples using a C^4D with optimized electrode geometry and operating parameters based on the



Lab-on-Chip Devices for Separation-Based Detection, Figure 5 Geometry overview and optical setup of a microchip incorporating CE separation and fluorescence detection [10]

understanding of the seven performance-affecting factors. The width, height and effective length of the CE separation channel were 50 µm, 50 µm and 75 mm respectively with a separation voltage of 3 kV. Anti-parallel detection electrode configuration shown in Fig. 3b was used for C^4D with the length, width and gap size being 1.4 cm, 1 mm and 0.5 mm respectively. The distance of the electrodes from the channel was 175 µm, being the thickness of the poly(methyl methacrylate) cover on the separation channel. The excitation voltage, frequency and feedback resistor were 20 V peak-to-peak, 500 kHz and 2.2 MΩ respectively.

Integrated Microchip Incorporating CE Separation and UV Absorbance Detection

Ro et al. [9] developed an integrated light collimating system incorporating a microlens, a pair of slits for extended optical path length and optical fibers for UV absorbance detection in a CE microchip. They fabricated three different detection units shown in Fig. 4a. Unit A was the simplest form with only two optical fibers on both sides of the separation channel, unit B was based on unit A and was incorporated with an extended optical path length and unit C was based on unit B but was equipped with an integrated light collimator consisting of a focusing microlens and a pair of slit channels. The microchip was fabricated by stacking three PDMS layers and Fig. 4b shows how unit C was arranged. Each unit had a pair of channels used for inserting optical fibers for the excitation and transmission light, whose size was 125 µm wide and 127 µm deep (50 µm from top plate, 27 µm in middle plate defining the depth of the separation channel, and 50 µm from bottom plate). A microlens with a radius of 50 µm was formed at the end of the excitation optical channel to collimate the divergent excitation light through an aperture. Another aperture was formed in front of the transmission optical channel. The 3D slit channels used to form two apertures were filled with black ink and sealed to serve as a barrier to prevent the vertically undesired divergent excitation light from entering the transmission optical fiber. The separation channel length from the injection point to unit C was 25 mm and a voltage of 1.5 kV was applied across the separation channel for CE. Separation detection of three reagents, fluorescein (10 µM), orange II (120 µM) and new coccine (60 µM), was completed after around 45 s for unit A and after around 63 s for unit C. An argon ion laser with a wavelength of 488 nm was used as the excitation light source. The researchers reported an approximately 10 times increase in sensitivity for unit C over that of unit A due to the 10 times longer optical path length of unit C [9]. The researchers also obtained 3.8% of stray radiation readout fractions for unit C compared with 31.6% for unit B, which was believed to be the significant reduction of the divergent and scattered light using the microconvex lens and slits of unit C.

Integrated Microchip Incorporating CE Separation and Organic Light Emitting Diode (OLED)

Yao et al. [10] presented a microfluidic device using a green organic light emitting diode (OLED) and a thin-

film interference filter as integrated excitation light source applied to fluorescence detection of proteins based on CE separation. Figure 5 shows the geometry overview and optical setup of the microchip. A p-n diode bottom emitting structure serving as the OLED was first fabricated on a 0.5 mm thick glass substrate. The OLED structure had an array of 250 μm × 250 μm illuminants which operated at 4.5 to 12 V and emitted green fluorescence with a peak excitation at 520 nm and approximately 60 nm bandwidth. The relatively wide excitation spectrum had an overlap with the emission spectrum, which increased the background noise and degraded the detection sensitivity. Thus, the researchers fabricated a thin-film interference filter of 300 μm in thickness consisting of 30 alternating layers of SiO_2 and TiO_2 to block nearly 80% of the unwanted light before entering the microchannel and the receiving optical fiber. A 12 μm thick silver foil with a pinhole used to confine the detection region was inserted between the excitation filter and a PDMS cover plate (100 μm in thickness). The microchip containing capillary microchannels was placed on top of the PDMS cover plate. The microchannels were 70 μm deep and 100 μm wide with a separation channel being 3 cm long and a sample channel being 1.5 cm long. An optical fiber of 500 μm in diameter was inserted into a 1 mm deep hole and was placed 0.7 mm above the separation channel to collect fluorescence signals. The researchers characterized the driving voltage for the OLED and found that high sensitivity and stable output were obtained at 12 V. The size of the pinhole also had an effect on the detection signal. The researchers found that a pinhole of 200 μm in diameter was the optimal dimension. In one of their experiments, CE separation was performed at 1.4 kV and two components, hydrolytes and photolytes of 140 μM Alexa 532, a fluorescent dye, were successfully separated and detected in less than 110 s. In another experiment, separation and detection of bovine serum albumin (BSA) conjugates labeled with Alexa 532 in less than 200 s was demonstrated. The researchers confirmed that the sensitivity of fluorescence detection was improved by using the thin-film excitation filter eliminating the undesired light.

Future Directions for Research

One important research trend in separation-based detection is to integrate more laboratory functionalities on the same chip to provide a complete device encompassing all that a macroscopic biochemistry laboratory has to offer. The second trend is to develop and explore biocompatible materials instead of traditional semiconductor materials to fabricate Lab-on-Chip devices. A typical example is cell manipulation where the materials that are in contact with the cells should maintain the natural states of the biological samples by not adversely affecting the cells. Another trend is to incorporate different separation techniques other than EP and DEP with the detection techniques for suitable applications.

Definition

Lab-on-a-Chip is a field of research and technological development with the goal of integrating onto monolithic platforms the micro(nano)fluidic functionalities and components necessary to accomplish one or more biochemical or chemical processes – often analytical – in an autonomous, typically parallel fashion, using orders-of-magnitude less sample, reagent, power and manual manipulation than conventional laboratory methods and instruments. The most highly integrated Lab-on-a-Chip devices include all processes and devices on a single chip or card so that the introduction of an unprocessed sample leads to the output of an analytical result – an "answer" – from that same chip. This is the *sample-to-answer* philosophy of Lab-on-a-Chip devices.

Principles

Imagine standing in a chemistry, biology or clinical laboratory and observing the activity: a chemist deciphering the composition of a new substance, a biochemist developing a new drug to cure a disease, technicians analyzing patients' blood samples for pathogens or diagnostic markers. Now, imagine the possibility of devices, some as small as electronic microchips, none much larger than a human hand, that perform these and many other laboratory tasks without human intervention, providing a more efficient, rapid and reliable way to detect the composition of a substance, to develop not just a new but a more effective drug, or to provide more comprehensive information about a patient's state of health. This possibility is gradually becoming reality; this article examines how such devices are developed, what impedes widespread implementation of the Lab-on-a-Chip vision and how implementing this philosophy generates advances in basic science and applied technology.

In general, laboratory processes, including biochemical or chemical syntheses, analytical assays and in vitro experiments with microorganisms, involve manipulation of samples and reagents and, in many cases, the subsequent detection or quantification of analytes using detectors and instruments. Diverse labware, balances, dispensers, mixers, filters and incubators, together with instruments such as spectrometers and chromatographs, enable such processes. Volumes from tens of nanoliters to many milliliters of solutions are typical. Time-consuming manipulations are carried out by a variety of personnel; qualified technicians operate costly equipment and instruments. It is remarkable, with feats of modern engineering surrounding us – particularly the many examples of miniaturization and automation – that some procedures have changed very little in more than a century, still relying on skilled human labor. How is it possible that such procedures, particularly the most common, have not been integrated into automated systems?

Decades ago, the manufacturing industry began adopting automation systems in the form of robots, increasing productivity, reducing costs, minimizing human error and avoiding hazardous situations. Clearly, automatic systems could mechanize many of the human manipulations in assays; except for minimizing human labor and error, however, merely automating established, lengthy procedures in their human-executable form provides minimal benefit in terms of time, efficiency, operating cost or other measures of performance. Still, criticizing modern engineering for failing to address the needs of complex laboratory manipulations and measurements would be unjust: flow-injection analysis (FIA) systems automate liquid handling and analysis for tiny samples; the fluorescence-activated cell sorter (FACS) analyzes and sorts single cells at rates near 100,000 per second; laboratory automation is a thriving commercial endeavor, with robotic dispensers, multiwell plate conveyors, plate-reading spectrometers and incubators linked together for high-throughput automated assays. Mass spectrometers and DNA sequencers, along with their sample-introduction *front ends* and software, are impressive examples of engineering integration applied to difficult analytical challenges. Impressive indeed, but the sizes of these instruments dwarf the scale of the samples they analyze: µl or pg of biological cells, biopolymers or small molecules. Furthermore, while the human genome sequencing project owes its ahead-of-schedule finish to the automated DNA sequencer [1], as much as 75% of the cost of sequencing the genome was associated with sample preparation involving manual manipulations, with highly automated electrophoretic sequencing accounting for just 25%. Protein analysis (proteomics) and drug candidate screening also need new tools to process large numbers of samples in a specified time period, i. e. they have throughput requirements to attain economic viability [2].

Simply automating human-executed steps or applying conventional automation and instrumentation engineering to laboratory procedures are not in accord with the Lab-on-a-Chip philosophy. Rather, to realize the vision of major scale-down, comprehensive integration and massive parallelization of laboratory tasks, new paradigms and architectures must be developed to shrink and adapt sequences of laboratory processes to the components and methods of microfluidics. The newly integrated Lab-on-a-Chip tools often must provide better limits of detection or enhanced resolution at lower cost than the laboratory systems they replace in order to be adopted by practitioners of traditional laboratory methods.

Can modern science and technology lead to the attainment of such ambitious goals? Are miniaturization and integration invariably beneficial? Can complex manipulations in fact be replaced by on-chip operations? How is all this to be accomplished? The following sections address these questions.

Historical Perspective

The use of modern microfabrication technologies to construct and integrate the components of miniaturized analytical instrumentation was inaugurated some 30 years ago when researchers at Stanford described a microfabricated gas chromatograph (GC) constructed on a single silicon wafer [3]. Just a few years earlier, advances in glass capillary-based chromatography had shown that high-performance separations were possible using column cross-sections measured in µm, provided column lengths were measured in cm to m. Advances in conventional chromatography were made in both gas and liquid phase, with the improved performance of liquid chromatography (LC) giving rise to the term *high-performance liquid chromatography* (HPLC).

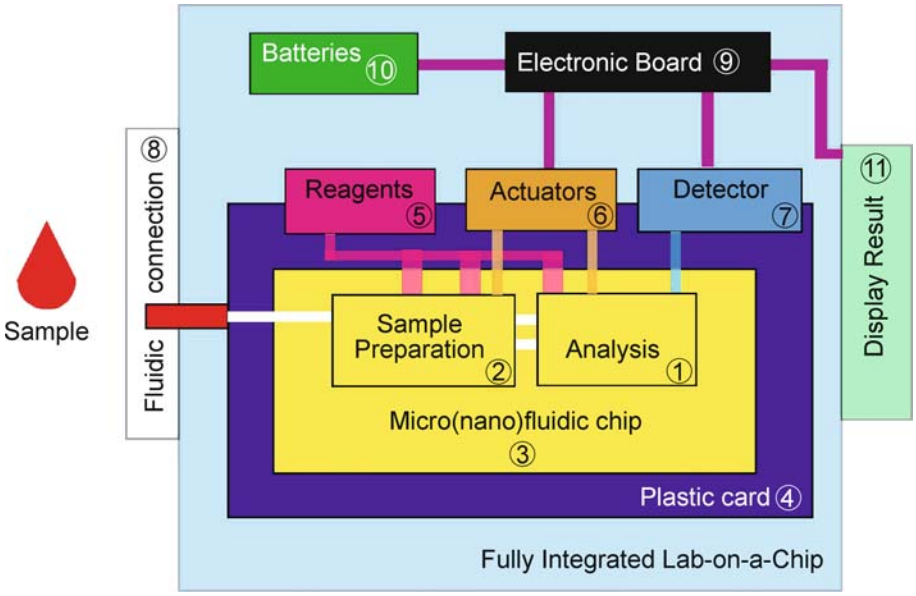
Comparable utilization of the tools of microfabrication for liquid-phase analyses came a decade later, when electrokinetic phenomena were proposed to separate dissolved species on chips: the application of a high electric field between the ends of a small-diameter column or channel can both transport and separate dissolved species in conductive solution without moving mechanical parts. The concept of *chip-CE* (capillary electrophoresis) was first described in the patent literature in 1990 [4], wherein CE separations are performed in microfabricated columns or microchannels on planar substrates. At the same time, publications appeared detailing the concept of integrating separations and other processing steps on a chip, extolling its potential to revolutionize chemical analysis [5].

Research and development of chemical and biological sensors preceded the first chip-integrated analytical separations systems by a decade or more, but the considerable enthusiasm for the elegant *immerse-and-read* sensor-based analytical method was damped by the realization that requirements for low limits of detection (LODs), high chemical specificity and rapid reversibility can be contradictory. This made the *ideal* sensor an elusive, often unattainable goal: rapid reversibility requires small interaction energies, while high specificity and low LODs imply strong binding. This potential Achilles' heel applies to some of the most important samples. Medical analytes, as well as many environmental, health-and-safety and industrial process-control samples, are often (bio)chemically complex mixtures, typically requiring one of three strategies to avoid errors due to interference with the target analyte: high selectivity, usually with accompanying irreversibility – making the sensor a dosimeter for all practical purposes; use of an array of sensors, wherein the pattern of responses from multiple partially selective sensors provides chemical discrimination without loss of reversibility; or coupling of the sensor – which in effect becomes a detector – with a chromatographic *front end* that separates complex mixtures into their components.

Many samples, both biological and chemical, require not only separation of interferences to provide meaningful sensor response, but may also require significant processing to cleanse the sample of debris, to add reagents, to change the concentration of background ions or change the solvent, to attach readily detectable *labels* to the target species, to carry out thermally stimulated reactions or to enhance LODs by pre-concentration or replication (termed *amplification* for nucleic acids) of the target species. Because of the success in miniaturizing LC, instead of employing traditional methods that use tubing to connect components and glassware for sample processing, scientists and engineers have embraced the Lab-on-a-Chip philosophy to miniaturize and integrate the purification, isolation, reaction, concentration and separation steps and, where applicable, the detectors or sensors, into one integrated chemical analytical system [5–7]. Because many such systems have analysis as the end goal, they are frequently referred to as micro-total analytical systems, or µTAS; the central role played by fluidics on the micrometer scale (detailed in the following sections) has resulted in these systems often being called simply *microfluidic devices*. Regardless of nomenclature, the Lab-on-a-Chip philosophy, even as it enables analyses not possible with discrete sensors alone, signals a paradigm shift in the way laboratory work is performed.

Miniaturization

The advantages of reducing the size of an integrated (bio)chemical processing/analysis system can be signif-



Lab-on-a-Chip (General Philosophy), Figure 1 Illustration of a fully integrated Lab-on-a-Chip (LOC) system, with components numbered according to their (approximate) historic integration with other LOC components, prevalence of research activities and publications that include that level of integration, and criticality of integration in order to accomplish an effective analysis. Historically, the analysis component (1) was first to be miniaturized and is indispensable to detect the analyte; it often includes a separation process. Sample preparation (2) is often required to make real-world samples amenable to analysis; the core microfluidic chip (3) thus consists of these two components connected by microchannels. For systems to be manufactured inexpensively in large volumes, the microfluidic chip might be fabricated on a plastic card (4) or other supporting substrate. Reagents (5) may be needed for sample preparation or analysis, for example to label the analyte with fluorescent molecules. Actuators (6) to motivate and regulate fluid movement through the various modules of the microfluidic chip can be integrated (or supported) on the same plastic card with the microfluidic device or remain external. The detector (7) is more often integrated in the case of electrical (electrochemical, impedance) detection approaches than for optical transduction. Sample is introduced to the chip through fluidic connections (8). An electronics board (9) controls the system and collects data; batteries (10) power the system. Following analysis with the aid of software, the answer is displayed (11)

icant, with overall enhancement of performance, measured in various ways, emerging as a common theme. Specific benefits can be deduced by assessing how some parameters, such as volume, reaction time and device density, change as the system is scaled down in size [2, 8]. Imagine a reaction of sample and reagent carried out in two different-sized cube-shaped flasks with edge length d. The first flask ($d = 1$ cm) is a macrosystem: it has a volume of 1 ml. The second flask ($d = 100\,\mu$m) is a microsystem: it has a volume of 1 nl. The 100-fold reduction in linear dimension results in a million-fold decrease in volume. Other factors being unchanged, the microscale system requires a million times less sample and reagent volume to perform an assay, so many times more analyses can be performed with the same amount of solution. Less chemical waste is produced; expensive reagents are consumed in smaller quantities. Also, chemical reactions including highly toxic or reactive species that are prone to cause accidents in laboratories are more easily controlled and safer using miniature systems because lower volumes mean less hazardous material and lower risk of thermal runaway.

Another relevant parameter is device density, which is well represented here by the number of reaction vessels per unit area. In the context of the two systems compared above, 100 vessels in the macrosystem would occupy 100 cm^2; in the microsystem, they occupy 1 mm^2, a 10,000-fold reduction in surface area. Further reducing the edge length of the vessels to 1 μm (assuming no space is required between adjacent reactions) would fit 10^{10} simultaneous reactions in the same area.

Now, for the same systems, consider a concentration of a certain *target* molecule of one nanomolar (nM). There will be almost 10^9 target molecules in the macrosystem and 1000 molecules in the microsystem. Further reduction of the edge length to 1 μm, easily attainable with current microfabrication techniques, provides just 1 molecule per μm^3. One must then consider the interplay between dimensions, numbers of molecules and detection: single-molecule detection is possible, but very challenging to implement on-chip, very limiting as to choice of detection

technologies and, at the single-molecule level, probability considerations mean that detection will only be successful some of the time.

Agitating and stirring (forcing convection) of a multicomponent solution or mixture of multiple solutions reduces the time for the solution to become homogeneous (completely mixed). Length, volume and concentration reductions in the microsystem require scale-specific assessment of the behavior of fluids and molecules in a restricted space. A localized group of molecules having a diffusion coefficient of 10^{-5} cm^2/s requires about one day to evenly diffuse, or spread, throughout the macrosystem in the absence of convection; in the microsystem, this process takes 10 s, and diffusion across 10 μm takes just 100 ms (diffusion time scales with the square of length). Such short diffusion times can allow reaction rates to be limited only by how fast the reaction takes place (reaction kinetics), rather than by forced movement of the substances involved.

In addition to performance enhancements related to volume, time and density of reactions, miniaturization also improves performance by other measures, for example, separations efficacy [5, 8]. Some components, however, are proving challenging or unsuitable for miniaturization or monolithic integration because of inherent complexities in their design [8], for example ultrahigh-sensitivity detectors. Attempts to miniaturize macrosystem components are often motivated primarily by gains in performance and time rather than a desire to minimize space [5], although some biomedical applications for which wearable or hand-held sensing systems are necessary, as well as remote military and aerospace applications, often place a high premium on size, mass and power.

Microfluidics: Fluid Movement and Handling

Fluid manipulation and transport of samples and reagents are often implemented in a network of microfluidic channels that interconnect the various components on a common substrate. These microchannels have dimensions ranging from hundreds of nm to hundreds of μm – comparable to, or in many cases much smaller than, a human hair. Flow in microchannels behaves very differently than in *macrochannels* such as laboratory tubing, water pipes or a river.

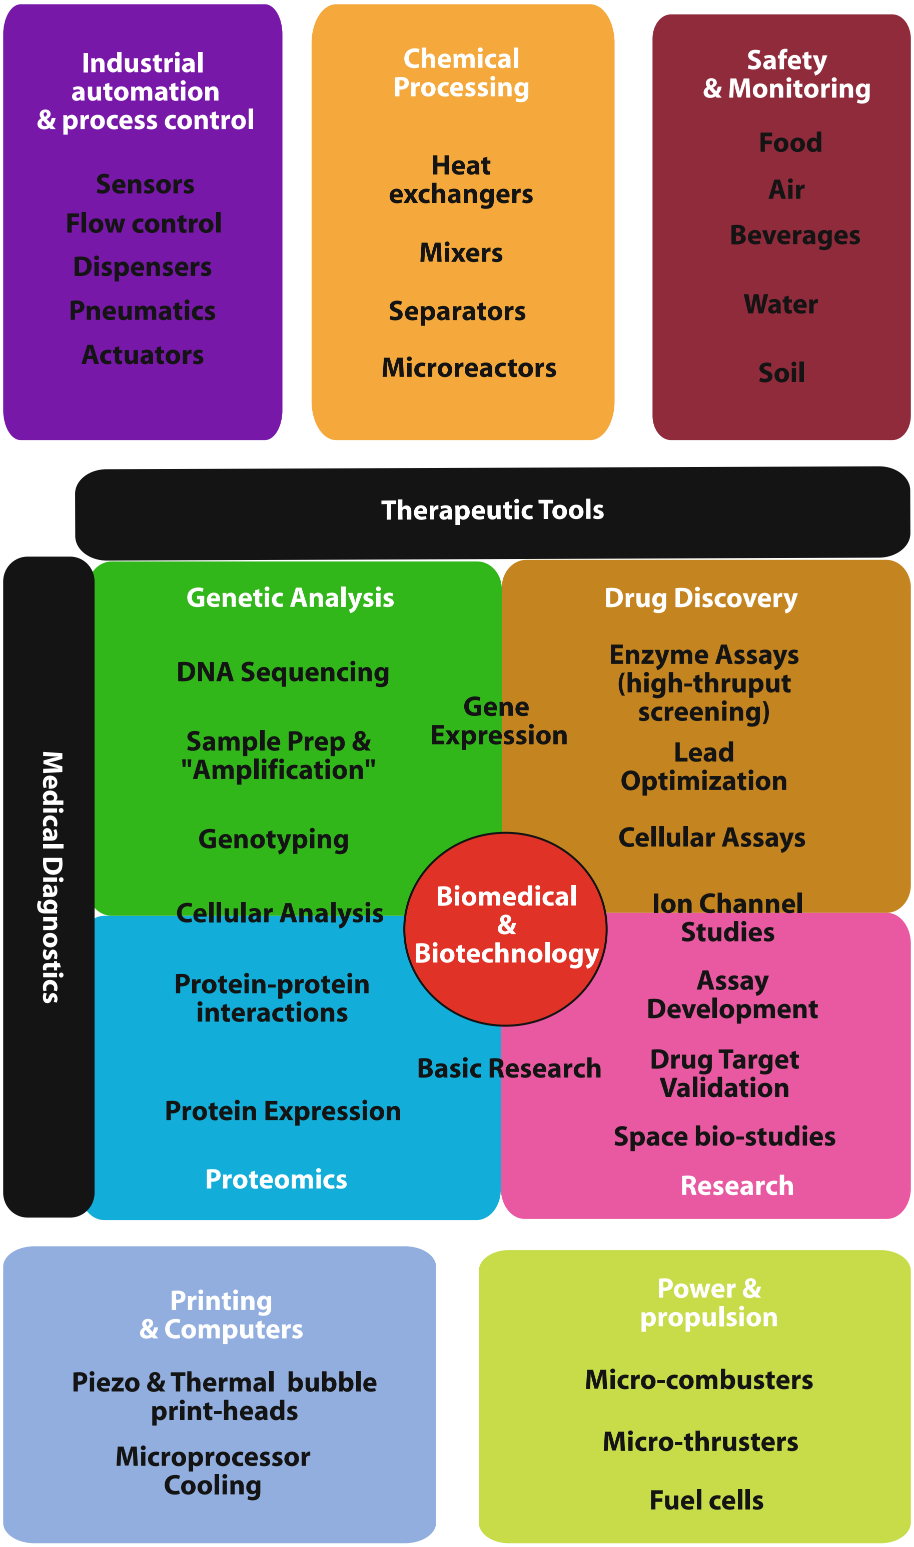
In microchannels, the viscosity and, in many situations, the surface tension of the fluid dominate inertial (mass-related) forces. Thus, fluid movement shows a smooth, predictable behavior known as laminar flow [9]. Turbulence in microchannels is always negligible, although in-channel convection (without turbulence) can be created in a number of often complex ways: rapid, effective mixing has proved to be one of the most interesting and well-studied fundamental challenges in microfluidics. In many cases, Fickian diffusion alone, without any deliberately created convection, is relied upon for mixing because of its rapidity on μm length scales, but the system must be carefully evaluated when taking this approach: two streams of liquid flowing parallel to one another in a 200 μm-wide channel at a velocity of 1 mm/s over a distance of 3 mm would have to be slowed by a factor of 3 to 30 (depending on the diffusing molecules) to mix to better than 95% homogeneity before exiting that short channel.

Because of the properties of microchannels, such as the material and coating of the surface, the high surface area-to-volume ratios can affect the behavior of the flow. Surface effects, many depending on interfacial tension (surface energy), can give rise to interesting applications such as the formation of droplet emulsions, the use of capillary forces to pump fluid and the modification of the surfaces to create hydrophobic-stop valves [9]. Also, high surface area-to-volume ratios facilitate rapid and controlled heating and cooling. Surface effects and topography (the route of the channel) define flow motion in the microchannel. The control and consequences of various microchannel characteristics make them useful as components in their own right. For example, by changing their geometry they can be used as mixers, filters, injectors, separators and the like [5, 9]. Other fluidics-relevant physical phenomena, including electrokinetic, acoustic and thermal effects, are described in a recent review [9].

Fabrication

The development of microfluidic devices has been both limited and spurred by limitations of and advances in the materials they are built from and how they are made. Without a doubt, the microelectronics industry gave a critical first impulse to the field by lending its microfabrication tools. Even today, the fabrication techniques used to make microfluidic devices are influenced by advances in the microelectronics industry.

Glass is ubiquitous in laboratory manipulations, while plastic dominates many modern molecular biology, biochemistry and drug development laboratories. Glass does not react with most substances and is optically transparent; certain plastics are biocompatible, readily moldable into complex structures and inexpensive enough to be discarded after a single use. The first microfluidic devices used glass or silicon as the substrate material, both substrates relying on microelectronics industry-type patterning methods. However, the time, cost and special (etching) facilities needed to fabricate devices with these methods and materials initially deterred some researchers



Lab-on-a-Chip (General Philosophy), Figure 2 Applications of Lab-on-a-Chip technologies

from entering the field. New fabrication techniques for microfluidics based on *soft polymers* as well as traditional thermoplastics began to be developed in 1991 [3], but not until the end of the 1990s were these approaches more widely described [10] and adopted for rapid prototyping of devices at minimum cost [6]. The *soft lithography* technique was quickly adopted as de facto for fabrication of biologically focused microfluidic devices in academic laboratories. Unfortunately, soft polymers are incompatible with many organic chemicals, including small molecules of interest in drug development; this approach has yet to be proven for mass fabrication of a commercial microfluidic device. Plastics are much "in vogue" nowadays, mainly because they are readily prototyped and suitable for manufacturing with long-standing techniques, such as hot embossing and injection molding, but also because they are inexpensive as a material and very familiar to the life sciences. To date, no single standard material has been adopted for the fabrication of microfluidic devices.

The Lab-on-a-Chip Concept

Scientists and engineers from diverse disciplines – physics, chemistry, biology and computer science, together with mechanical, chemical, electrical and materials engineering – have broadened the approaches and concepts of μTAS and microfluidics. Contributions from and interactions among these fields have created more complex, sophisticated and novel devices, which, together with the merging of the μTAS and microfluidics concepts, have led to the field of research and technology called Lab-on-a-Chip (LOC). The reader should note that these three terms, Lab-on-a-Chip, microfluidic devices and micro-total chemical analysis system, are often, and erroneously, used interchangeably.

The workhorse and core of a LOC is the microfluidic system. Built around it is some combination of detectors and sensors, actuators, electronic controls (microprocessors, field-programmable gate arrays, A-to-D converters, etc.), software and reagents [7]. The microfluidic device consists of microchannels and components that effect operations such as filtration, pre-concentration, washing, mixing, purification, isolation and separation. The configuration of the components of a microfluidic device should be dictated by whether the goal is to synthesize a compound, to grow an organism, to detect the presence of a target or to determine the concentration of an analyte.

Analysis requires appropriately sensitive and, if separations are not part of the fluidic system, selective detectors; these have varying degrees of sensitivity, accuracy, performance, ease of integration and cost. Common detector technologies include optical, electrochemical, magnetic, impedimetric (conductance and/or capacitance), mechanical and thermal. The specific type and configuration of detector depends on the details of the application. Non-optical detectors tend to be less sensitive and, in some cases, less selective (optical detectors can include wavelength-based selectivity), but are generally smaller than optical detectors and easier to integrate with the microfluidic device.

Optical detection, particularly laser-induced fluorescence, is widely used with microfluidic devices due to high sensitivity, but infrequently integrated on chip. For most optical detection approaches, *labels*, i. e. molecules that fluoresce or strongly absorb light of a selected wavelength, must be (bio)chemically attached to *tag* the analyte, adding an additional, sometimes challenging, process step. The more sensitive and readily implemented optical detectors also require an external optics system, which usually occupies significant physical space, often consumes more power than all the rest of the system and can be the most expensive part of a LOC system.

Unlike optical detection, integrated electrical detectors (impedimetric, electrochemical, most mechanical and thermal, certain magnetic) require electrode interconnections and on-chip electrical *traces* (conductive pathways) to connect to external electronics. Although this is an added complication, it is typically easier to implement than full monolithic integration of an optical excitation-and-detection system.

Actuators, such as valves or pumps, can be either integrated or external to the microfluidic device, and are needed to regulate the movement of fluids in the microchannels. Strict fluid regulation and control is important because the tasks executed by the fluidic components need to be completed in a systematic and timely fashion for the analysis to be successful.

Because vast amounts of information can potentially be generated in LOC systems, and because sophisticated analysis may be required to generate meaningful information from raw data, e. g. for protein analysis or drug discovery, data analysis requires appropriate computational power and speed. Thus, when data volume and analysis complexity are minor, appropriate microprocessors and affiliated components can be integrated in a hybrid fashion with the microfluidics or, more commonly, included on an external electronics board, eliminating the need for an external computer.

Reagents often must be mixed with the sample at one or more process steps to facilitate purification, separation, amplification or labeling (for detection). It is possible, and for many commercial applications desirable, to integrate the reagents in liquid or powder (often lyophilized)

form on the chip. Optimally, the sample will be the only assay component dispensed onto the microfluidic device for analysis or reaction, making the LOC system easier to use, more efficient in reagent and power consumption and more robust to errors in measurement or sequence.

Easily integrable, user-friendly and, ideally, standardized fluidic connections that facilitate microfluidic input/output (I/O) are vital. Because of the varying size of microfluidic devices – sub-mm^2 to the size of a multiwell plate ($> 100\ cm^2$) – a related key challenge is an easy-to-handle, standard user interface.

The term *Lab-on-a-Chip* has been used in a wide variety of contexts. Some of the best-studied applications are in chemical analysis, biological research and medical diagnosis, with many other exciting uses under development, such as chemical synthesis, space studies, industrial automation and process control, fuel cells and power generation, printing devices, and environmental and food-safety monitoring. LOC may refer to a chemical or biological microreactor, a micro-cytometer, a screening tool for drug discovery, a diagnostic device for clinical use or a sampling-and-analysis system for environmental monitoring. The ultimate goal of LOC is to integrate the microfluidic components with detectors, actuators, electronics, fluidic connections and reagents in a single (often single-use) device that enables a complete process, whether synthetic, analytic or life support, in an autonomous and automated fashion.

Key Research Findings

LOC is now an area of intense research and technological development, having grown exponentially in the past two decades. Initially, LOC began by proving its feasibility and justifying its existence: postulating and demonstrating that miniaturization and integration of the components of biochemical and chemical systems were not only possible, but would bring substantial improvement relative to traditional macroscale systems. A vast number of proof-of-concept components have been developed during the past few years and, when successfully integrated together, will form the basis of a range of functional LOC systems.

Simple LOC systems, lacking sophisticated integration and focusing on the detection of a small concentration of a certain molecule or measuring one parameter like pH, are already a reality and have found their way to market [1, 6]. The creation of a LOC that is capable of processing and analyzing high-volume, complex samples with low analyte concentrations, such as the sets of biological markers for cancer or other diseases, remains elusive, though there are a few commercial success stories (http://www.biosite.com; http://www.abbottpointofcare/isat/). Although many of the necessary components are already available or demonstrated, progress in monolithically integrating disparate technologies has been slower than expected.

There are two explanations for why realization of the LOC vision is proving difficult. First, challenges are many, development is gradual and many refinements are needed before the technology is accepted, reliable and robust. Frequently, components are built in vastly different ways, with different geometries or structures, different performance and fundamental incompatibilities. Often, the more effective or successful components require cumbersome fabrication procedures and/or exotic materials. Additional components that would ideally be integrated may require a completely different set of fabrication steps that render integration incompatible with low-cost, automated manufacturing. Clearly, adopting standard components that are robust, give reproducible results, perform well and are amenable to integration is essential for successful implementation of the LOC philosophy. Second, this field, like few others, requires synergistic expertise and multidisciplinary cooperation in engineering, physics, chemistry, biology, computer science. If LOCs are to be applied successfully to relevant and needy problems, engineers and physicists must more often liaise and communicate with biologists or chemists to understand their needs and questions. For success, those working in each of these fields must become knowledgeable in the basics and language of the disciplines with which they interact to make collaborations fruitful. The additional education and training for all the involved parties are essential, so more universities should establish undergraduate and graduate programs encouraging an interdisciplinary, *applications-aware* education [1]. This will expand the ranks of scientists and engineers with the skills necessary to make fundamental and unconventional advances in LOC science and technology [1].

LOC systems have the potential to enhance, perhaps transform, our understanding of cell biology and biochemistry. It is likely they will play a major role in the development of new drugs, and almost certainly in the earlier, more accurate diagnosis of disease. Nonetheless, much is still to be discovered and conceived: the promise of nanofluidics, ways to include optics directly on fluidic chips, the integration of multiple detector types, more efficient means to detect small numbers of molecules, etc. LOC technology is already finding special application niches in environmental monitoring and space exploration, with promise for everything from power generation to therapeutics to information technology. Most importantly, LOCs are poised to impact the world economy and society as a whole, in much the same way as microelectronics technology now shapes our world.

Examples of Applications

Figure 2 shows examples of applications developed and envisioned for LOC technologies. The largest number of applications is in biomedicine and biotechnology, but other fields are benefiting from the advantages of these technologies, including industrial automation and process control, chemical processing, safety and monitoring, power and propulsion, and printing and computing.

Laser machining

Definition

Laser ablation is one of the laser machining processes in which materials are removed in vapor or plasma form directly from the solid state by irradiation of an intense pulsed laser beam.

Overview

Laser machining is a very mature technology. There is a long history of using lasers for cutting, slicing, drilling, marking, welding and surface modification in mechanical and electronic industries. Conventional laser machining is a thermally based process, i. e. a laser beam of high energy density generates highly localized heating on a work piece, causing material to melt and then to vaporise, so that material can be removed layer by layer, according to the depth of photon absorption. Laser ablation, on the other hand, is a non-thermally based process. Laser ablation of metallic materials, whether it is a thermal process or an ablation process, primarily depends on the duration of the laser pulse compared to heat diffusion time. This is not an abrupt but a gradual transition process, because different materials have different thermal conductivities, hence different heat diffusion times. When a laser pulse is longer than the material heat diffusion time, the heat generated by laser energy is accumulated, causing material melting and boiling. Evaporation occurs from the liquid state of the material. There are also other associated processes, such as ejecting blobs of molten material and surface shock waves causing microcracks in the heated zone. The machining quality using long laser pulses is generally poor. For laser pulses shorter than the heat diffusion time, the photon energy deposited in the material does not have time to leak away from the spot by thermal diffusion. So much energy is deposited in the material so fast that the material is forced into a state of plasma. This plasma then expands away from the material as a highly energetic gas (seen as a plume), taking almost all the heat away with it. Essentially, the material goes from a solid to a gas phase without first going through the liquid phase. Consequently, very little heat is left behind to damage the material. Figure 1 compares two holes drilled into a 100 μm thick steel foil, one with nanosecond pulse laser and the other with femtosecond pulse laser [1].

The physics behind laser ablation is much more complicated than as explained above. Three characteristic time scales are involved to define the nature of laser interaction with a metallic material [1]. They are the electron cooling time τ_e, lattice heating time τ_i and laser pulse duration τ_L. For a nanosecond pulse laser, $\tau_L \gg \tau_i$: the process is predominantly laser heating. For a picosecond pulse laser, $\tau_e \ll \tau_L \ll \tau_i$: the process is in between ablation and heating. For a femtosecond pulse laser, the process is exclusively a laser ablation process. Laser ablation of semiconductor and dielectric materials involves different mechanisms [2].

In contrast to the laser ablation of inorganic materials, such as metals, semiconductors and dielectrics, organic polymer materials interact with photons very differently. Laser ablation of polymers is dependent less on laser pulse duration and more on laser wavelength and energy. Ablation of polymers with an excimer laser at UV wavelengths was first reported in 1982. It was found that an ArF excimer laser (193 nm wavelength) irradiating a poly(ethylene terephthalate) film could cause etching of the film in air [3]. The polymer material simply sublimed under the excimer laser irradiation. Since the first report, extensive research and development in laser ablation of polymers have taken place. Although still not fully understood, the mechanism of laser ablation of polymers is broadly considered as a photochemical decomposition process. High-energy photons break up the polymer chain to oligomers of much lower molecular weight along with the production of gases such as C_2, CO and CO_2 and monomers. Gaseous products are ejected in the form of plumes from the surface at supersonic velocity carrying with them oligomer particles [4]. Figure 2 shows an array of ink jet printer nozzles drilled into a polyimide sheet by a KrF laser. The hole is 30 μm in diameter. It is very clean cut with a smooth edge. However, there are debris visible surrounding the holes, which are the ejected polymer particles landing on the surface.

The photochemical decomposition process occurs exclusively at UV wavelengths with excimer lasers, such as XeCl (308 nm), KrF (248 nm) and ArF (193 nm). The laser pulse duration has much less effect on ablation. Long pulses of laser irradiation of the order of microseconds can still cause polymer ablation. However, there is a thresh-

old fluence (mJ/cm^2) above which the ablation occurs. The threshold fluence is different for different polymers, for different photon wavelengths and for different pulse durations [5].

Laser ablation has become a versatile machining technique, particularly in machining of microstructures. Although there are other microfabrication techniques, such as lithography, wet chemical and reactive ion etching, laser ablation provides a direct and fast structuring method. For some materials, laser ablation seems to be the only means to achieve microstructures. Laser ablation of polymers is of particular importance in constructing microfluidic systems. Laser ablation can achieve deep trenches with near vertical side walls in polymer materials, which is often called a LIGA-like micromachining technique. This is ideal for polymer-based microfluidic devices, and polymers are low-cost materials compared with other materials such as silicon and glass.

Basic Methodology

Laser ablation requires an appropriate combination of laser and ablated materials. Many lasers have been used for machining of microstructures, including CO_2 lasers, solid-state lasers, copper vapour lasers and excimer lasers. Pulsed lasers are used because of their ability to deliver high peak power. For a continuous laser a shutter control can provide the necessary pulsation. The peak power, laser intensity and fluence are calculated by the following equations:

$$\text{Peak power (W)} = \frac{\text{pulse energy (J)}}{\text{pulse duration (s)}} \tag{1}$$

$$\text{Intensity (W/cm}^2) = \frac{\text{peak power (W)}}{\text{focal spot area (cm}^2)} \tag{2}$$

$$\text{Fluence (J/cm}^2) = \frac{\text{laser pulse energy (J)}}{\text{focal spot area (cm}^2)} \tag{3}$$

Excimer lasers usually have very low duty cycles or repetition rates (1 – 100 Hz). However, because the pulse can

be very short, the peak power can be very high even though the average power from an excimer laser is low. Each type of excimer laser has a fixed wavelength, e. g. XeCl laser ($\lambda = 308$ nm), KrF laser ($\lambda = 248$ nm) and ArF laser ($\lambda = 193$ nm). They are large in size and expensive to operate. Solid-state lasers offer many advantages. Solid-state lasers include Nd:YAG lasers ($\lambda = 1064$ nm) and Ti:sapphire lasers ($\lambda = 800$ nm). A frequency-tripled Nd:YAG laser can deliver photon wavelength at 355 nm. Solid-state lasers can offer [6]:

- Wide choice of wavelengths (either through direct tunability or via harmonic generation)
- Variety of temporal pulse widths (ranging from milliseconds to a few femtoseconds)
- High pulse repetition rates (from tens to hundreds of kilohertz)
- Large choice of output powers
- Excellent *wall-plug* efficiencies (especially with diode-pumped systems)
- Compact sizes
- Economically favorable running costs.

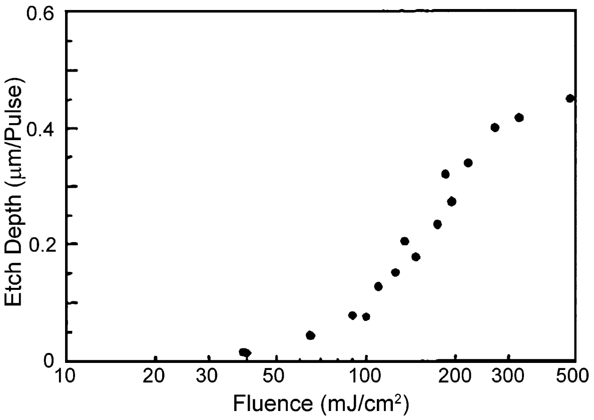
There are several parameters critical to laser ablation. The first is the wavelength of the laser, which should have a minimum absorption depth in the ablated material. This will ensure a high energy deposition in a small volume for rapid and complete ablation. The second is a short pulse duration to maximize peak power. The third is the pulse repetition rate. At high repetition rate the residual heat generated by laser irradiation can be retained, thus limiting the time for conduction, and the ablation will be more efficient. More of the incident energy will go toward ablation and less will be lost to the surrounding work material and the environment. The fourth is the beam quality. Beam quality is measured by the intensity, as shown above, and is related to a small and well-focused beam spot.

For laser ablation of polymers, the key parameter is the laser fluence. Each combination of polymer material, laser wavelength and pulse duration has a distinctive threshold fluence, below which no ablation takes place. The typical ablation depth vs. laser fluence is shown in Fig. 3. It plots the average ablation depth of poly(methyl methacrylate) at different fluences with a 193 nm excimer laser [4].

There is an empirical relation between ablation rate and the threshold fluence, as shown in Eq. (4) [7]:

$$R = \frac{1}{k} \ln \left(\frac{F}{F_t} \right) \tag{4}$$

where F is the laser fluence, F_t is the threshold fluence and k is the UV absorption coefficient of the polymeric material. The threshold fluence can be measured from experiment, as shown in Fig. 3. The formula is then useful



Laser Ablation, Figure 3 Etch depth vs. log fluence for laser ablation of poly(methyl methacrylate) at 193 nm wavelength

to determine the UV absorption coefficient k. Because the UV absorption is different for different polymers at different UV wavelengths, the threshold fluence is also different. High UV absorption results in low threshold fluence. Generally, a longer wavelength photon has a smaller absorption coefficient, therefore a larger threshold fluence. For example, the threshold fluence of polyimide (Kapton) ablation is 30 mJ/cm^2 for an ArF laser, 70 mJ/cm^2 for a KrF laser and 100 mJ/cm^2 for a XeCl laser.

Key Research Findings

Laser ablation is a simple and straightforward process. It has been used as a material processing technique for several decades. From the practical application point of view, R&D in laser ablation has been focused on improving efficiency and precision of machining, and on reducing the heating effect and debris-induced contamination. The most significant development in laser ablation has been the advent of femtosecond lasers and their application in micromachining processes. Femtosecond laser ablation can avoid all the problems associated with laser heating of materials. There are no thermal damages, unmatched machining accuracy down to 100 nm and no wavelength dependence, which means that any materials can be machined with the same laser.

Excimer lasers have been the primary tools for ablation of various polymeric materials, due to their strong absorption of UV photons. However, commercially available polymers often perform poorly in UV laser ablation, such as high ablation threshold, low ablation rate and redeposition of debris, and it becomes worse at longer UV wavelengths. An interesting development in recent years has been that of *designer* polymers, with properties tailored to improve ablation characteristics for specific applications [8]. New

polymers based on a triazene chromophore were specially designed. These polymers exhibit superior laser ablation properties (sharp ablation edges, no debris, low threshold fluence and high etch rates at low fluences) and a high absorption coefficient for the XeCl excimer laser wavelengths.

Future Directions for Research

Although laser ablation has been practiced since lasers were invented and is considered as a mature technology, the mechanism, particularly the mechanism of polymer ablation, is still not fully understood. For polymer ablation, there is the ablative photodecomposition model, the thermal ablation model and the thermal–photochemical ablation model [9]. Many time-resolved measurement techniques have been used to observe what exactly is happening at the laser ablation site and to measure the products generated from laser ablation [10]. These investigations are likely to go on. On the engineering side, there is growing interest in laser ablation of organic tissue materials for biological applications and organic light emitting polymers for photonic applications. The application for prototyping micro- and nanofluidic devices and systems will also expand in the near future.

Laser micromachining; Microfabrication

Definition

Laser Micromachining refers to a broad range of processes used to form materials through the use of intense light with high spatial resolution and feature sizes down to the submicron level. Laser micromachining typically involves the removal of material through ablation or thermal processes, but also includes formative processes where the light can be used to control deposition or molecular reactions.

Overview

Laser micromachining is one of many commonly used methods for the formation of microfluidic devices. Laser micromachining has direct write capabilities, can be used to form high aspect ratio channels and features, and can be used for the fabrication of 3D fluidic structures. These characteristics prove advantageous in many applications and differentiate it from other methods for the fabrication of microfluidic devices, including wet chemical etching, polymer casting, hot-embossing and deep reactive ion etching. Laser micromachining has been used with numerous microfluidic substrates, including silicon dioxide (glass) and numerous polymers.
Laser ablation refers to the removal of material from a substrate surface when the photon flux overcomes a threshold that causes breaking of covalent bonds and expulsion of material from the solid to the gas phase. To overcome the desorption threshold extremely high irradiances (power/area) must be achieved. Lasers are well suited for providing such high irradiances over small areas, because they are characterized by high irradiance (power/area),

low beam divergence, and high coherence. The low divergence and high coherence make it straightforward to further increase the intensity through optical focusing. In the direct write mode, the laser is focused onto the substrate, and either the optics or substrate is moved to mill out channels, holes, or other features. Static machining can also be used to mill multiple features within a small area in parallel by using an optical mask to define the areas that are ablated. During static machining a beam expander can be used, but the irradiance must be high enough to overcome the ablation threshold.

The phenomenon of laser ablation was first reported in 1973 by Emmony et al. where the group reported damage in a germanium mirror of a TEA CO_2 laser at a wavelength of 10.6 μm [1]. In 1982, Srinivasan and Mayne-Banton of IBM reported the laser ablation of polyethyleneterphthalm (PET) [2].

Two fundamental modes of laser micromachining can be differentiated based on the temporal width of the laser pulses used. Ultrashort pulses provide rapid bursts of photons that interact with a material in time frames that are shorter than time scales of thermal processes and are less than 10 ps in width. Therefore, in ultrashort laser pulses dissociative processes dominate and thermal conduction of heating to the surrounding areas is minimized, which nearly eliminates cracking and thermal damaging of the surrounding areas. The resulting plasma that forms is a highly energetic gas that expands away from the material taking most of the heat away with it [3]. In processes that use laser pulses greater than 10 ps, thermal heating and conduction are important processes that lead to increased heating and damage. In yet longer and continuous wave processes, thermal heating leads to melting of the material before it is evaporated. Long pulsed lasers may be used for additive processes such as welding.

Clearly, the precision and reproducibility of the laser micromachining process are largely dependent on the characteristics of the laser beam used. First and foremost, the wavelength of radiation used by the laser must be absorbed by the substrate that is being micromachining. The minimum spot size and depth of focus are critical in determining the minimum size of features that can be micromachined with a given system. For ablation to occur, the irradiance of the light must exceed the ablation threshold. Thus the laser intensity and intensity distribution must be carefully considered. The laser pulse helps define the peak power and the degree to which heat dissipation can occur.

Laser Wavelength

Laser micromachining is based on the absorbance of electromagnetic radiation in by the substrate material. Thus most basic requirement is that the substrate must be capable of absorbing the wavelength of the electromagnetic used for the micromachining to be successful. Absorption by the molecular or inorganic substrate relies on the electronic transitions from the ground to excited states. For short wavelengths, of less than ~ 200 nm, the photons have enough energy to cause $\sigma \rightarrow \sigma*$ and $n \rightarrow \sigma*$ transitions that cause electrons in bonding orbitals to be excited to antibonding orbitals and electrons in non-bonding orbitals to be excited to antibonding orbitals, respectively. The volatile fragments produced by bond cleavage are removed from the substrate surface during the machining process. At longer wavelengths above 300 nm for example, the energy of a single photon is not sufficient to break the bonds of the substrate and multiphoton process are required for laser micromachining of glass and polymers. Longer wavelength lasers are still used for micromachining, but rely on thermal processes that heat, melt, and evaporate the substrate. For longer wavelength lasers, it is still necessary that the substrate absorbs at the wavelength of the laser for the thermal processes to occur.

Most laser micromachining is achieved with single-photon absorption, in which a single photon whose energy matches an electronic transition of the substrate, is absorbed and causes an electronic transition. With single photon mechanisms, the absorption increases linearly as the intensity of the radiation or laser light is increased.

Two-photon absorption is a nonlinear optical phenomenon that occurs when two photons are absorbed simultaneously and the combined energy of two photons matches an electronic transition. Under normal conditions, the probability of two photons being absorbed simultaneously is extremely low, and therefore to utilize two-photon absorption processes for ablation very high irradiances much be achieved. An important part of the aspect of the optical instrument used for two-photon processes is the use of high numerical aperture optics that can provide very small focal spots with minimal depth of field. The probability of a two-photon absorption increases non-linearly, as a function the intensity squared [4]. Thus, when properly tuned the ablation by two-photon processes is constrained to a very small volume centered at the beam waist and limited by the depth of focus. The excitation wavelength is selected such that before the light is focused to the beam waist, the material is transparent to single photon absorption. This penetration of the excitation enables 3-dimensional micromachining with two-photon processes. Femtosecond lasers are used because the irradiance delivered by their short pulses is extremely high. In addition to ablation, two-photon processes can be used for photopolymerization of material within the focal spot in a similar manner.

Spot Size of Laser and Depth of Focus

For both one and two photon processes the irradiance is greatest at the beam waist. Consequently, precise control of the spot size is required for accurate micromachining. A poorly controlled spot size can result in larger features widths and increased sloping of the side walls. The smallest obtainable spot size determines the minimum feature size, which is limited to half the wavelength of the light used. Under the conditions where a perfect lens with no spherical aberration is used to focus a laser beam that is collimated, the minimum diameter of the focused laser beam d_{min} is given by:

$$d_{min} = \frac{4M^2 \lambda f}{\pi d_0} \tag{1}$$

Where λ = wavelength of radiation
M^2 = the beam mode parameter
d_0(mm)= diameter of the beam at the focusing lens
f = focal length of the lens.
Therefore improved spatial resolution can be achieved by reducing the wavelength, using a large diameter lenses, fully filling the lens, and using a short focal length. A large diameter lens with short focal length has low f-numbers, making the use of low f-number lenses advantageous.
The depth of focus is defined as the distance between the values where the beam diameter is $\sqrt{2}$ times greater than what it is at the beam waist as shown in Fig. 1. It may be expressed by the following equation [5]:

$$DOF = \pm \left(\frac{8\lambda M^2}{\pi}\right)\left(\frac{f}{d_0}\right)^2 \tag{2}$$

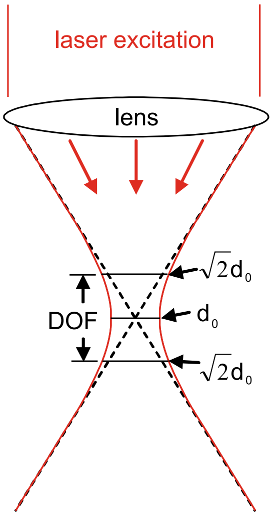
For surface micromachining, a short depth of focus requires a very flat substrate surface.

Laser Irradiance or Power Density

The irradiance has units of W/cm^2 and is defined as the power divided by the focal spot area, where the power is the pulse energy divided by the pulse duration in time. For a given number of photons, the intensity increases as the area the photons are focused on decreases and the time period during which the photons arrives decreases. The fluence describes the energy per unit area and has units of J/cm^2.

Laser Spot Intensity Profile for TEM_{00}

The spatial profile of a laser beam at the exit of the laser aperture is determined by the geometry of the laser cavity and the propagation of light within the cavity. The transverse electromagnetic modes are represented by TEM_{mn}



Laser Based Micromachining, Figure 1 The focal spot at the beam waist has a diameter of d_0. The depth of focus (DOF) is typically defined as the region bounded by above and below the beam waist. The beam waist, as shown by the red line (light grey in the print version), is normally greater than or equal to the diffraction limit. The irradiance is greatest in the volume contained in the region defined by the DOF, and consequently ablation will be centered about this volume

where m and n represent the number of nodes in the orthogonal directions. The TEM_{00} mode has no nodes in either orthogonal directions, and consequently has the greatest symmetry and is most often used for laser micromachining. The intensity of a TEM_{00} spot is cylindrically symmetrical, and the cross-section of the intensity profile is Gaussian. This intensity as a function of distance from the spot center (r) is given by the following equation:

$$I(r, t) = I_0(t) \exp\left[-\frac{r^2}{w^2}\right] \tag{3}$$

where I_0 = peak intensity at the spot center where $r = 0$, w =radius of the point where the intensity drops by a factor of 1/e with respect to I_0, and r = the radial coordinate that expresses distance from the spot center.

Laser Pulse Length

Pulsed lasers provide intermittent periods of photon emission. Averaged over time, the time off is usually much greater than the time on when photons are emitted. The laser pulse length is the length in time during which photons are emitted from the laser during each individual pulse. For laser micromachining, the major difference between a long pulse laser and a short pulse laser is nature of the heat diffusion into the material. In the

case of a long pulse laser, the material experiences considerable thermal diffusion which reduces the overall efficiency of the process. Energy that could have been used to remove material through ablation is lost into the surrounding material. In contrast, when a short pulse laser is used, the heat deposited by the light does not have the time to move away from the area ablated. This pulse creates a plasma on the surface, and the force from the plasma causes the material to expand outward and away from the surface. The zone around the machined area is referred as the heat affected zone (HAZ). The waves propagating through the HAZ may cause mechanical stress that may cause substrate cracking. This effect is more prominent in systems with long pulse lengths more than short pulse length systems, because the heating in the surrounding zone is diminished in short pulse systems. For a given number of photons the irradiance during the pulse decreases as the pulse length increases. Therefore, with longer pulse a higher fluence must be used to reach the ablation threshold.

Femtosecond laser machining, with pulses of femtosecond duration, has attracted much attention due to advantages such as small heat-affected zones (HAZ), and the ability of three-dimensional processing inside a transparent substrate. When femtosecond laser pulses are focused into a transparent medium, ultrahigh fluence in the neighborhood of the focus can result in nonlinear multiple photon absorption including optical breakdown and subsequent formation of localized three-dimensional features inside the medium. The most common applications of using femtosecond lasers are laser direct writing to create embedded three dimensional microfluidic structures in glass and polymer substrates, such as poly(dimethylsiloxane) (PDMS) and PMMA, and drilling microholes for the microfluidic devices [6–9]. The use of glass-based microfluidic channels in Lab-on-Chip devices has led to increasing attention being paid to glass micromachining. It is desirable to avoid damage and microcracks around the laser machined region and femtosecond lasers have proven to be excellent sources for such precise machining work [6, 10].

Typical Channel Profile

The morphology of an ablated microfluidic channel is determined by a number of parameters. These include the laser irradiance, spot size, speed of the x-y stage, repetition rate of the laser, properties and characteristics of the substrate being ablated, and the chemical environment under which the ablation occurs. It is also dependent on the temporal and spatial profile and wavelength of the laser pulse. Waddell et al. determined that as the fluence is increased above the ablation threshold for a particular substrate, the depth of the ablated channels increases and the roughness of the area surrounding the channel is increased [11]. In contrast, a lower fluence produces a shallower and smoother channel, but decreasing the power below the ablation threshold will result in the removal of no material. The nature of the substrate material and the external environment of the substrate during the ablation process play an important role in the morphology of the ablated channels. Waddell et al. studied these aspects of laser-ablated channel, and noted that ablated poly methyl methacrylate (PMMA) structures have a rougher surface and exhibits more cracking when compared with poly ethylene terephthalate glycol (PETG), polycarbonate (PC) and poly vinyl chloride (PVC) [11]. These differences are attributed to the light absorption properties of the respective materials at the laser wavelength and thermal conductivities of the materials.

When PMMA was ablated in an atmosphere of nitrogen and in methanol the channels were rectangular. On the other hand, when the ablation was under water, the profile was wedge shaped. This change in channel geometry was attributed to the change in the path of the laser beam through the water [11].

Commonly Used Lasers

A variety of lasers can be used for machining the microfluidic channels, from nanosecond lasers to femtosecond lasers or from IR lasers to UV lasers, depending on the materials to be fabricated and desired applications.

The most widely used lasers for fabricating microfluidic channels in polymer substrates are UV lasers, excimer, and Nd:YAG laser. UV lasers are typically operated in pulsed mode with pulses of nanosecond duration. Excimer lasers produce various wavelengths depending on the gas composition; 157 nm F_2, 193 nm ArF, 248 nm KrF, 351 nm XeF and 308 nm XeCl. The excimer laser- due to low coherence beam with high pulse energies- is generally used for fabrication by mask projection methods.

The solid state Nd:YAG lasers can be frequency converted from fundamental 1064 nm wavelength to 355 nm and 266 nm by using non linear crystals. The Nd:YAG lasers generally have highly coherent beam and are able to focus more tightly to enable more rapid material removal. Thus, these lasers are suited to direct writing dynamic mode.

Their applications of machining the microfluidic channels in polymers include a number of substrates: poly(ethylene terephtalate) (PET), polystyrene, poly carbonate, cellulose acetate, poly(methyl methacrylate) (PMMA), poly (vinyl chloride) (PVC), poly(ethylene terephthalate glycol) (PETG), polytetrafluoroethylene (PTFE) and poly-

imide [11–14].

In contrast to UV lasers, IR lasers ablate the substrates photothermally. When the focused laser beam hits the substrate surface, the temperature of the irradiated spot will rise rapidly that the material will first melt and then decompose, leaving a void in the substrate. The actual decomposition mechanism depends on the strength of the chemical bonds of the monomers that make up the polymer and the structure of the polymer itself.

The most widely used IR laser for machining microfluidic channels in polymers are CO_2 lasers, which are continuous wave lasers. The primary emission wavelengths of CO_2 lasers are in the IR region and centered at 9.4 and 10.6 μm produced. Poly(methyl methacrylate) (PMMA) is highly compatible with CO_2 laser machining due to its high absorbance in IR region, low heat capacity, low heat conductance, and good thermal decomposition into volatile byproducts [15, 16].

Basic Methodology

Micromachining System Instrumentation

The basic laser micromachining system is quite simple and requires a laser, focusing optics, and translation stages or masks. The minimal requirements vary somewhat depending on the mode of operation used. The two basic modes of operation are direct writing and parallel processing. In direct writing, as the name suggests, the laser beam is focused on the surface and is used to directly ablate the material where the laser is tightly focused. Each area to be machined is ablated sequentially in a serial fashion. In the parallel processing mode, the laser is not focused into a tight spot but is expanded to illuminate a mask. The transparent areas of the mask allow for the light to pass through, and ablate the exposed regions. One mask or several masks may be used to complete the machining process depending on the size of the patterns and the maximum area over which the intensity is sufficient for ablation.

In order to maintain the proper spatial orientation of the channels and other features, the translational stage must have the required resolution and reproducibility. Typically x-y stages are used for controlling the location along the surface of the substrate. The vertical or z-dimension is often controlled by translating the focusing optic in the vertical dimension. Off-axis optics can be used to form a circular scribing or trepanning head. For cutting microchannels of greater dimension than the laser spot, multiple parallel passes or trepanning with linear translation can be used. To trepan a linear channel the diameter of rotation of the spot on the substrate surface is equal to the channel width, and the linear translation increases the length.

The minimum feature size is largely dependent on spot size and accuracy and reproducibility of the positioning system. Commercial systems provide well developed control programs and platforms that allow for rapid production of prototype designs. Digital cameras can be used for real-time monitoring of the micromachining process and can aid in alignment of features. Masks can also be used with direct write systems to tailor the shape of the laser spot and provide different channel cross-sections. As the mask aperture is reduced the laser fluence and the rate of material removal is reduced. The local environment around the ablated area may be controlled to the benefit of the process in various ways. One such method flow a gas of the ablated site for removal of the particles produced during ablation and minimize the recast. Another approach is to immerse the material in a liquid that is transparent to the laser light.

The parallel mode for batch processing uses a mask imaging technique. A mask is placed between the laser and the substrate, and the collimated light from the laser is used to ablate an image of the mask on the substrate surface. Typically the optics are chosen to give a demagnified image (*10 times smaller*) to give high power densities on the surface and avoid damage to the mask [17] .

L

Laser Etching with Chemical Assistance

The process of micromachining may be assisted by either dry or wet chemical etchants for building high quality 3D micromachines. As an example, chlorine may be used as an etchant and is photodissociated to react with the substrate. If the ablation is performed in Cl_2 gas, the silicon vapour leaving the surface react with chlorine to form $SiCl_4$ gas and is removed from the surface. Reducing recast through chemical assistance produces significantly higher removal rates and produces cleaner and more sharply defined parts.

Key Research Findings

It was the groundbreaking paper published by Manz group in 1990 that established the field of miniaturized total chemical analysis systems (μTAS) and the area of μTAS, also called *Lab-on-a-Chip*, microfluidic system, is a rapidly developing field. A standard architecture consisted of a network of microchannels etched into the surface of a planar substrate using standard photolithography, and chemical wet-etching techniques. Laser micromachining provides an alternative and complimentary method to wet chemical etching. In terms of microfluidic devices, laser micromachining provides three main benefits: 1) it can be used to produce high aspect ratio channels, 2) it

can be used to create 3D channel structures, and 3) it is well suited for rapid prototyping.

The surface characteristics of a microfluidic channel are very important in determining the flow in electrokinetically driven systems. In electrokinetically driven systems, the bulk flow is created by movement of the mobile diffuse layer near the channel wall/solution interface that is termed electroosmotic flow (EOF). The EOF is dependent on the surface of the microchannel walls. Roberts et al. demonstrated the generation of EOF on laser ablated polymer substrates for the first time, using the parallel processing mode with a photomask an ArF excimer laser at 193 nm [17]. A variety of polymer substrates such as polystyrene, polycarbonate, cellulose acetate, and poly (ethylene terephthalate) (PET) were ablated to fabricate microfluidic channels. The laser ablation process alters the surface chemistry of the machined regions and produced negatively charged, functionalized polymer surfaces capable of generating EOF.

There are differences in the surface of the laser ablated polymer depending on the mode of operation, static and dynamic laser ablation mode. Rossier et al. investigated differences in surface states of polymer PET as a result of these two modes of ablation [18]. Their studies revealed that the static ablation mode produced a homogeneous and hydrophobic surface with poor wettability, whereas the dynamic ablation mode produced an inhomogeneous and hydrophilic surface with high wettability. These differences were attributed to the redeposition of fragments.

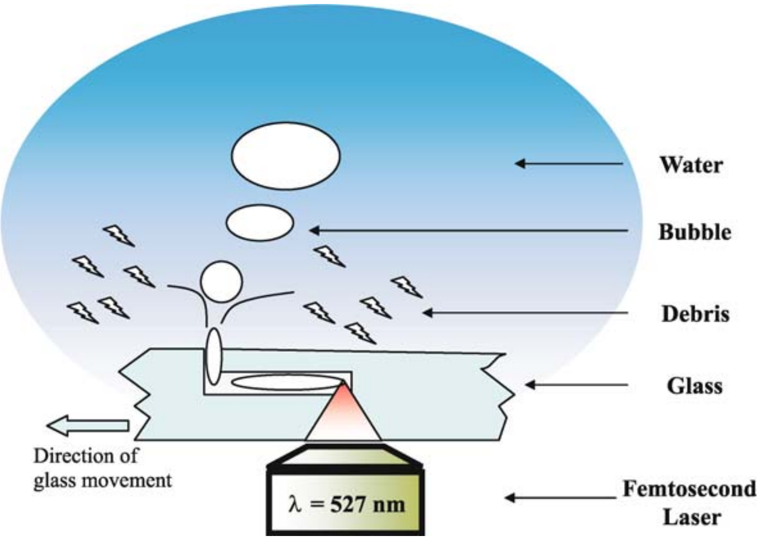
Alterations in the charge on the channel surface are important to consider because the surface charge density is important for electrokinetic microfluidic applications such as maintaining electro osmotic flow (EOF) in the micro channel. Pugmire et al. investigated changing the ablation atmosphere during the excimer laser ablation of polymer microchannels as well as controlling their surface properties and associated electro osmotic mobility in a single step process [12]. The ablation of polycarbonate under the different atmospheres, such as argon, nitrogen, and oxygen, results in channels with different EOF's [12]. The changes in the surface charge are thought to be because of altered chemical functionality of the surface of the polymer. This result is of significance in Microfluidic applications where the wall charge is used to alter the electroosmotic flow. Unlike the case where dynamic or permanent coatings are used to alter the EOF which requires additional fabrication, laser ablation allows the modification of the surface chemistry under different atmospheres.

Combining electrokinetically and hydrodynamically driven systems can be challenging. Razunguzwa et al used laser micromachining with a copper vapour laser to form hydrodynamic restrictors that allowed coupling an electrokinetically driven system with low EOF and hydrodynamic flow. The narrow width of the channels formed with laser micromachining provides increased frictional resistance to flow, while the increased depth and ability to fabricate many channels in parallel increases the cross-sectional area. Increasing the cross-sectional area is required to decrease the current density below levels where Joule heating causes bubble formation. Bubble formation causes current break-down that stops electrokinetically driven systems [19].

From a microfluidic system perspective, one of the most advantageous features of laser micromachining lies in its capability to construct three dimensional structures both in silicon materials and polymeric materials. The three dimensional processing of polymers and glasses is of significance to the development of advanced solutions for bonding process in fabricating microfluidic systems. In the following discussion, recent publications will be introduced that show development of three-dimensional processing of glasses and polymer toward the one-step processing for the fabrication of enclosed micro-nano fluidic devices.

Giridhar et al. used femtosecond direct laser writing technique at a wavelength of 1660 nm to ablate the glass substrate at or below the surface [10]. The well defined spot of the pulsed laser was focused into the bulk substrate, resulting in localized ablation below the surface. Though silicate glass is normally transparent at this wavelength, the extremely high intensity of the focused beam causes multiphoton absorption, resulting in subsurface ablation localized at the beam waist. This process relies on multiphoton excitation to drill a micro tunnel under the substrate surface connecting two adjacent pits machined by the same laser in a glass substrate. To prevent substrate fragments from depositing in the working area, dry nitrogen gas was used during the entire writing process. An important advantage of using pulsed laser micromachining is its ability to drill subsurface tunnels into glass substrates and form 3D channel networks.

Direct three dimensional laser machining of submicrometer subsurface fluidic channels in glass through optical breakdown near critical intensity using a femtosecond pulsed laser was demonstrated by Ke et al. [6]. Glass substrate was machined using laser systems with 800-fs pulses at 527 nm. In this technique, no postprocessing is required, such as etching and bonding. Extremely long, deep channels ($> 200\ \mu m$) of extremely small diameter (< 700 nm) were produced. Subsurface channels can be successfully fabricated with this method because microbubbles play a critical role by transporting the fluid-entertained debris away from the machining site. Salient advantages of this method include production of 3D nanochannels with arbi-



Laser Based Micromachining, Figure 2 Schematic of laser micromachining system for rapid prototyped three-dimensional channel networks using a femtosecond laser. The femtosecond laser provides intensities that overcome the ablation threshold at the tightly focused beam waist. The glass substrate is immersed in water and bubbles formed by heating remove debris from the channel. The substrate is articulated with a micro-positioning stage that is similar to other systems, but positioning along the vertical dimension controls channel depth

L

trary channel geometries, aspect ratios larger than 280 and roughness within the channel of the order of 10 nm as well as avoiding the need for bonding. The small feature sizes and the ability to machine in 3D enable integration of microfluidic channels for HPLC devices, micro-sensors, and integrated nanopores for patch-clamp studies of cell.

Fabrication of subsurface microchannels in polymer substrate is very challenging process because of clogging of channels by debris and rough fractured channel walls. However, Farson et al. successfully made subsurface microchannels in PMMA substrate [8]. They used $Ti:Al_2O_3$ chirp-pulse amplified laser producing 150 fs pulses at a repetition rate of 2 kHz. The maximum output power of the laser was 1.6 W, corresponding to an average pulse energy of 0.8 mJ. The laser beam was focused inside the material, resulting in the ablation of an internal channel. The debris was evacuated from the channel by blowing a stream of Ar gas through a vent channel, providing a vacuum for removal of the debris gas. The venting technique resulted in smooth channels without obvious cracking. The fabricated channel diameter ranged from 2 μm to 20 μm and the maximum length of smooth channel ranged from 5 mm to 10 mm.

Future Directions for Research

Research in laser micromachining will continue to new methods for the fabrication of microfluidic devices, particularly from polymers and glass. The development of 3D channel networks is important for numerous fluidic applications which will fuel future the demand for more research in this area. As these methods are refined the processes will be tailored to processing of many different types of polymers. Future work will continue to seek methods to decrease the roughness of microchannels. Analysis of complex mixtures of biomolecules requires surfaces that minimize non-specific adsorption. In order to minimize problems with surface adsorption, characterization of the ablated surface will continue.

Planar laser-induced fluorescence

Definition

Laser-induced fluorescence (LIF) is a non-intrusive flow visualization technique that can provide instantaneous whole-field measurements of a variety of flow characteristics, including concentration, density, temperature and velocity with high spatial and temporal resolution. In a typical LIF experiment, a fluorescent dye is used to mark the fluid and a region of the flow is illuminated with incident light whose wavelength can excite electronic transition of the fluorophores. The light fluoresced by the dye is imaged using one or more CCD cameras after it is separated from the illuminating wavelength using optical filters. These intensity fields can then be related to a flow variable of interest following an a priori calibration of the dye's fluorescence intensity as a function of variations in the flow variable.

Lattice Boltzmann equation

Definition

The lattice Boltzmann method is a mesoscopic simulation method for complex fluid systems. The fluid is modeled as fictitious particles as they propagate and collide over a discrete lattice domain at discrete time steps. Macroscopic continuum equations can be obtained from this propagation–collision dynamics through a mathematical analysis. The nature of particulates and local dynamics also provide advantages for complex boundaries, multiphase/multicomponent flows, and parallel computation.

Overview

The lattice Boltzmann method (LBM) is a relatively new simulation technique for complex fluid systems which has attracted a great deal of interest from researchers in computational physics. Unlike the traditional computation fluid dynamics (CFD), which numerically solves the conservation equations of macroscopic properties (i. e., mass, momentum, and energy), LBM models the fluid consisting of fictitious particles, and such particles perform consecutive propagation and collision processes over a discrete lattice mesh. Due to its particulate nature and local dynamics, LBM has several advantages over conventional CFD methods, especially in dealing with complex boundaries, incorporation of microscopic interactions, and parallel computation [1].

Historically, LBM originated from the lattice gas automata (LGA), which can be considered as a simplified, fictitious molecular dynamics in which space, time, and particle velocities are all discrete. Each lattice node is connected to its neighbors by, for example, six lattice velocities from a hexagonal FHP (Frisch–Hasslacher–Pomeau) model. There can be either one or zero particle at a lattice node moving along a lattice direction. After a time interval, each particle then moves to the neighboring node in its direction, and this process is called the propagation. When there are more than one particles arriving at the same node from different directions, they collide and change their directions according to a set of collision rules. Good collision rules should conserve the particle number (mass), momentum, and energy before and after the collision. However, it was also found that LGA suffers from several native defects including the lack of Galilean invariance, presence of statistical noise, and absence of exponential complexity for three-dimensional lattices.

The main motivation for the transition from LGA to LBM was the desire to remove statistical noise by replacing the Boolean particle number in a lattice direction with its ensemble average, the so-called density distribution function. Accompanying this replacement, the discrete collision rules also have to be modified as a continuous function – the collision operator. In the LBM development, an important simplification is to approximate the collision operator with the Bhatnagar–Gross–Krook (BGK) relaxation term. This lattice BGK (LBGK) model makes simulations more efficient and allows flexibility of the transport coefficients. On the other hand, it has been shown that the LBM scheme can also be considered as a special discretized form of the continuous Boltzmann equation. Through a Chapman–Enskog analysis, one can recover the governing continuity and Navier–Stokes equations from the LBM algorithm [2]. In addition, the pressure field is also directly available from the density distributions and hence there is no additional Poisson equation to be solved as in the traditional CFD methods.

Simulating multiphase/multicomponent flows has always been a challenge to conventional CFD because of the moving and deformable interfaces. More fundamentally, the interfaces between two bulk phases (e. g., oil and

L

water) originate from the specific interactions among different molecules. Therefore it is difficult to implement such microscopic interactions into the macroscopic Navier–Stokes equation. However, in LBM, the particle kinetics allows a relatively easy and consistent avenue to incorporate the underlying microscopic interactions by modifying the collision operator. Several LBM multiphase/multicomponent models have been developed [3, 4]. Phase separations can be generated automatically from particle dynamics and no special treatment is needed to manipulate the interfaces as in traditional CFD methods. Successful applications of the multiphase/multicomponent LBM models can be found in various complex fluid systems, including interface instability, bubble/droplet dynamics, wetting on solid surfaces [4], interfacial slip [5], and droplet electrohydrodynamic deformations [6].

Despite the increasing popularity of LBM in simulating complex fluid systems, one should also be aware of the limitations of this novel approach. At present, high Mach number flows in aerodynamics are still difficult for LBM, and a consistent thermohydrodynamic scheme is absent. For multiphase/multicomponent models, the interfacial thickness is usually large and the density ratio across the interface can only be small when compared with real fluids. Nevertheless, applications and advancements of this method during the past 20 years have proven its potential in computational physics, including microfluidics.

Basic Methodology

LBM Algorithm

In LBM, a fluid is modeled as fictitious particles moving in a lattice domain at discrete time steps. The major variable in LBM is the density distribution $f_i(\boldsymbol{x}, t)$, indicating the number of particles moving along the i-th lattice direction at position $\boldsymbol{x}$ and time t. The time evolution of density distributions is governed by the so-called lattice Boltzmann equation with a BGK collision term [1, 2]:

$$f_i(\boldsymbol{x}+\boldsymbol{c}_i\Delta t, t+\Delta t) - f_i(\boldsymbol{x}, t) = -\frac{f_i(\boldsymbol{x}, t) - f_i^{\mathrm{eq}}(\boldsymbol{x}, t)}{\tau} \quad (1)$$

where $\boldsymbol{c}_i$ denotes the i-th lattice velocity, Δt is the time step, and τ is a relaxation parameter toward the equilibrium distribution f_i^{eq}, which can be expressed as [2]

$$f_i^{\mathrm{eq}} = \rho t_i\left[1 + \frac{\boldsymbol{u}\cdot\boldsymbol{c}_i}{c_{\mathrm{s}}^2} + \frac{1}{2}\left(\frac{\boldsymbol{u}\cdot\boldsymbol{c}_i}{c_{\mathrm{s}}^2}\right)^2 - \frac{u^2}{2c_{\mathrm{s}}^4}\right] \quad (2)$$

Here the fluid density ρ and velocity $\boldsymbol{u}$ can be obtained from local density distributions through

$$\rho = \sum_i f_i$$
$$\rho\boldsymbol{u} = \sum_i f_i\boldsymbol{c}_i \quad (3)$$

Other parameters, including the lattice sound speed c_{s} and weight factor t_i, are lattice structure dependent. For example, for a typical D2Q9 (two dimensions and nine lattice velocities; see Fig. 1) lattice structure, we have $t_0 = 4/9$, $t_{1-4} = 1/9$, $t_{5-8} = 1/36$, and $c_{\mathrm{s}}^2 = \Delta x^2/3\Delta t^2$, where Δx is the spatial distance between two nearest lattice nodes. Through the Chapman–Enskog expansion, one can recover the macroscopic continuity and momentum (Navier–Stokes) equations from the above-defined LBM dynamics:

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\boldsymbol{u}) = 0$$
$$\frac{\partial\boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = -\frac{1}{\rho}\nabla P + \nu\nabla^2\boldsymbol{u} \quad (4)$$

where ν is the kinematic shear viscosity given by

$$\nu = \frac{2\tau - 1}{2}c_{\mathrm{s}}^2\Delta t \quad (5)$$

and P is the pressure expressed as

$$P = c_{\mathrm{s}}^2\rho \quad (6)$$

An external force $\boldsymbol{F}$ can be included in the above LBM algorithm by adding an extra term to the collision operator (RHS of Eq. (1)) and the lattice Boltzmann equation becomes

$$f_i(\boldsymbol{x}+\boldsymbol{c}_i\Delta t, t+\Delta t) - f_i(\boldsymbol{x}, t) = -\frac{f_i(\boldsymbol{x}, t) - f_i^{eq}(\boldsymbol{x}, t)}{\tau} + \frac{t_i\Delta t}{c_{\mathrm{s}}^2}\boldsymbol{F}\cdot\boldsymbol{c}_i \quad (7)$$

or by redefining an equilibrium velocity

$$\boldsymbol{u}^{\mathrm{eq}} = \frac{1}{\rho}\left(\sum_i f_i\boldsymbol{c}_i + \tau\Delta t\boldsymbol{F}\right) \quad (8)$$

and utilizing it in the calculation of equilibrium distribution f_i^{eq} in Eq. (2) [3]. After such modifications, the

total fluid momentum increases an amount of $\Delta t\boldsymbol{F}$ during a time step, while the total fluid density remains unchanged.

As with other numerical approaches, appropriate boundary conditions (BCs) are necessary for meaningful simulations. Since the principal variables in LBM are the density distributions f_i, LBM BCs are implemented through specifying the unknown f_i entering the simulation domain across boundaries, instead of the macroscopic fluid properties such as velocity and pressure. This feature poses both conveniences and difficulties. For example, to model a no-slip boundary over a solid surface, one can simply reverse the particle directions toward the boundary back to their original locations, the so-called bounce-back scheme. Periodic boundaries are even easier to implement: all particles which leave the domain across a periodic boundary will re-enter the domain from the opposite side. However, for the general pressure and velocity boundary conditions, there are usually more unknown incoming density distributions than the number of constraint equations from the boundary conditions (see Eq. (3)), i. e., more unknowns to be determined from less constraints. To have a valid system of equations, assumptions are sometimes necessary and inappropriate choices could lead to unphysical boundary effects and also hamper simulation stability. Tremendous efforts have been devoted to develop accurate and efficient boundary schemes for different situations, and detailed descriptions can be found in the literature [7].

It can be seen from the above description that the LBM dynamics is local (i. e., only the very neighboring lattice nodes are involved in updating the density distributions), and hence LBM algorithm is advantageous for parallel computations.

Multiphase/Multicomponent LBM Models

It can be seen from the pressure–density relationship of Eq. (6) that the fluid in the general LBM is an ideal fluid. To simulate a multiphase/multicomponent system, the above method must be modified to incorporate any microscopic intermolecular interactions or the macroscopic equation of state. Such a modification can be carried out by applying an additional force term as in Eqs. (7) and (8), or by reformulating the equivalent density distribution given in Eq. (2). New sets of density distributions are also introduced in multicomponent models to represent the individual components. Different from those in traditional CFD methods, the LBM multiphase/multicomponent algorithm is uniform throughout the entire domain and phase separation as well as interface evolution can be obtained with ease without front-capturing and front-tracking treatments. So far, several models have been proposed. These models typically have been validated by means of stationary bubbles for the Laplace law of capillary and dynamic interfacial waves for the wavelength–frequency dispersion relations. Applications of these multiphase/multicomponent models in micro- and nanofluidics include bubble/droplet dynamics, sample mixing, interfacial slip, and dynamics of wetting.

A LBM-like Algorithm for Electrical Field

In addition, LBM-like algorithms have been proposed to solve problems with convection, diffusion, heat transfer, and electrical field. Such algorithms are designed so that the corresponding macroscopic equations can be recovered through a Chapman–Enskog analysis. However, such algorithms are purely differential equation solvers, the *density distributions* here have no physical meaning as in the original LBM for fluid mechanics. For the sake of clarity, an LBM-like algorithm for electrical field in the description of electroosmotic flow is illustrated below.

Generally, the electric potential ϕ in an electrolyte due to charged surfaces is governed by the Poisson equation

$$\nabla \cdot (\varepsilon \nabla \phi) = -\frac{\rho_\mathrm{e}}{\varepsilon_0} \tag{9}$$

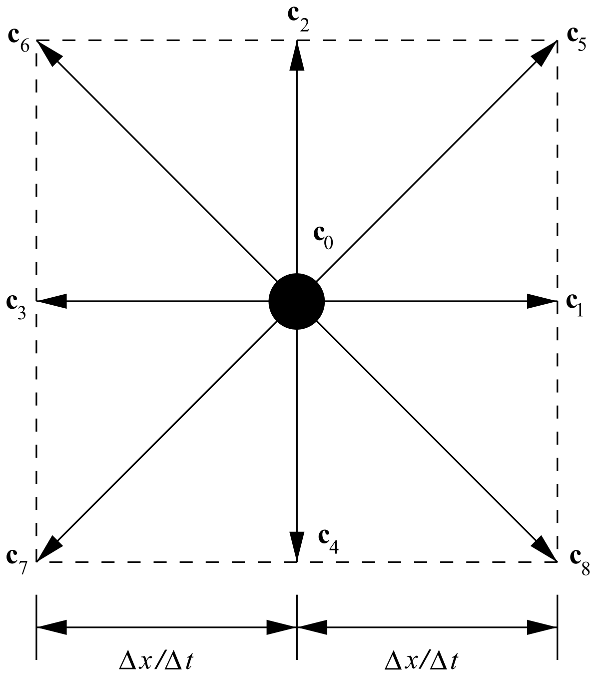
where ε and ε_0 are, respectively, the dielectric constant of the electrolyte and the permittivity of the vacuum, and ρ_e is the net charge density, which can be related to the electric field through the Boltzmann distribution. To solve this equation in the framework of LBM, He and Li [8] proposed the following lattice equation for the potential distribution h_i:

$$h_i(\boldsymbol{x} + \boldsymbol{c}_i \Delta t, t + \Delta t) - h_i(\boldsymbol{x}, t) = -\frac{h_i(\boldsymbol{x}, t) - h_i^\mathrm{eq}(\boldsymbol{x}, t)}{\tau_\phi} + \frac{t_i \rho_\mathrm{e}}{\varepsilon_0} \tag{10}$$

where $h_i^\mathrm{eq} = t_i \phi$ and $\tau_\phi = 3\varepsilon + 0.5$. The interested electrical potential ϕ is just a sum of all potential distributions h_i, i. e., $\phi = \sum_i h_i$. Again the Chapman–Enskog analysis can be applied to Eq. (10) and the original Poisson Eq. (9). Other similar schemes exist for convection–diffusion and heat transfer equations.

Key Research Findings

In recent years, LBM has been applied to study many microscale and nanoscale transport phenomena and processes, including gas flows, electroosmotic flows, interfacial phenomena, and colloid suspensions. In the following, we briefly review major advances of LBM in the description of electrokinetics and interfacial phenomena.



Lattice Boltzmann Method (LBM), Figure 1 The discrete lattice velocities of a D2Q9 lattice structure; $\boldsymbol{c}_0 = (0, 0)$ corresponds to the rest portion of the particles f_0

Electroosmotic Flows

Application of LBM to single-phase flows in microsystems is straightforward. To simulate electroosmotic flows, one needs to incorporate the electrical forces in the electrical double-layer region near the solid–liquid interface due to the net charge and external electrical field. Joule heating effect and sample mixing in microchannels have also been studied. In these studies, the general LBM is utilized for the fluid dynamics, and the electrical potential, temperature, and sample concentration fields were also solved by the appropriate LBM-like algorithms. For example, Tian et al. [9] investigated the electroosmotic flows in microchannels with heterogeneous surface potentials, and found that local circulations can be produced near the heterogeneous region. It was also noted that there is a clear tradeoff between mixing and transport in microfluidics with heterogeneous surfaces: A higher mixing efficiency is associated with a lower volumetric flow rate. These numerical studies could be useful for the design of microfluidic devices.

Solid–Liquid Interfacial Slip

In fluid mechanics, the no-slip boundary condition between a fluid and a solid surface has traditionally been an assumption in solving the Navier–Stokes equation. Despite macroscopic experimental supports, it still remains an assumption without physical principles. In fact, studies on fluid slip have long been an interesting subject since the pioneering work by Navier and Maxwell. Recent measurements indeed indicate significant slip on solid surfaces, and this fact has also been confirmed by molecular dynamics simulations. In general, both experimental and molecular dynamics simulation results show that there is a strong relationship between the magnitude of slip and the surface hydrophobicity: larger slip is usually observed on more hydrophobic surfaces and no slip on hydrophilic surfaces.

Recently, LBM has also been employed to study this interesting phenomenon (e. g., [5]). The fluid was modeled as a nonideal fluid and surface hydrophobicity was adjusted by tuning the specific solid–fluid interactions. For a liquid droplet sitting on a flat solid surface, the resulting contact angle is directly related to the solid–fluid attractions. High contact angles are observed on surfaces with week attractions (hydrophobic surfaces) and the liquid will completely wet the surface if the attraction is strong enough (hydrophilic surfaces). These are very similar to molecular dynamics results. Furthermore, the flow rate of the liquid in a channel with such surfaces also deviates from the theoretical prediction of a Poiseuille flow. A larger flow rate was found by using a more hydrophobic channel and, from a macroscopic viewpoint, this can be interpreted as an interfacial slip. The slip magnitude can be characterized by the apparent slip length which was found to increase with surface hydrophobicity (contact angles). For relatively hydrophilic surfaces, even negative slip lengths could result due to the strong solid–fluid interactions. These findings are in good agreement with other experimental and molecular dynamics studies. Since such an interfacial slip is generated by direct variation of the solid–fluid interactions instead of an applied slip boundary, these results demonstrate that the underlying microscopic interactions have been well represented and LBM could be useful in microfluidic and nanofluidic studies.

Dynamic Wetting

Since with LBM it is relatively easy to incorporate microscopic interactions, it certainly allows an attractive alternative to study wetting dynamics of a liquid on a surface. Dynamic contact angles from LBM simulations have been compared to a theoretical adsorption/desorption model with good agreement [4]. Furthermore, the LBM results also imply more adsorption sites and a higher displacement frequency on a hydrophilic surface when the solid–fluid attractions are strong. These suggest that the underlying physics in the LBM model has been reasonably repre-

sented. Wetting behaviors over chemically heterogeneous surfaces and capillary flows have also been examined.

Recently, superhydrophobic surfaces have attracted great interest for their potential in reducing flow resistance. Due to the geometrical and physical complexity of the system, traditional theoretical and numerical methods encounter severe challenges to study this phenomenon. Several LBM attempts have been performed (e. g., [10]) and the results are promising. For example, it has been found that the advancing contact angle increases and resistance to droplet sliding decreases with decreasing fractional solid area. Further LBM simulations could be valuable to improve our understanding of the phenomenon.

Future Directions for Research

We have noticed that most current LBM applications to microfluidics utilize LBM as a differential equation solver; and the true merit of this method – a good representation of the underlying microscopic interactions – has not been well exploited. Solid–fluid interfacial phenomena in microsystems could be particularly suitable for LBM, since it couples the fluid and interface dynamics in a natural way. Future directions for research may include utilizing non-uniform or unstructured lattice meshes for complex microstructures (e. g., surface roughness), combining LBM with molecular dynamics and CFD (hybrid algorithms), and applying LBM to bio-microfluidics.

Definition

Electroosmotic microfluidics have many promising applications in microsystems. However, the simulation and analysis of electroosmotic flows have always been large challenges especially for complex geometries. By introducing a high-efficiency lattice Poisson–Boltzmann method, this contribution presents the latest progress in the simulation and analysis of electroosmotic flows in either homogeneously or heterogeneously charged channels, either straight or rough channels, either isotropic or anisotropic porous media. The results agree with some of the existing experimental data. The results will improve our understanding of the electroosmotic flow mechanism in micro- and nanoscale geometries and provide valuable information for the design and optimization of microsystems.

Overview

Micro- and nanofluidic devices have gained much recent attention due to their increasing applications in chemical analysis, biological and medical diagnostics and energy supply [1, 2]. The inherent advantages of miniaturization

lie in the integration of complex multifunctions while retaining precise control of objects. Actuating without any moving parts is a new and promising direction for microsystem designs despite the low efficiency [3]. Electrokinetic flow (EKF) is one of the most important nonmechanical techniques for micro- and nanofluidics, and has been widely applied for pumping, mixing, and separating [2–5]. Recently, charged porous media structures have been employed in microdevices to change the fluid behavior. A low flow rate together with a high pumping pressure is therefore obtained, which has been used in capillary electrochromatography (CE) and improved high-performance micropumps [3, 5].

Due to their many applications, electrokinetic microfluidics and nanofluidics have been much studied in the past decades, both theoretically and numerically. From the macroscopic point of view, the EOFs are governed by the Poisson–Boltzmann equation for electrical potential distributions and the Navier–Stokes equations for flows [1, 6]. Accurate and efficient solution of the nonlinear Poisson–Boltzmann equation is a challenge for both mathematicians and physicists. Hundreds of research papers related to this topic appear every year. Most previous research has employed conventional partial differential equation (PDE) solvers, such as the finite difference method (FDM) and the finite element method (FEM) to solve the nonlinear Poisson–Boltzmann equation in its linearized form. Good predictions have been obtained by solving the original nonlinear Poisson–Boltzmann equation using FDM or FEM [7, 8], however, they have suffered from the huge computational due to the strong nonlinearity. The fast Fourier transform (FFT) and the multigrid techniques greatly improve the efficiency of the numerical solution of the nonlinear Poisson–Boltzmann equation; however, it is a large challenge to extend them for complex geometries.

In recent years, a mesoscopic statistics-based method, the lattice Boltzmann method (LBM), has been developed for electrokinetic transports in microdevices. He and Li [9] have proposed a lattice Boltzmann scheme to analyze the electrochemical processes in an electrolyte based on a locally electrically neutral assumption. Li and Kwok [10] have simulated the electrokinetic flows in microchannels using a LBM with a one-dimensional linearized solution of the Poisson–Boltzmann equation. Melchionna and Succi [11] have solved the nonlinear Poisson–Boltzmann equation by an efficient multigrid technique and have predicted the flow behavior using a lattice Boltzmann scheme. The multigrid technique is very efficienct at solving the nonlinear Poisson–Boltzmann equation; however, it has rarely been extended to complex geometries. Guo et al. [12] have presented a finite-difference-based lattice Boltzmann algorithm for electroosmotic flows with the Joule heating effect. Wang et al. [13] have developed a lattice Poisson–Boltzmann method (LPBM) which combined a lattice Poisson method (LPM) for solving the nonlinear Poisson–Boltzmann equation for electric potential distribution with the LBM for solving the Boltzmann–BGK equation for fluid flow. The LPBM has been applied to study the electroosmotic flows in straight or rough microchannels [13–15] and in various charged microporous media [16–18]. This essay introduces the latest progress in the analysis of electroosmotic microfludics using the LPBM. The results will be compared with existing theoretical and experimental data and the fluid mechanisms will be analyzed and discussed.

Basic Methodology

Governing Equations

When the polarization and chemical absorption effects are negligible, consider an N-component Newtonian electrolyte flowing with velocity $\boldsymbol{u}(\boldsymbol{r}, t)$ in the interstices of a porous material. Let $\psi(\boldsymbol{r}, t)$ be the electric potential prevailing within the solution; the flux $\boldsymbol{j}_i$ of each ith ion species, composing the solute, is given by the following constitutive equation [19]:

$$\boldsymbol{j}_i = -D_i \nabla n_i - e z_i b_i n_i \nabla \psi + n_i \boldsymbol{u} \tag{1}$$

where n_i is the number density of the ith ion species, z_i is the ith ion algebraic valence, and e is the absolute charge of the electron. D_i and b_i are, respectively, the ion's diffusivity and electric mobility, related by the Stokes–Einstein equation

$$D_i = b_i kT \tag{2}$$

where k is the Boltzmann constant and T is the absolute temperature. The ionic flux $\boldsymbol{j}_i$ and the concentration n_i obey the continuity equation

$$\frac{\partial n_i}{\partial t} + \nabla \cdot \boldsymbol{j}_i = 0 \tag{3}$$

For an incompressible laminar flow, the movement of the electrolyte is governed by the continuity and momentum equations

$$\nabla \cdot \boldsymbol{u} = 0 \tag{4}$$

$$\rho \frac{\partial \boldsymbol{u}}{\partial t} + \rho \boldsymbol{u} \cdot \nabla \boldsymbol{u} = -\nabla p + \mu \nabla^2 \boldsymbol{u} + \boldsymbol{F}_{\mathrm{E}} \tag{5}$$

where ρ is the solution density, p is the pressure, μ is the dynamic fluid viscosity and $\boldsymbol{F}_{\mathrm{E}}$ is the electric force density vector. In general, the electrical force in electrokinetic fluids can be expressed as

$$\boldsymbol{F}_{\mathrm{E}} = \boldsymbol{F}_{\mathrm{ext}} + \rho_{\mathrm{e}}\left(\boldsymbol{E}_{\mathrm{int}} + \xi \times \boldsymbol{B}_{\mathrm{int}}\right) + \boldsymbol{F}_{\mathrm{V}} \tag{6}$$

where $\boldsymbol{F}_{\mathrm{ext}}$ represents the external field body forces, including the Lorentz force associated with any externally applied electric and magnetic field. For only an electrical field, $\boldsymbol{F}_{\mathrm{ext}} = \rho_{\mathrm{e}}\boldsymbol{E}$, where$\rho_{\mathrm{e}}$ is the net charge density and $\boldsymbol{E}$ is the electrical field strength. $\boldsymbol{E}_{\mathrm{int}}$ and $\boldsymbol{B}_{\mathrm{int}}$ are, respectively, the internally smoothed electrical and magnetic fields due to the motion of the charged particles inside the fluid. $\boldsymbol{F}_{\mathrm{V}}$ is a single equivalent force density due to the intermolecular attraction [10]. In the present contribution, we are concerned with steady-state electroosmosis so that the electromagnetic susceptibility is negligible. The net charge density ρ_{e} can be expressed as

$$\rho_{\mathrm{e}} = \sum_i e z_i n_i \tag{7}$$

The local electrical potential is governed by the Poisson equation

$$\nabla^2\psi = -\frac{\rho_{\mathrm{e}}}{\varepsilon_{\mathrm{r}}\varepsilon_0} = -\frac{1}{\varepsilon_{\mathrm{r}}\varepsilon_0}\sum_{i=1}^{N} e n_i z_i \tag{8}$$

where ε_{r} is the dimensionless fluid dielectric constant and ε_0 is the permittivity of a vacuum. Eqs. (3)–(8) are the governing equations for electroosmosis and can be solved subject to the following boundary conditions on the liquid–solid interface Ω:

$$(\boldsymbol{v} \cdot \boldsymbol{j}_i)_{\Omega} = 0 \tag{9}$$

$$\boldsymbol{u}_{\Omega} = 0 \tag{10}$$

$$\psi_{\Omega} = \zeta \tag{11}$$

where $\boldsymbol{v}$ is the outer normal to Ω, and ζ is the zeta potential. For the electroosmotic flow of dilute electrolyte, the macroscopic velocity is low so that the equilibrium is satisfied everywhere in the flow field base, so one can obtain the Boltzmann distribution for n_i

$$n_i = n_{i,\infty}\exp\left(-\frac{e z_i}{kT}\psi\right) \tag{12}$$

where $n_{i,\infty}$ is the bulk ionic number density. Substituting Eq. (12) into Eq. (8) yields the famous nonlinear Poisson–Boltzmann equation for electrokinetic flows [6]

$$\nabla^2\psi = -\frac{1}{\varepsilon_{\mathrm{r}}\varepsilon_0}\sum_i e z_i n_{i,\infty}\exp\left(-\frac{e z_i}{kT}\psi\right) \tag{13}$$

The present contribution actually solves the governing equations (Eqs. (4)–(7), (12), (13)) subject to the boundary conditions (Eqs. (9)–(11)) by the numerical methods described in the next section.

The LPBM

The continuity and momentum equations can be solved by tracking the movements of molecule ensembles through the evolution of the distribution function [20] using the popular LBM. The lattice Boltzmann equation (LBE) can be derived from the Boltzmann equation. For the flows with external forces, the continuous Boltzmann–BGK equation with an external force term, F, is

$$\frac{Df}{Dt} \equiv \partial_t f + (\xi \cdot \nabla)f = -\frac{f - f^{\mathrm{eq}}}{\tau_\nu} + F \tag{14}$$

where $f \equiv f(x, \xi, t)$ is the single particle distribution function in the phase space (x, ξ), ξ is the microscopic velocity, τ_ν is the relaxation time, and f^{eq} is the Maxwell–Boltzmann equilibrium distribution. For a steady fluid immersed in a conservative force field, the equilibrium distribution function is defined by adding a Boltzmann factor to the Maxwell–Boltzmann distribution

$$f^{\mathrm{eq}} = \frac{\rho_0}{(2\pi RT)^{D/2}}\exp\left(-\frac{U}{kT}\right)\exp\left(-\frac{(\xi - \boldsymbol{u})^2}{2RT}\right) \tag{15}$$

where U is the potential energy of the conservative force field, ρ_0 is the fluid density where U is lowest, R is the ideal gas common constant, D is the dimension of the calculation space, k is the Boltzmann constant, and $\boldsymbol{u}$ is the macroscopic velocity. The external force term, F, needs to be chosen carefully. Dimensional analysis leads to the following form of F:

$$F = \frac{\boldsymbol{G}\cdot(\xi - \boldsymbol{u})}{RT}f^{\mathrm{eq}} \tag{16}$$

where $\boldsymbol{G}$ is the external force per unit mass [20]. The Chapman–Enskog expansion can be used to transform the Boltzmann–BGK equation (Eq. (14)) into the correct continuum Navier–Stokes equations.

For the two-dimensional case, third-order Gauss–Hermite quadrature leads to the nine-speed LBE model with the

L

discrete velocities

$$\boldsymbol{e}_\alpha = \begin{cases} (0,0) & \alpha = 0 \\ (\cos\theta_\alpha, \sin\theta_\alpha)c, & \theta_\alpha = (\alpha-1)\pi/2 \\ & \alpha = 1,2,3,4 \\ \sqrt{2}(\cos\theta_\alpha, \sin\theta_\alpha)\,c, & \theta_\alpha = (\alpha-5)\pi/2 + \pi/4 \\ & \alpha = 5,6,7,8 \end{cases} \tag{17}$$

where c is the speed of sound and the density equilibrium distribution is

$$f_\alpha^{\mathrm{eq}} = \omega_\alpha \rho_0 \exp\left(-\frac{U}{kT}\right) \times \left[1 + 3\frac{\boldsymbol{e}_\alpha \cdot \boldsymbol{u}}{c^2} + \frac{9}{2}\frac{(\boldsymbol{e}_\alpha \cdot \boldsymbol{u})^2}{c^4} - \frac{3\boldsymbol{u}^2}{2c^2}\right] \tag{18}$$

with

$$\omega_\alpha = \begin{cases} 4/9 & \alpha = 0 \\ 1/9 & \alpha = 1,2,3,4 \\ 1/36 & \alpha = 5,6,7,8 \end{cases} \tag{19}$$

Thus, the discrete density distribution satisfies the evolution equation

$$f_\alpha(\boldsymbol{r} + \boldsymbol{e}_\alpha\delta_t, t+\delta_t) - f_\alpha(\boldsymbol{r}, t) = -\frac{1}{\tau_\nu}\left[f_\alpha(\boldsymbol{r}, t) - f_\alpha^{\mathrm{eq}}(\boldsymbol{r}, t)\right] + \delta_t F_\alpha\,, \tag{20}$$

where $\boldsymbol{r}$ is the position vector, δ_t is the time step, and τ_ν is the dimensionless relaxation time which is a function of the fluid viscosity

$$\tau_\nu = 3\nu\frac{\delta_t}{\delta_x^2} + 0.5 \tag{21}$$

where ν is the kinetic viscosity and δ_x is the lattice constant (or grid size).

For electrokinetic flows in dilute electrolyte solutions, the external electrical force in Eq. (5) can be simplified to

$$\boldsymbol{F}_{\mathrm{E}} = \rho_{\mathrm{e}}\boldsymbol{E} - \rho_{\mathrm{e}}\nabla\Phi \tag{22}$$

where Φ is the stream electrical potential caused by the ion movements in the solution based on the Nernst–Planck theory. Generally, the stream potential dominates the electroviscosity effect in pressure-driven flows, but its value is much less than the external potential and can be ignored in electrically driven flows. Therefore, the external force in the discrete LBE should include the pressure and electric force

$$F_\alpha = \frac{(-\nabla P + \rho_{\mathrm{e}}\boldsymbol{E} - \rho_{\mathrm{e}}\nabla\Phi)\cdot(\boldsymbol{e}_\alpha - \boldsymbol{u})}{\rho RT} f_\alpha^{\mathrm{eq}}\,. \tag{23}$$

The macroscopic density and velocity can be calculated using

$$\rho = \sum_\alpha f_\alpha \tag{24}$$

$$\rho\boldsymbol{u} = \sum_\alpha \boldsymbol{e}_\alpha f_\alpha \tag{25}$$

Borrowing from the LBM, one can rewrite Eq. (13) as a Boltzmann-like equation by expanding a time-dependent term

$$\frac{\partial\psi}{\partial t} = \nabla^2\psi + g_{\mathrm{rhs}}(\boldsymbol{r}, \psi, t) \tag{26}$$

where

$$g_{\mathrm{rhs}} = \frac{1}{\varepsilon\varepsilon_0}\sum_i z_i e n_{i,\infty}\exp\left(-\frac{z_i e}{k_{\mathrm{b}}T}\psi\right)$$

represents the negative right-hand side term of the original Poisson–Boltzmann equation. The solution of Eq. (13) is actually the steady-state solution of Eq. (26). The evolution equation for the electrical potential on the two-dimensional discrete lattices can then be written as

$$g_\alpha(\boldsymbol{r} + \Delta\boldsymbol{r}, t + \delta_{\mathrm{t,g}}) - g_\alpha(\boldsymbol{r}, t) = -\frac{1}{\tau_{\mathrm{g}}}\left[g_\alpha(\boldsymbol{r}, t) - g_\alpha^{\mathrm{eq}}(\boldsymbol{r}, t)\right] + \left(1 - \frac{0.5}{\tau_{\mathrm{g}}}\right)\delta_{\mathrm{t,g}}\omega_\alpha g_{\mathrm{rhs}} \tag{27}$$

where the equilibrium distribution of the electric potential evolution variable g is

$$g_\alpha^{\mathrm{eq}} = \varpi_\alpha\psi, \quad \text{with} \quad \varpi_\alpha = \begin{cases} 0 & \alpha = 0 \\ 1/6 & \alpha = 1,2,3,4 \\ 1/12 & \alpha = 5,6,7,8 \end{cases} \tag{28}$$

The time step in Eq. (27) is

$$\delta_{\mathrm{t,g}} = \frac{\delta_x}{c'}\,, \tag{29}$$

where c' is a pseudo-speed of sound in the potential field [13]. The dimensionless relaxation time for Eq. (27) is

$$\tau_g = \frac{3\chi\delta_{t,g}}{2\delta_x^2} + 0.5 \tag{30}$$

where χ is defined as the potential diffusivity which equals unity in these simulations.

The evolution equations (Eqs. (27)–(30)) were proved to be consistent with the macroscopic nonlinear Poisson–Boltzmann equation (Eq. (6)). After evolving on the discrete lattices, the macroscopic electrical potential can be calculated using

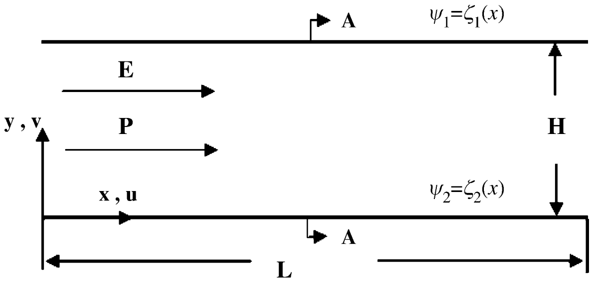
$$\psi = \sum_{\alpha}(g_\alpha + 0.5\delta_{t,g}g_{rhs}\omega_\alpha) \tag{31}$$

Though the electrical potential evolution equations are in an unsteady form, only the steady-state result is realistic, because the electromagnetic susceptibility has not been considered. Although the lattice evolution method for the nonlinear Poisson equation is not as efficient as the multigrid solutions due to its long wavelength limit, it has the advantage that it is suitable for complex geometries and parallel computing. Although this essay only presents two-dimensional cases, the algorithm can easily be extended to three-dimensional cases.

Boundary Treatments

The boundary condition implementations play a very critical role in the accuracy of the numerical simulations. The hydrodynamic boundary conditions for the LBM have been studied extensively. The conventional bounce-back rule is the most popular method used to treat the velocity boundary condition at the solid-fluid interface due to its easy implementation, where momentum from an incoming fluid particle is bounced back in the opposite direction as it hits the wall [20]. However, the conventional bounce-back rule has two main disadvantages. First, it requires the dimensionless relaxation time to be strictly within the range (0.5, 2), otherwise the prediction will deviate from the correct result. Second, the nonslip boundary implemented by the conventional bounce-back rule is not located exactly on the boundary nodes, as mentioned before, which will lead to inconsistence when coupling with other partial differential equation (PDE) solvers on a same grid set [17].

To overcome the inconsistence between the LBM and other PDE solvers on a same grid set, an alternative solution is to modify the boundary condition treatments of the PDE solver for the electric potential distribution to be consistent with the LBM bounded by the bounce-back rule.



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 1 Boundary conditions for electroosmotic flow in a microchannel

In this contribution, the half-way bounce-back rule for nonequilibrium distribution proposed by Zou and He [21] is introduced and extended to both hydrodynamic and electrodynamic boundary implementations to deal with the complex geometries.

At the boundary the following hydrodynamic boundary condition holds:

$$f_\alpha^{neq} = f_\beta^{neq} \tag{32}$$

where the subscripts α and β represent opposite directions. Analogously, the nonequilibrium *bounce-back* rule for the electric potential distribution at the wall surfaces is suggested as

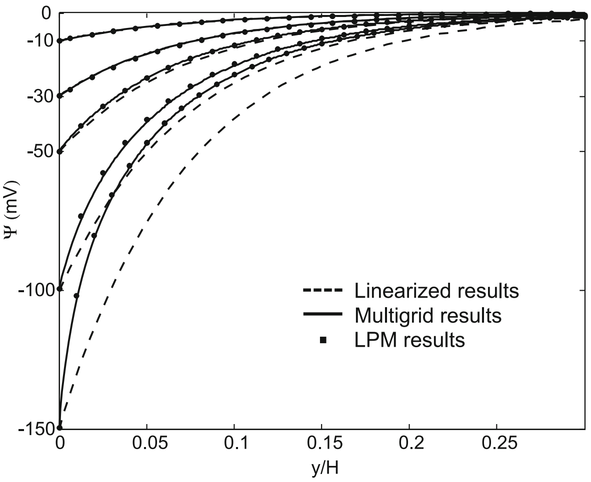
$$g_\alpha^{neq} = -g_\beta^{neq} \tag{33}$$

The *half-way* bounce-back scheme with interpolation is used to deal with the curved surfaces [22]. This boundary treatment has a superlinear accuracy when the wall surface varies between two adjacent nodes and approximately second-order accuracy if the wall surface is in the middle. This method is easy to implement for complicated boundary conditions without special considerations for the corners.

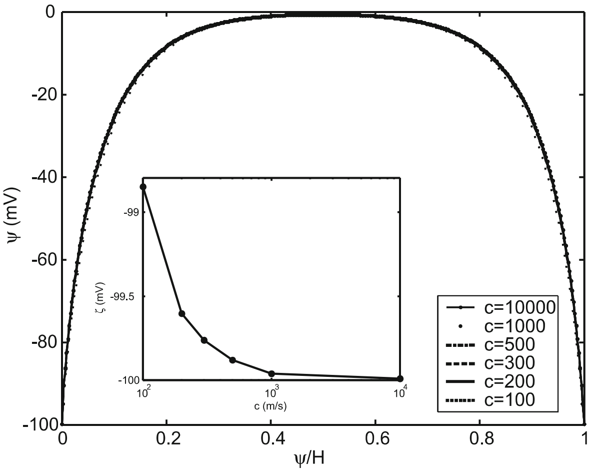
The LPBM simulates the EOF in two steps: first, the lattice method solves the nonlinear Poisson–Boltzmann equation for a stable electrical potential distribution; second, the LBM is used to simulate the steady electrically driven fluid flow in the microchannel.

Key Research Findings

After validation, the LPBM has been employed to simulate the electroosmotic flows in microgeometries. Besides the straight channel, complex geometries have also been considered, including a rough channel, porous arrays, and even random porous media. The simulation results are also compared with the existing experimental data.



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 2 LPM results compared with the linearization results and multigrid solutions for various surface zeta potentials (−10 mV, −30 mV, −50 mV, −100 mV, −150 mV)



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 3 Effects of the pseudo speed of sound values on the potential distribution and the zeta potential (inset) for the Dirichlet boundary condition calculations at $\zeta_0 = -100$ mV

Numerical Issues

Figure 1 shows a two-dimensional straight microchannel which is charged homogeneously or heterogeneously on the walls. The zeta potential distributions on the upper and lower walls are $\zeta_1(x)$ and $\zeta_2(x)$. The channel is H wide and L long. The electrolyte solution in the channel is driven by an electrical field, a pressure field, or both of these.

For a 1 : 1 electrolyte solution flowing in a microchannel with periodic inlet/outlet boundaries and homogeneous walls, the Poisson–Boltzmann equation (Eq. (13)) can be simplified into the one-dimensional form

$$\frac{d^2\psi}{dy^2} = \frac{2n_\infty ze}{\varepsilon\varepsilon_0} \sinh\left(\frac{ze}{kT}\psi\right) \tag{34}$$

If $ze\psi/kT$ is small, $\sinh(ze\psi/kT) \approx ze\psi/kT$. Eq. (33) can be linearized as

$$\frac{d^2\psi}{dy^2} = \frac{2n_\infty z^2e^2}{\varepsilon\varepsilon_0 kT}\psi = \kappa^2\psi \tag{35}$$

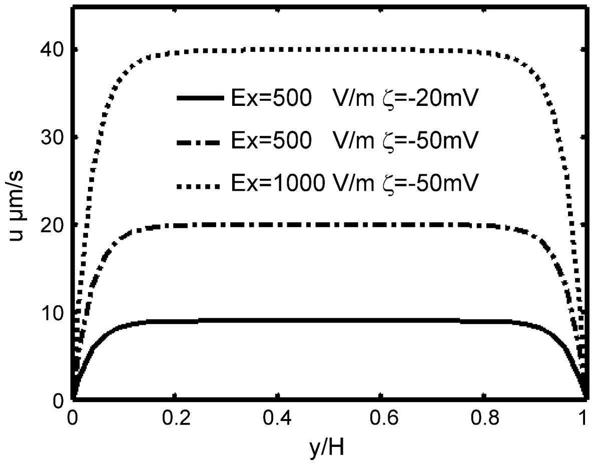
where $\kappa = \sqrt{2n_\infty z^2e^2/\varepsilon\varepsilon_0 kT}$ is defined as the reciprocal of the Debye length in Debye–Huckel theory. The linear one-dimensional ordinary differential equation in Eq. (35) has a simple analytical solution for a specified set of boundary conditions.

Figure 2 compares the LPM results for the nonlinear Poisson–Boltzmann equation (Eq. (13)) and the analytical solutions of the linearized equation (Eq. (35)), together with a numerical solution using the multigrid method. The parameters are: the bulk ionic molar concentration $c_\infty = 10^{-4}$ M, $n_\infty = c_\infty N_A$ where N_A is Avogadro's number, $z = 1$ is the dielectric constant of the solution $\varepsilon\varepsilon_0 = 6.95 \times 10^{-10}\ C^2/J\,m$, the temperature $T = 273$ K, and $\psi_1 = \psi_2 = \psi_s$ with ψ_s as a constant.

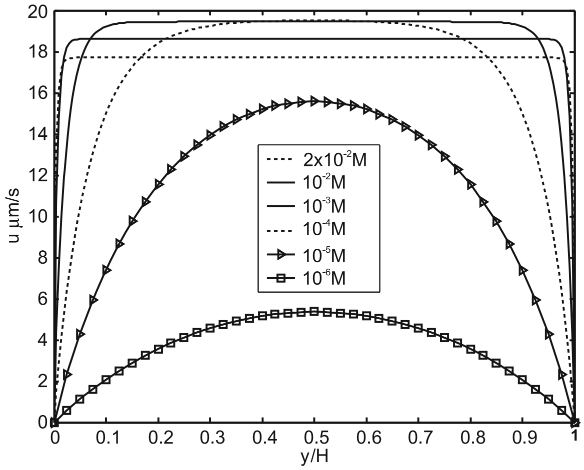
In general, the linearization is accurate when ψ is small. Figure 2 shows that the LPM results agree perfectly with multigrid solutions at all zeta potentials and with the analytical solution of the linearized equation when the absolute value of the surface zeta potential ζ is small, less than about 30 mV. This validates the accuracy of the LPM. When the absolute value of the zeta potential is large (> 30 mV), the numerical results of the LPM depart from the linearized analytical solutions as expected.

The accuracy of the present LPBM relies on the size of the lattice relative to the width of the electric double layer (EDL). Previous study showed that the lattice should be smaller than the EDL width for an accurate numerical simulation [13]. In the simulations of this work, the size of the lattice is set much smaller than the width of the EDL, i. e., δ_x is usually between 1/10 and 1/3 for each EDL width. We can initialize a still system and judge the steady status of the electrical potential and velocity distributions by the relative errors every 100 steps with the middle point being smaller than 10^{-10}.

The computational efficiency also depends on the dimensionless relaxation times (τ_ν and τ_g) that are chosen. When the lattice size and the fluid properties are given, the relaxation time is determined by the lattice speed of sound (c and c'). Figure 3 shows the effects of c' on the LPM simulation results. The results show that the electric potential distribution is little influenced by c'. The inset in Fig. 3



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 4 Velocity profiles for various external electrical fields and different zeta potentials

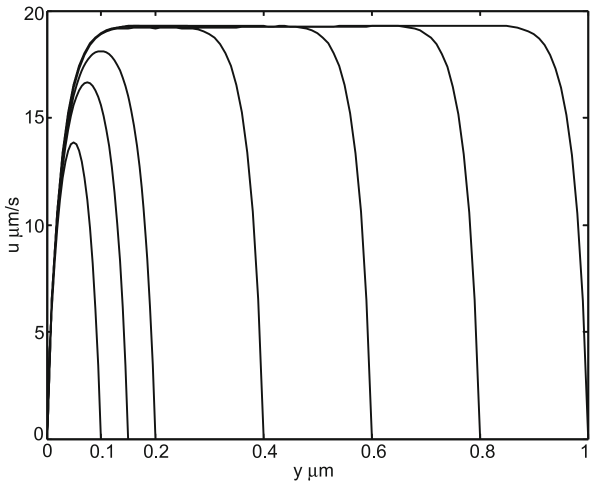


Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 5 Velocity profiles for various ionic molar concentrations for electrically driven flow

shows that the c values affect the calculated zeta potential on the surface. A larger c' value leads to a value of the zeta potential which is closer to the prespecified value. However, when c' is larger than 300, the deviation may be below 0.3%. Calculations at a larger value of c' need more computational time to reach stable results. One can obtain a balance between efficiency and accuracy according to the level of detail required.

Straight Microchannel Flow

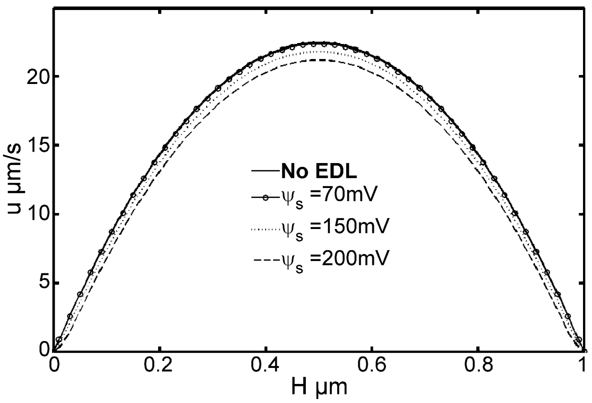
The first example considers a flow driven by only the electrical field in a homogeneous microchannel. The inlet and



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 6 Velocity profiles for different channel widths: $c_\infty = 10^{-4}$ M, $E = 5 \times 10^2$ V/m, $\psi_s = -50$ mV

outlet boundaries are periodic. The channel is 0.8 μm wide and the ionic molar concentration far from the wall surface is 10^{-4} M for the results shown in Fig. 4. As has previously been observed in qualitative results both experimentally and numerically [1], the velocity in the electrically driven osmotic flow is nearly proportional to the external electrical field strength, as well as the surface zeta potential in a homogeneous channel. These results have also been observed in MD simulations in nanochannel flows [23].

Figure 5 shows the velocity profiles for the various bulk ionic concentrations c_∞. The channel width is 0.4 μm, the external electric field strength $E = 5 \times 10^2$ V/m, and the surface zeta potential $\psi_s = -50$ mV for both walls. The fluid properties are the same as those of water at the standard state which are the dielectric constant $\varepsilon\varepsilon_0 = 6.95 \times 10^{-10}\, C^2/J \cdot m$, the density $\rho = 1.0 \times 10^3\, kg/m^3$ and the viscosity $\mu = 0.89$ Pa s. The results show an optimal ionic concentration that maximizes the average velocity. As the ionic molar concentration decreases from a high value (2×10^{-2}), the EDL thickness increases so that although the force is slightly reduced, the electrical force domain increases and thus the average velocity increases. There is a concentration at which the effect of the electrical force can dominate the entire channel and make the velocity reach maximum (10^{-4} – 10^{-3} M for current simulations). As the ionic concentration decreases (e. g., from 10^{-4} to 10^{-6}), the reduction in the force becomes the most important factor and the average velocity decreases. The lower ionic concentrations also result in a more parabolic-like velocity profile.



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 7 Velocity profiles for various surface zeta potentials in a homogeneous channel with pressure driven flow

Figure 6 shows the velocity profiles for various channel widths for $c_\infty = 10^{-4}$ M, $E = 5\times10^2$ V/m and $\psi_s = -50$ mV. The channel width varies from 0.1 µm to 1 µm. For channel widths larger than double the thickness of the EDLs, the maximum velocity seldom changes with the channel width. However, for channels widths less than double the size of the EDL thickness, a smaller channel width leads to a smaller velocity.

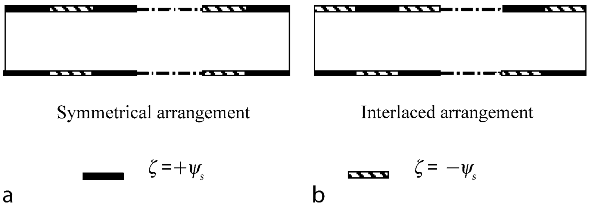
When an electrolyte solution flows in a microchannel driven only by the pressure gradient, the charged wall surface will increase the resistance, which is defined as the electroviscosity effect. This effect has been proven experimentally [1]. Dynamic models based on the Navier–Stokes equations have been built to model this effect [1]. The following example investigates this effect using the LPBM.

For a two-dimensional electrokinetic steady-state flow in microchannels, the streaming potential, Φ, in Eq. (22) can be defined by the constraint of current continuity [1, 10]

$$\Phi = -L\frac{\int_0^H u(x,y)\rho_e(x,y)\,dy}{(\lambda_b + \lambda_s\kappa)H} \tag{36}$$

where λ_b is the electrical conductivity of the bulk fluid and λ_s is the surface conductance. In the present simulations, λ_b is 1.42×10^{-3} S/m and λ_s is 1.64×10^{-9} S.

Velocity profiles for flow in a homogeneous channel are show in Fig. 7 for a channel having a width of 1×10^{-6} m, $c_\infty = 10^{-4}$ M, $dP/dx = 1\times10^6$ Pa/m, and the surface zeta potentials, ψ_s, range from 0 to −200 mV. When $|\psi_s|$ is very small (< 100 mV), the velocity profile is almost same as the non-EDL channel flow profile. When $|\psi_s|$ is larger than 100 mV, the electroviscosity effect becomes noticeable and the effect increases with $|\psi_s|$. Unlike the regular viscosity effect, the electroviscosity effect mainly affects the velocity distribution near the wall away from the parabolic shape.



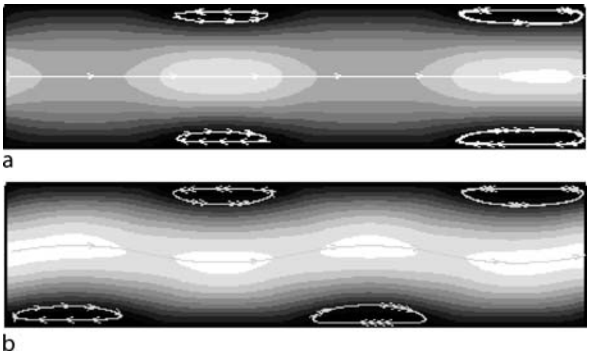
Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 8 Two typical charge arrangements of the zeta potential

It is difficult to obtain a complete mixing in the microfluidic systems because the operations are always limited to low Reynolds number regimes characterized by laminar flow. Therefore a number of microfluidic mixing-enhancement devices [1, 4], which can be broadly classified as either passive or active mixers, have been develpoed. The electrokinetic flow can be used as an active mixer with no mechanically moving parts. It has many promising applications due to its easy control and suitability for integration with M/NEMS devices.

Figure 8 shows two typical zeta potential arrangements on the wall surfaces: the symmetrical arrangement (Fig. 8a) and the interlaced arrangement (Fig. 8b). Each wall is divided into N parts each of which is charged $+\psi_s$ or $-\psi_s$. Figure 9 shows the calculated velocity contours for these two arrangements when other conditions are same. The parameters are $H = 0.4$ µm, $c_\infty = 10^{-4}$ M, $dP/dx = 1\times10^6$ Pa/m, $\psi_s = -50$ mV, and $E = 5\times10^2$ V/m. The electrical force causes vortices to appear near the surface that act as small stirrers in the channel. If two kinds of fluids or a suspension flows in the channels, the vortices will enhance the mixing. The mixing strength can easily be controlled by changing the electrical field strength or the zeta potentials. A quantitative investigation has been carried out on the effects of the arrangement scheme, division part number (N), and external electric field strength on the mixing enhancements in a heterogeneously charged microchannel by adding another lattice evolution method for concentration propagation [14]. The results showed that the mixing enhancement effect for the interlaced arrangement was 35% higher than for the symmetrical arrangement for a certain condition [14].

Roughness and Cavitation Effects

Although the electroosmotic flow in smooth straight microchannels has been much studied, the results are some way from realistic applications because there is much roughness and cavitations on the wall surfaces instead of



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 9 Velocity contours for different heterogeneous zeta potential distributions in electro-pressure driven flows. (**a**) Symmetrical arrangement of surface potential; (**b**) interlaced arrangement of surface potential.

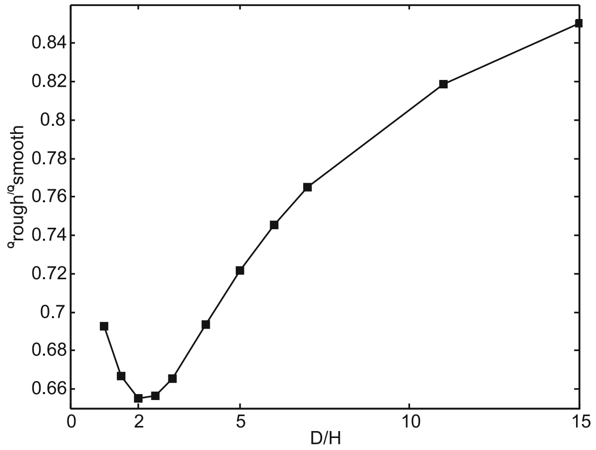
Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 11 Variation of flow rate with height of roughness: $c_\infty = 10^{-4}$ M, $E = 5\times10^2$ V/m, $\psi_s = \psi_r = -50$ mV, $H = 0.4$ μm, $w = H/4$, $D = 3H/4$

ideal smoothness. Sometimes the roughness or cavitation could be used for some special function in microchannel flows. To the author's knowledge, there is only a small amount of published literature which presents an analysis of the EOF in rough channels [1]. This section will introduce some new results for the roughness and cavitation effects on EOF in microchannels using the LPBM.

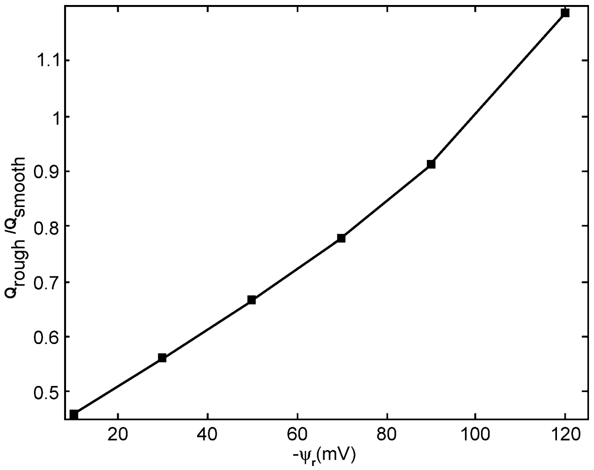
The roughness is simplified as a group of rectangles on the lower channel wall here, as shown in Fig. 10. The channel is H in width, with both walls charged with a surface zeta potential ψ_s. The channel is periodic in the x-direction. The roughness is w in width and h in height. The roughness is uniformly arranged in the channel with an interval space D. The three surfaces of each roughness are charged at a surface zeta potential ψ_r. The A–A section is the middle cross-section for each roughness. The electrolyte solution is driven by an external electrical field E. The fluid parameters are the same as those used in Sect. Straight Microchannel Flow. We now consider various cases for different roughness heights (h), different arrangement interval spaces (D), and different surface zeta potentials (ψ_r).

Figure 11 shows the flow rate changing with the height of the roughness. The ionic concentration of the electrolyte solution is $c_\infty = 10^{-4}$ M. The external electrical field strength is $E = 5\times10^2$ V/m. Both the channel and roughness surfaces are homogeneously charged at $\psi_s = \psi_r = -50$ mV. The channel is 0.4 μm wide and is divided into 40 lattices. The roughness width is $w = H/4$ and the interval space $D = 3H/4$. The roughness height h changes from 0 (smooth case) to $H/4$. The results indicate that the electrically driven flow rate changes very slowly with the height of the roughness when the roughness is very small ($h/H < 0.05$). A very short roughness ($h/H < 0.025$) even seems to slightly enhance the flow rate. The charged roughness plays two roles: first it changes the electrical field distribution which may enhance the electric driving force, and second it increases the flow resistance. When the former factor dominates, the flow rate could increase; otherwise the flow rate will decrease. When the roughness height is larger than 1/10 of the channel width, the flow rate will decrease sharply with the height of the roughness. The interesting anomalous variation of flow rate with the height of the roughness has not been reported and validated. A further analysis and consideration on the flow mechanism will be performed in future work using our multiscale simulation tools by coupling atomistic and continuum methods.

Figure 12 shows the flow rates influenced by the roughness interval space when the width and height of the roughness are $H/4$. The other parameters are $c_\infty = 10^{-4}$ M, $E = 5\times10^2$ V/m, $\psi_s = \psi_r = -50$ mV, and $H = 0.4$ μm.



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 12 Variation of flow rate with roughness interval: $c_\infty = 10^{-4}$ M, $E = 5\times10^2$ V/m, $\psi_s = \psi_r = -50$ mV, $H = 0.4\,\mu$m, $w = H/4$, $h = H/4$

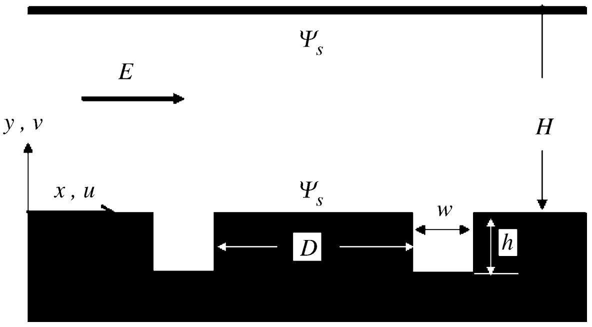


Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 13 Variation of flow rate with roughness surface potential for heterogeneously charged roughness: $c_\infty = 10^{-4}$ M, $E = 5\times10^2$ V/m, $\psi_s = -50$ mV, $H = 0.4\,\mu$m, $w = H/4$, $D = 3H/4$, $h = H/4$

When the roughness interval is smaller than twice the width of the roughness, the flow rate decrease with the interval space. However, when the roughness interval is larger than twice the width of the roughness, a larger interval space leads to a larger flow rate. Even for very sparse roughness cases, such as $D = 15$ w, the flow rate is lower than 90% that of a smooth channel, which shows that the roughness effect is not negligible in the analysis of electroosmotic flows in microfluidics.

The heterogeneously charged rough channel is also simulated here. The channel surface zeta potential remains at $\psi_s = -50$ mV and the roughness surface zeta potential ψ_r is changed from -10 to -120 mV. The asymmetric potential boundaries destroy the symmetry of the flow. Larger values of the surface zeta potential induce larger velocities near the surface. The flow rate also increases superlinearly with the roughness surface zeta potential. as shown in Fig. 13. In the current case, when the roughness surface zeta potential is -120 mV, the flow rate of the rough channel is even higher than that of the homogeneously charged smooth channel. Such characteristics could be used to enhance the flow rate in microfluidics by inserting high-surface-potential objects into the microchannel.

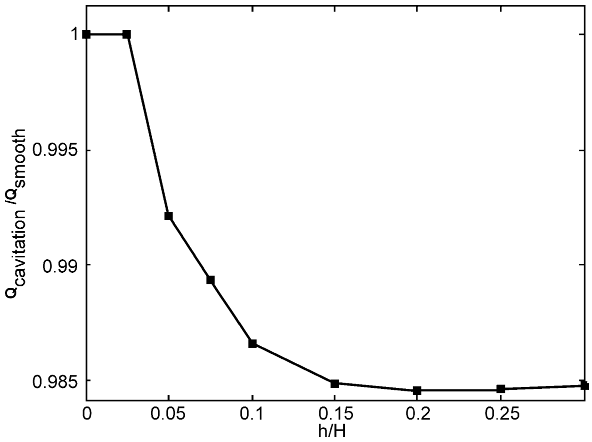
Both roughness and cavitations are fundamental aspects of the surface of a rough channel. In macroscopic flow, no divisions have been made between them. However, in microchannel flow, some difference has been reported on the flow friction between roughness and cavitations. Here the electroosmotic flows in microchannels with cavitations are simulated and analyzed, which has been seldom studied before.



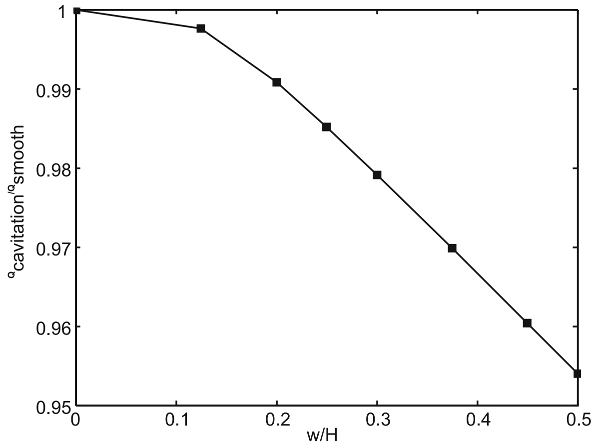
Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 14 Geometries and boundary conditions for a microchannel with cavitations

A microchannel with cavitations is shown in Fig. 14. The geometry and boundaries are quite similar to those for the roughness. The cavitation is h in depth, w in width and there is an interval, D, between each of them. Here the homogeneously charged case is only considered at $\psi_s = -50$ mV.

Figure 15 shows the relationship between the flow rate and the depth of the cavitations when $w = H/4$ and $D = 7H/4$. The other parameters are $c_\infty = 10^{-4}$ M, and $E = 5\times10^2$ V/m. The relative depth h/H changes from 0 (smooth channel) to 0.3. When the cavitations are very shallow ($h < 3\%H$), the flow rate remains almost unchanged with the depth of the cavitations. As the depth of the cavitations increases, the electrically driven flow rate decreases sharply. If the cavitations are deep enough (e. g., $h > 10\%H$), the flow rate decrease becomes slow

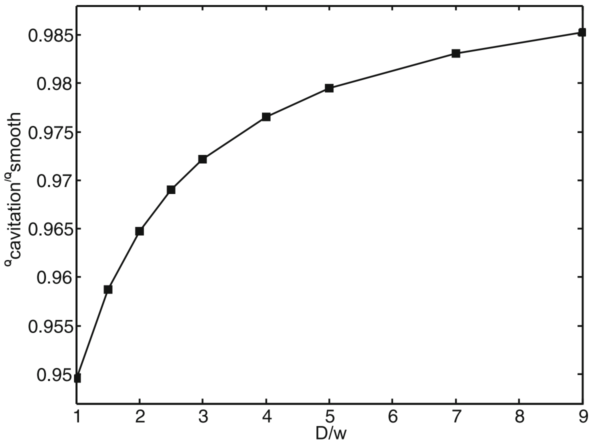


Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 15 Variation of flow rate with depth of cavitations at $w = H/4$ and $D = 7H/4$ where $c_\infty = 10^{-4}$ M, $E = 5 \times 10^2$ V/m, $\psi_S = -50$ mV, $H = 0.4$ μm



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 16 Variation of flow rate with width of cavitations: $c_\infty = 10^{-4}$ M, $E = 5 \times 10^2$ V/m, $\psi_S = -50$ mV, $H = 0.4$ μm

and the flow rate is asymptotically stable to a constant when the cavitations are very deep ($h \gg 20\%H$). Figure 9 indicates that the effect of the cavitations on the flow rate is not as significant as the roughness. The electrically driven flow rate difference in between a smooth channel and a cavitational channel is less than 3% for the current situations. The cavitations decrease the flow rate in the electroosmotic channel flows, which is different from the reported results in previous pressure driven flows, however, this is consistent with the atomistic simulation results [24]. The reason may be that the cavitations decrease the electric driving force more than they decrease the surface resistance to electroosmotic flows.



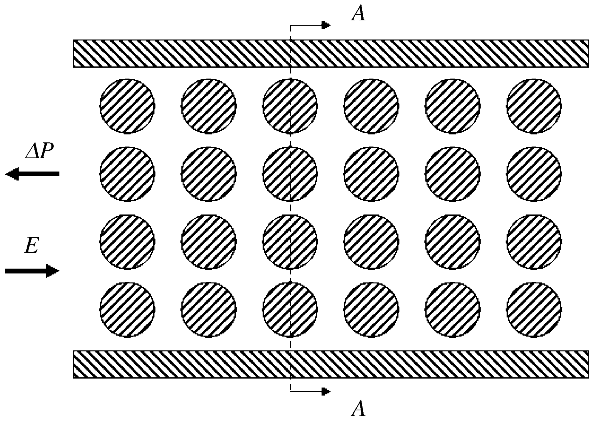
Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 17 Variation of flow rate with the cavitation intervals: $c_\infty = 10^{-4}$ M, $E = 5 \times 10^2$ V/m, $\psi_S = -50$ mV, $H = 0.4$ μm

The width and interval effects of the cavitations on the flow rate are shown in Figs. 16 and 17. In Fig. 16, the cavitations are deep enough, $h = 0.3H$, to eliminate the depth effect on the flow rate and the cavitations interval $D = 7H/4$. The results in Fig. 16 indicate that the flow rate decreases with the width of the cavitations. In Fig. 17, both the width and depth of the cavitations are fixed at $H/4$, and the interval space changes from one width to nine widths. The results indicate that the sparser the cavitations are, the larger the flow rates are and closer the flow rate is to the value of a smooth channel. Comparing Fig. 17 with Fig. 6 shows that the effect of the cavitations on the flow rate is much smaller than that of the roughness.

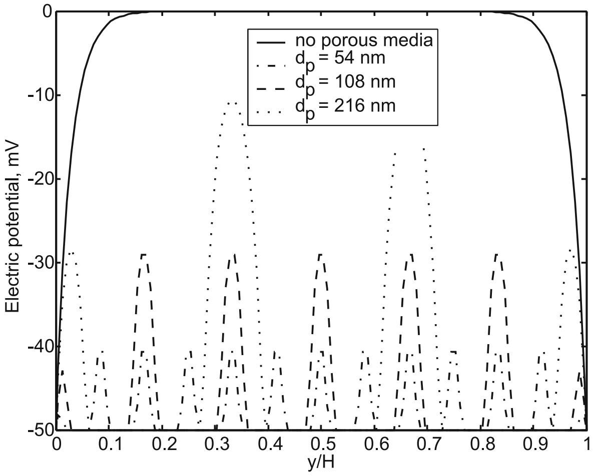
Pumping Effects of Charged Porous Media

Electrokinetic transport phenomena in porous media have been studied much in the past decade both theoretically and numerically; however, most results were actually based on linearization approximations of the Poisson–Boltzmann equation [5] so that reliable applications were limited to cases where the EDL length was very thin or very thick compared to the channel size. To our knowledge, there are very few publications that present successful numerical simulations for the electrokinetic flows in charged porous media by solving the nonlinear Poisson–Boltzmann equation and the Navier–Stokes equations by the classical CFD techniques [3, 5]. Because of easy implementation and high efficiency for fluid-solid boundary conditions, the LPBM great advantage in simulations of such flows.

Figure 18 shows a typical illustration of electrokinetic flows in structured porous media packed in a microchan-



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 18 Schematic illustration of electrokinetic flow in a microchannel packed with charged porous media. The *A–A* section crosses the centers of the cycles in the same section



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 19 Electric potential and velocity profiles of *A–A* section for different particle sizes

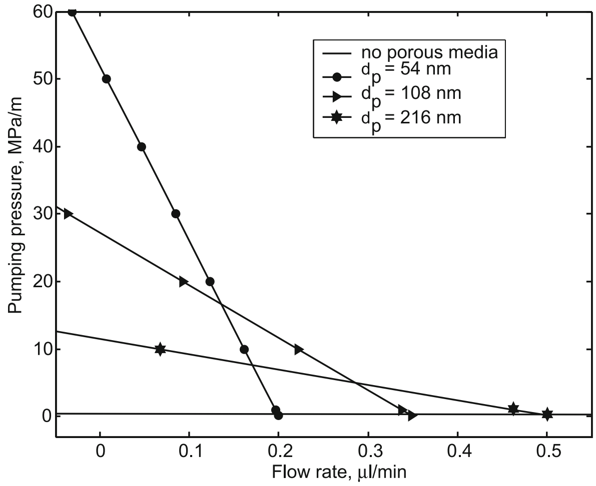
nel. Both the channel walls and the particle surfaces are charged. The flow of the electrolyte solution is driven by an external electric field, a pressure drop or both effects. In this section, we will simulate the electrokinetic pumping effects in charged porous media using the mesoscopic evolution numerical methods. The effects of particle size, ionic concentration, external electric field strength, and particle surface zeta potential on the electrokinetic pump performance are analyzed.

In the following two-dimensional simulations, the channel walls are homogeneously charged with the zeta potential $\psi_w = -50$ mV. The channel width H is 1 μm. The charged microspheres are arranged as a structured array with equal spaces between the channels. The particle diameter d_p varies in the range 54 – 325 nm, with the porosity remaining constant at 0.33. The particle surfaces are homogeneously charged. Their potentials ψ_p vary from -10 mV to -90 mV. The electrolyte solution is driven through the porous media, whose properties are: the relative dielectric constant $\varepsilon = 81$, the density $\rho = 1000\,\text{kg/m}^3$, and the dynamic viscosity $\mu = 0.889$ mPa s. The bulk ionic concentration c_∞ changes from 10^{-6} to 10^{-3} M and the external electric field strength E changes from 1 to 5 kV/m.

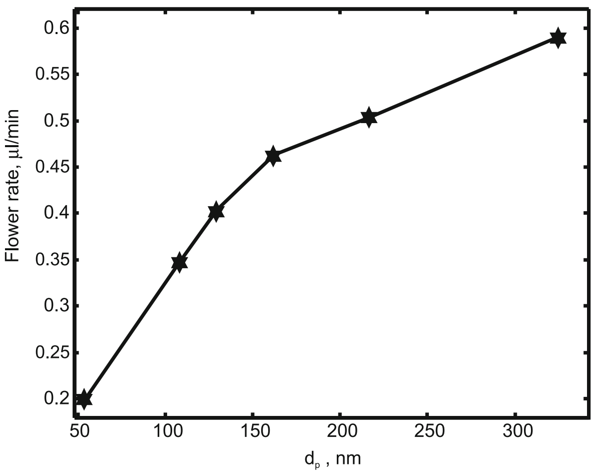
The effects of particle size on the electric potential distribution are first considered. In most previous analytical or numerical modeling of electroosmosis in porous media, the EDL was mostly assumed to be small compared to the particle size so that the Debye–Huckle theory would lead to simplified expressions for the electric potential and velocity fields [5]. However, when the particle size is the same as or even smaller than the EDL thickness, the particle surface zeta potential will significantly affect the bulk electric potential distribution, not only on the boundary conditions. Figure 19 shows the electric potential profiles across the *A–A* section for different particle sizes. Because the particle diameter and the gap distance are both comparable to the EDL thickness, the electric potential distribution is significantly affected by the particle surface charge. The electric potential profile in a channel packed with charged porous media is quite different from that in a vacant channel. Smaller particles lead to smaller electric potential maxima across the channel.

Since the porous media additive has been reported to improve the performances of the electroosmotic micropump, the nanoscale particle size effects on the pumping performance are investigated here. Figure 20 shows the backpressure versus flow rate for different particle sizes when $E = 1$ kV/m, $\psi_p = -50$ mV, and $c_\infty = 10^{-4}$ M. Compared with the no porous media additivity case, the porous media additivity improves the pump performance significantly with much higher pumping pressures and lower flow rates. A smaller particle size leads to a higher backpressure maximum and a lower zero-pressure-drop flow rate. Under the current parameters and conditions the backpressure maximum reaches over 50 MPa/m for $d_p = 54$ nm. For each case, the pressure and flow rate are in a linear relationship, which agrees with the experimental data in [5].

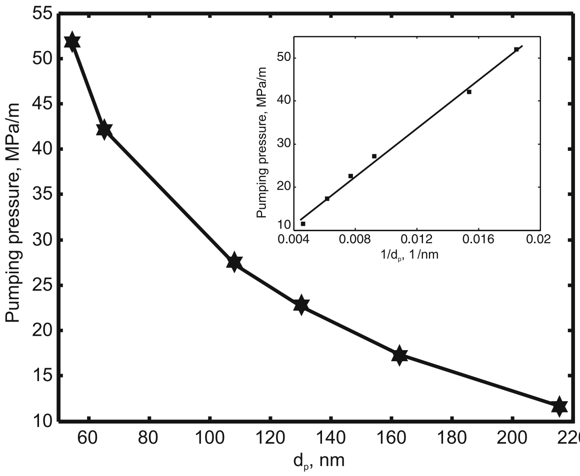
The maximum pumping pressure for each case can be obtained from the intercept of the pressure-flow rate curve on the y-axis. The curves of the maximum pumping pressure versus particle diameters are plotted in Fig. 21. The results indicate that the smaller the particle diameter, the higher the maximum pumping pressure. The subplot in Fig. 21 shows that the maximum pumping pressure is almost inversely proportional to the particle diameter. This



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 20 Backpressure versus flow rates for different particle sizes



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 22 Flow rate versus particle diameter under zero pressure drop



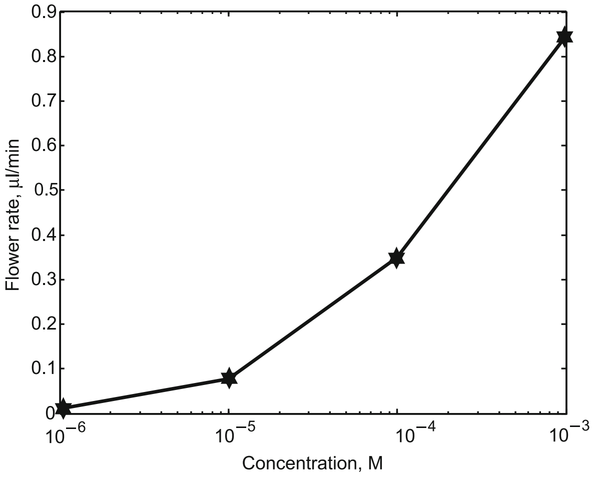
Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 21 Maximum pumping pressure versus particle diameter

result disagrees with the macroscopic linearized analytical solution which results in a maximum pumping pressure which depends on the inverse square of the diameter of the particle [5]. The reason for this is that the surface electric potentials of nanoscale particles change the bulk potential distribution and the consequent driving force differently from those at macroscale.

In macroscale analysis, the flow rate is independent of the particle size for given structural parameters of porosity and tortuosity [5]. However, things change at nanoscale. Figure 22 shows the pumping flow rate versus particle size when $E = 1\,\text{kV/m}$, $\Delta P = 0\,\text{Pa/m}$, $\psi_\text{p} = -50\,\text{mV}$, and $c_\infty = 10^{-4}\,\text{M}$. The flow rate increases sharply with the particle size when the particle is smaller than 160 nm and a small plateau when the particle becomes larger. For macroscale cases, the variety of particle size only changes the locations of the boundaries but never changes the shape and maximum value of the electric potential profiles under the thin EDL assumption. However, for nanoscale, the particle size not only changes the maximum electric potential but also changes the profile shape, as shown in Fig. 19. This is why the current results disagree with the macroscale predictions. This result also suggests that fine porous media can be used to control electric fluids precisely.

Since the ionic concentration has a great effect on the electric potential distribution in microchannels [13], we can model the flow rate versus the ionic concentration in an electroosmotic micropump packed by nanoscale charged porous media when $E = 1\,\text{kV/m}$, $\Delta P = 0\,\text{Pa/m}$, $\psi_\text{p} = -50\,\text{mV}$, and $d_\text{p} = 108\,\text{nm}$. Figure 23 indicates that the flow rate increases monotonically with the ionic concentration.

Besides the isotropic porous media represented by an array of spheres, the anisotropic structure effects on EOF characteristics can also be studied by modeling the electrically driven flows through ellipse arrays packed in a microchannel whose shape and orientation angle are used to control the anisotropy of porous media [17]. The results show that flow rates increase with the axis length along the external electric field direction for a certain porosity and decrease with the angle between the semimajor axis and the bulk flow direction when the orientation angle is smaller than $\pi/2$. After introducing random fac-



Lattice Poisson–Boltzmann Method, Analysis of Electroosmotic Microfludics, Figure 23 Flow rate versus ionic concentration

tors into the microstructures of porous media, the statistical results for the flow rate show that the anisotropy of the microstructure decreases the permeability of EOFs in porous media.

Future Directions for Research

Since a mesoscopic numerical tool for simulating electroosmotic microfludics has been established, it should be extended to other scientific and engineering applications. A few promising directions include:

- *Electroosmotic flows in random porous media.* A full simulation and analysis of electroosmosis in natural porous media has always been a big challenge due to the geometric complexity of porous media and the consequent computational cost though lots of applications exist in geophysics, the environment, and microdevices such as the microfuel cell. The LPBM has an inherent advantage when dealing with complex boundary conditions and provides a chance to work them out. Various methods have been developed to reproduce the microstructures of random porous media in computer data [25]. When the microstructures of the porous media have been correctly described, the governing equations can be solved by our high-efficiency LPBM. The flow characteristics and mechanism of electroosmosis in random porous media will therefore be analyzed.
- *Electroosmotic multiphase flows.* Multiphase flows driven by electric force have attracted increasing levels of interest and potential applications in biomedical techniques. Such flows include unchanging-interface suspension flows, such as blood cell or DNA molecules suspension, and multiphase interface flows, such droplet movement in a microchannel driven by an electric field. No good solutions by conventional CFD have been found for such flows. Since much progress has been made in solving the multiphase interface problems by LBM, the LPBM is very promising to provide full simulations and analysis of electroosmotic multiphase flows.
- *Multiphysical transports in electroosmotic flows.* Multiple physical transports may accompany the electroosmotic flow, such as heat transfer, oscillation spreading, etc. Some transports may be coupled. Probably the geometry is complex in the real world. The LPBM provides a method though it also faces challenges due to such complicated problems.

In most microfluidics and nanofluidics, the atomistic effects on electroosmotic flows are negligible. But when the characteristic length is comparable with the molecular size of fluid, it should be considered. Molecular dynamics methods have been used to simulate the particle effects in nanoscale electroosmotic flows [23, 24]. However, it is too time-consuming to simulate a real electroosmotic micro- and nanofluidics by molecular dynamics. The multiscale modeling and analysis would be a possible research direction.

Least Square

Synonyms

Ordinary least square; Discrete least square; Regular least square; Weighted least square

Definition

Least square is a mathematical optimization method which attempts to find a function (a best fit) which closely approximates a set of given data. Assuming that the approximation function $g(x)$should approximate a function $f(x)$, for $x \in [a, b]$, the method attempts to minimize the sum of the squares of the ordinate differences (called residuals) between points generated by the function and corresponding points in the data. In other words, if there are n data points, then the residual is formed by

$$e = \sum_{i=1}^{n} \left[f(x_i) - g(x_i)\right]^2$$

for a discrete set of data and by

$$e = \int_a^b W(x). \left[f(x) - g(x)\right]^2 \mathrm{d}x$$

for continuous functions, where $W(x)$ is a weight function. When $W = 1$, the so-called regular least square method is recovered.

If the approximation function is described as a linear combination of shape functions $\varphi_j(x)$so that

$$g(x) = \sum_{j=1}^{m} c_j \varphi_j(x)\,,$$

then the least square method requires that

$$\frac{\partial e}{\partial c_j} = 0 \quad for \quad j = 1, \ldots, m$$

giving m linear equations to be solved simultaneously to find m unknowns c_j.

Deep lithography; HARMST (High Aspect Ratio Micro-Structure Technology)

Definition

LIGA is the German acronym of *Lithographie (LI) Galvanoformung (G) Abformung (A)*. In English it is *lithography, electroforming, moulding*, a combination of three microfabrication techniques. As originally developed, the lithography was based on irradiation of highly parallel X-rays from a synchrotron radiation source (SRS), which was capable of producing very high aspect ratio polymer structures. The technology became synonymous with high aspect ratio micro-structure technology (HARMST). LIGA allows the fabrication of structures which have vertical dimensions from hundreds of microns to millimeters and horizontal dimensions which can be as small as microns.

Overview

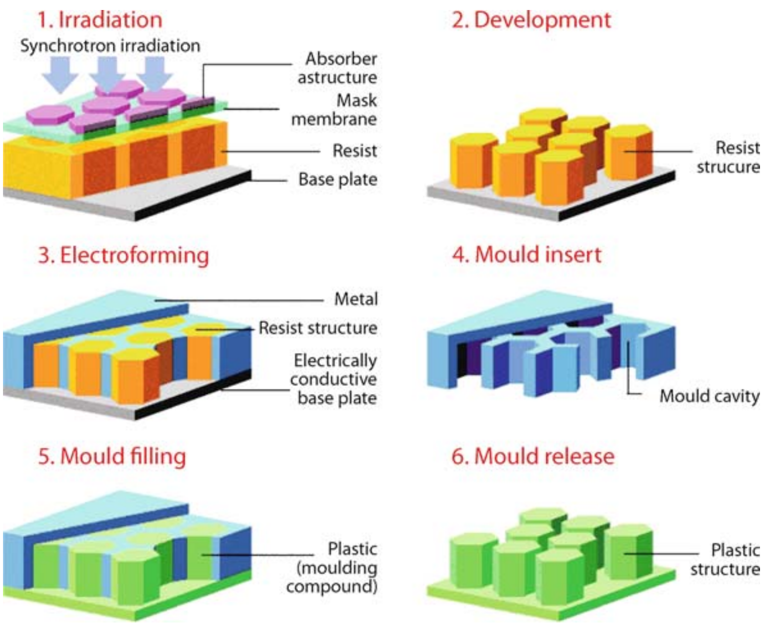
Microfabrication techniques, developed from CMOS integrated circuit manufacturing, are primarily thin film based, i.e. the structures are less than a few micrometers in height (or thickness, depth). However, there are many applications which require microtructures to be deep or thick in Z direction, particularly for those MEMS devices for delivering high mechanical force/torque or for those microfluidic systems of deep flow channels. Conventional lithography is not able to penetrate deep in photoresist or to produce high aspect ratio microstructures. LIGA is a unique microfabrication technique in that microstructures with aspect ratio as high as over 100:1 can be made, with the help of hard X-ray irradiation. The so-called *hard* X-ray is the X-ray radiation of very short wavelength, generally around a few angstroms. Such hard X-ray can penetrate over 1mm thick PMMA resist.

LIGA technology was first developed at Karlsruhe Nuclear Research Institute (KFK) in Germany in early 1980s [1]. That's where the German acronym LIGA came from. The basic LIGA process is illustrated in Fig. 1. X-ray first exposes a thick layer of resist, normally PMMA resist, through a LIGA mask. The deep resist structure after development serves as a mould and is filled with metal, normally nickel, by electroplating. Metal microstructures are formed after removal of the resist mould. The metal microstructures can then be used as a mould for moulding or embossing of plastic. In this way, hundreds and thousands of plastic replications of the original resist structures can be made.

The original motivation to develop the LIGA technology was to make micronozzles for the refinement of uranium isotopes [1]. These micronozzles have minimum feature of micrometers, but the overall structure is of millimetres. Fig. 2a is one of such micronozzles in PMMA resist, Fig. 2b is the electroplated nickel structure from the resist mould and Fig. 2c is the plastic replication of the micronozzle.

Traditionally, mould insert for injection moulding and hot embossing of plastic microcomponents are made from metals by precision machining or wire electro discharge machining (EDM). LIGA technology offers a new route for making such mould inserts with much better accuracy and much higher aspect ratio. Though making mould inserts was the original motive to develop the LIGA technique, metal structures themselves made by LIGA have also been widely used as MEMS components and systems. There were plenty of examples reported that LIGA made metal structures were used as micromotors, microgrippers and microtwizers. LIGA has the unique capability to make precision metal components that no conventional precision machining tool can compete with.

It has to mention that the LIGA described here is specifically for LIGA using X-ray for the lithography. The X-ray has to be of very short wavelength which can only be produced in a synchrotron radiation source. The SRS is a very expensive large scale instrument not readily available to a wider community. Therefore, many low cost LIGA-like



LIGA, Figure 1 Schematic of LIGA process steps

technologies have been developed after the advent of X-ray LIGA. Generally, LIGA-like technologies use non X-ray methods to make high aspect ratio microstructures, such as laser LIGA, UV LIGA. The LIGA-like micromachining technologies will be described in a separate entry in this Encyclopaedia.

Basic Methodology

The basic elements of X-ray based LIGA technology consist of X-ray source, LIGA mask and thick resist process [2].

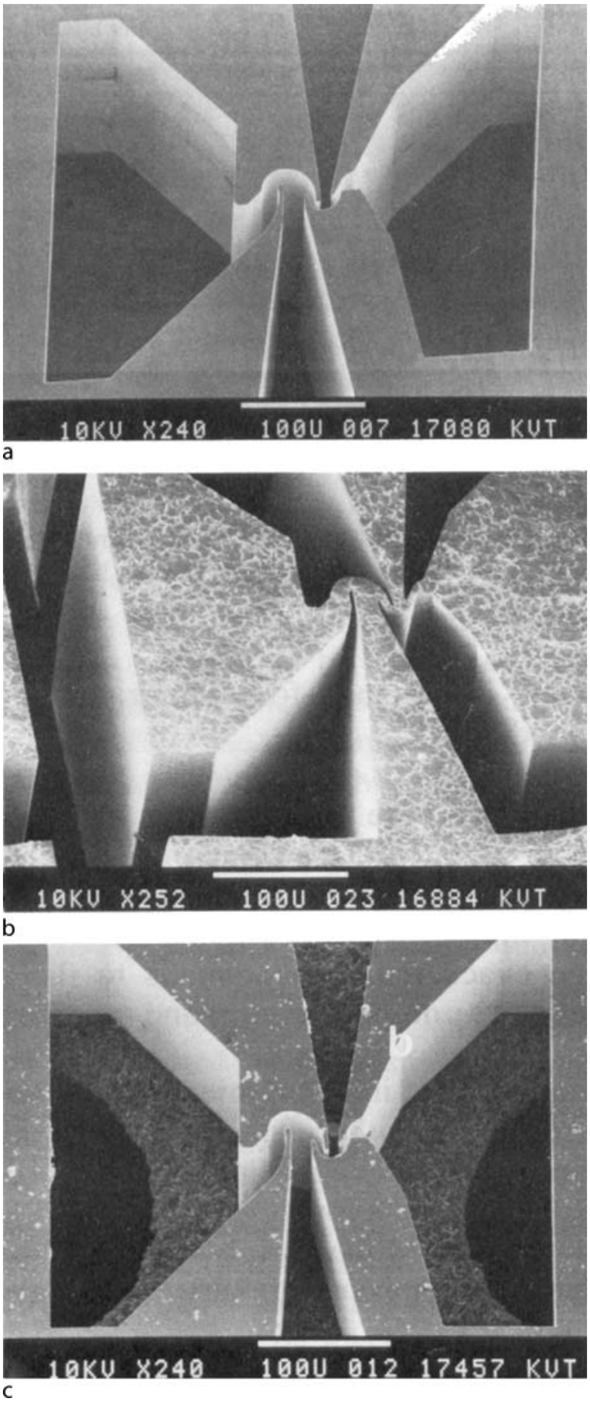
X-ray Source

The synchrotron radiation source (SRS) is the only lithography light source for X-ray LIGA. The principle of synchrotron radiation is that high energy electrons travelling in a speed approaching speed of light on a circular orbit (storage ring) can radiate wide spectrum of electromagnetic wave along the tangential direction of the orbit. Because of the wide range of wavelengths of radiation coming out of SRS, special magnetic wiggler has to be fitted to the beam line in order to let out the very short wavelength of X-ray beam. The penetration depth of X-ray in PMMA resist is wavelength dependent. For example, if a X-ray source with 7 A wavelength is used to expose 400 μm thick PMMA, 4 repeated exposures are needed in order to fully expose thick resist layer. If 2 – 3 A wavelength X-ray is used one exposure can penetrate 500 μm thick PMMA layer [3]. X-ray with wavelength above 10 A is generally called soft X-ray. Soft X-ray has the photon energy normally at 1 – 2 keV, whereas the photon energy of hard X-ray is above 20 keV. Another important feature is that the X-ray beam from a SRS is highly parallel, with beam divergent angle less than 1 mrad. Such a parallel irradiation makes possible the exposure of high aspect ratio structures with very vertical sidewalls.

LIGA Mask

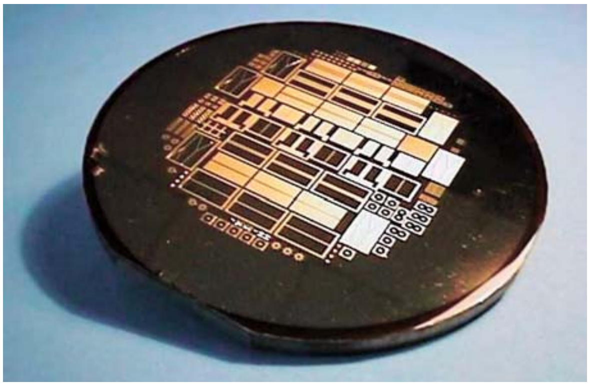
LIGA mask consists of supporting membrane which is a low density material and near transparent to the hard X-ray, and high density metal patterns which absorb most of the X-ray photon energy so that it becomes opaque to the X-ray. The requirements on the supporting membrane of a LIGA mask are:

- Low absorbance and high transparency to X-ray
- High resistance to X-ray irradiation. Material property does not change at long period of X-ray irradiation
- Good stability in lateral structure (low internal stress and bowing), which will be less likely to cause distortion of absorber patterns
- Compatible with photoresist process and electroplating process
- It would be desirable if the membrane is also optically transparent, which would facilitate alignment and overlay exposure



LIGA, Figure 2 Micronozzle fabrication by LIGA at different stages (**a**) PMMA resist mould by X-ray lithography (**b**) nickel structure after electroforming and removal of resist mould (**c**) Plastic replication by moulding from the nickel mould

Materials which can meet most of above requirements are silicon, silicide, beryllium, titanium, graphite, diamond and kapton. The thickness of the supporting membrane



LIGA, Figure 3 A LIGA mask made from beryllium membrane with gold absorber patterns on the membrane

depends on the transmission of X-ray through the membrane. The better the transmission, the thicker the membrane is allowed. Beryllium is the best membrane material for LIGA masks. Gold is commonly used as the absorber material because of its high density and mature electroplating process to deposit the absorber layer. To absorb the hard X-ray the thickness of gold absorber is in the range of 10 – 20 µm thick. To expose 1mm thick PMMA, the gold absorber has to be 50 µm thick. Fig. 3 shows a typical LIGA mask. The beryllium membrane is supported by a steel frame. Gold absorber patterns are clearly visible on the membrane surface.

Thick Resist Process

LIGA structures are firstly made into a polymer resist by X-ray exposure. The commonly used polymer resist for LIGA is PMMA. Upon exposure to X-ray, the PMMA degrades from high molecule weight to low molecule weight, so the PMMA can be dissolved in a developer solution. There are many practical process issues when the PMMA layer becomes a few hundreds of micrometers thick. Spin coating such thick PMMA layer is difficult. Multi coating process has to be used, or the thick PMMA layer is formed by gluing a PMMA sheet (Perspex) onto the substrate. To expose thick layer of PMMA, high exposure dose is needed, which means very long exposure time under X-ray irradiation. X-ray decays in PMMA. The energy absorbed in PMMA produces heat. In order that the bottom part of a thick PMMA layer receives enough exposure dose, the top part of PMMA layer may get over exposed. Excessive heating may cause surface foaming at the top layer of PMMA. Shorter wavelength X-ray has less decay in PMMA, therefore, can achieve much uniform exposure over the thickness of PMMA.

Once the PMMA deep structures are made by X-ray lithography, the electroplating of metal and replication from the metal mould insert are all standard processes. The most commonly used metal for electroplating is nickel, because electroplating of nickel is a mature technique and nickel has the necessary hardness as a structure material for mould insert or functional microcomponents.

Key Research Findings

Although PMMA has been used for a long time as the only resist for LIGA, its biggest drawback is low sensitivity, which requires long exposure time. It becomes more serious at ultra thick resist exposure. For example, to expose 1mm thick PMMA will need nearly 24 hours exposure time. In recent years, a new type of chemical amplified resist, SU-8, found wide applications in MEMS. SU-8 is a photoresist and can be patterned by UV exposure. SU-8 can also be exposed by X-ray. The biggest advantage of SU-8 over PMMA is its high sensitivity to X-ray. The exposure, which may take more than 10 h with PMMA, only needs over 10 min with SU-8 [4]. In optical lithography, SU-8 has demonstrated very high contrast and high aspect ratio. It has become the key photoresist for the UV LIGA (see LIGA like micromachining). The contrast of SU-8 patterns obtained by X-ray lithography is even better, because of the high parallelism of X-ray from a SRS. Conventional UV lithography of SU-8 can achieve pattern aspect ratio of 20:1 to 30:1. With X-ray lithography, the SU-8 patterns can reach aspect ratio of 50:1 or even 100:1. The only problem with SU-8 as the resist is its removal after electroforming. With PMMA, the resist mould after electroforming of metal can be easily dissolved in acetone. However, acetone has little effect on SU-8. Other removal methods have been developed, though not as effective as removal of PMMA [5].

Although LIGA technology is able to make microstructures with very high aspect ratio and very vertical sidewalls, there are some factors which have limited further improvements in pattern accuracy, minimum feature size and sidewall verticality in LIGA. These factors include X-ray diffraction and photoelectron scattering, penumbra effect, non-vertical sidewall in absorber patterns, mask distortion and secondary electrons induced by X-ray in substrate material [6]. However, the detrimental effects to the accuracy of LIGA patterning is only relative. As LIGA technology is mainly for making microstructures used in MEMS and Microsystems, which are normally in the dimension of a few tens or few hundreds micrometers, these inaccuracies in the range of sub-micrometers are generally negligible compared with the overall dimension of microstructures.

Future Directions for Research

X-ray based LIGA technology has been developed for over two decades. It has become a mature manufacturing technique for making mould inserts or special metal microcomponents. There is less fundamental research being carried out but more development in practical applications. The main aim of application oriented research is to expand the scope of its application, particularly for making high value added microcomponents, so that the cost of using this technology can be offset.

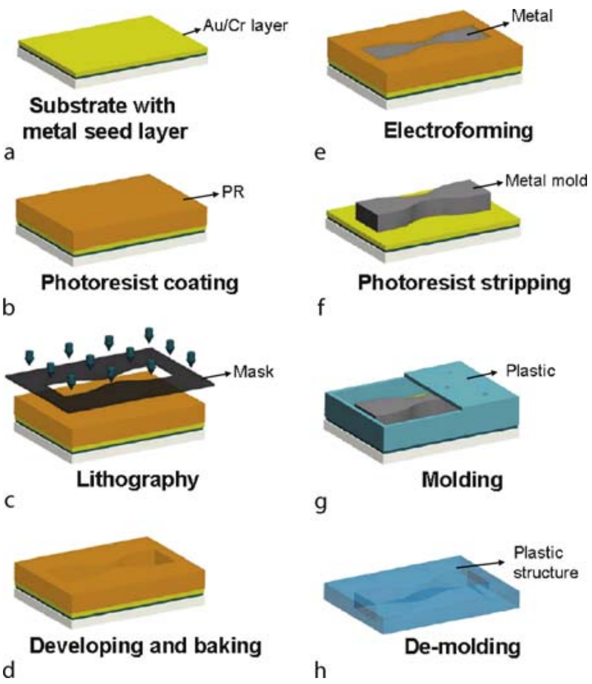
Definition

LIGA is a micromachining technique which utilizes X-ray lithography, electroforming and micromolding processes to produce precise and high-aspect-ratio microstructures. Like the LIGA process but without accessing a synchrotron radiation source, LIGA-like techniques use alternative micromachining technologies such as UV lithography, laser writing, focused ion beam, electron beam

and reactive ion etching to produce high-aspect-ratio microstructures for molding purposes. A series of fabrication processes including electroforming and molding is then used to reproduce the microstructures.

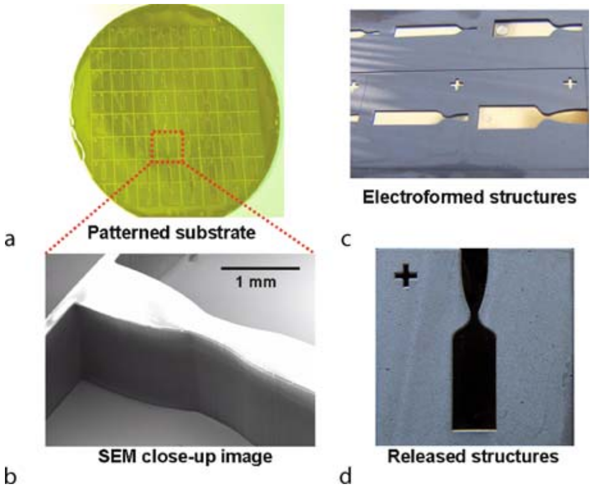


LIGA-Like Techniques, Figure 1 Schematic of a simplified fabrication process of a LIGA-like technique

Overview

LIGA is a micromachining technique including lithography, electroforming and micromolding processes, which usually uses X-ray lithography to generate ultra-thick microstructures with millimeter-sized thickness. This process was first developed at Karlshruhe and the Institute for Micromechanics (IMM) in Germany, such that the term *LIGA* is an acronym formed from the German words *Lithographie* (lithography), *Galvanoformung* (electroforming) and *Abformung* (molding). High-intensity and highly collimated X-rays generated from a synchrotron radiation source are used to provide high-resolution and ultra-deep lithographic capability. However, the need for a synchrotron radiation source limits its application for researchers and the process is inherently time consuming and expensive. In this regard, cheaper light sources and alternative micromachining technologies incorporating new photoresist materials to produce thick microstructures were soon reported. The LIGA-like process usually uses a UV aligner or laser writer as exposure energies and also includes electroplating and molding processes. Most LIGA-like techniques focus on the lithography method for generating the first micromold for molding purposes. Since EPON SU-8 epoxy resin, a negative-tone photoresist, was reported, LIGA-like techniques have become popular in the microelectromechanical systems (MEMS) community. Microstructures with a thickness of several hundred micrometers can be obtained by a single coating and a thickness of up to a millimeter can also be achieved by multiple coating [1]. Ultra-thick microstructures can be fabricated in a simple and low-cost way with this new technique. However, surface flatness of the coated photoresist layer and the long processing time are also critical issues for the multicoating process. Therefore, a modified process for fabricating ultra-thick microstructures in SU-8 photoresist was reported, which used a single coating technique, a modified backing process and a new mask design to overcome the problems that matter seriously during LIGA-like processes [2]. Micromolds with millimeter thickness and large area can be fabricated in a fast and simple method with this LIGA-like technique.

Figure 1 presents a simplified schematic for the fabrication process of the proposed LIGA-like technique in SU-8 epoxy resin. Briefly, a substrate is firstly coated with metal seed layers for the electroforming process (Fig. 1a). A chromium or titanium layer with a thickness of several hundred angstroms is usually used as the adhesion layer. A gold or copper seed layer of several micrometers in thickness is then deposited on the adhesion layer to be the bottom conductive layer for the electroplating process. A thick layer of SU-8 photoresist is applied on the substrate with a modified single-coating process as mentioned above (Fig.1b). The coated substrate is then soft-backed on a hot-plate and exposed with a standard UV lithography procedure (Fig.1c). SU-8 is a negative-tone photoresist which needs a postexposure bake process at 95 °C to enhance the further cross-linking of the exposed photoresist. Note that the exposed area of SU-8 photoresist and the stiffness of the substrate may cause undesired problems in an ultra-thick photoresist process because the residual stress in the cross-linked photoresist is considerable which may bend the substrate. In general, a small and discrete pattern design for the lithography mask is preferred. After the exposure and postexposure bake process, the substrate is developed using pure propylene glycol monomethyl ether acetate (PGMEA) with a gentle ultrasonic agitation and then baked at 90 °C for 10 min to remove the residual organic solvent. The patterned SU-8 structure is finally hardbaked to stabilize and further cross-link the polymer structures (Fig. 1d). The electroforming process is then carried out after the lithography process to produce



LIGA-Like Techniques, Figure 2 Images of (**a**) silicon substrate with ultra-thick photoresist, (**b**) the patterned photoresist, (**c**) electroformed nickel structure and (**d**) released nickel structure

metal-based microstructures (Fig. 1e). A nickel sulfamate bath is popular in the MEMS community due to the low residual stress in the electroformed nickel structures. Note that other materials including copper, cobalt, ferroalloy or even metal–ceramic composites can also be chosen for this plating process. The SU-8 photoresist is stripped after the electroforming process to release the fabricated metal mold (Fig. 1f). The metal mold is then used as the master for reproduction purposes (Fig. 1g) and the final plastic product is formed after the de-molding process (Fig. 1h). Hot embossing, injection molding and other polymer casting methods are usually adopted for reproducing plastic products.

Figure 2 presents images of a LIGA-like process at different stages. Figure 2a shows the patterned substrate after the UV lithography process (see Fig. 1d). The seed layer for this process is composed of 500 Å of chromium and 2 μm of gold. Figure 2b shows a scanning electron micrograph of the UV-patterned SU-8 structure. The height of the SU-8 microstructure is 1.5 mm and the minimum line width is 100 μm, resulting in an aspect ratio of 15. Figures 2c and 2d show images of a substrate after the electroforming process and a released nickel structure, respectively. The nickel structures are formed from a nickel sulfamate bath and have a thickness of around 1 mm. Although the cost and process complexity for fabricating microstructures using the LIGA-like process are significantly reduced, the X-ray LIGA process still provides the best linewidth precision, smallest sidewall roughness, deepest structure and largest aspect ratio compared with the reported LIGA-like techniques. However, LIGA-like technology is undoubted a valuable alternative to the original LIGA process especially for research institutes and small- to medium-sized companies.

Ligand

Definition

In the context of proteomics, a ligand is any molecule, atom, or ion that is capable of binding to a specific site on a protein via a chemical bond. Ligand binding is often essential for the protein to become fully functional, and often more than one type of ligand can compete for a particular binding site.

Light Sheet

Definition

A light sheet has a bigger width than thickness and is used to specially illuminate the part of the scene which is interesting for the photography. Compared to the volume illumination less background noise occurs. Light sheets are generated with cylindrical lenses for laser light and with slits for white light.

Linear Peristaltic Pump

Definition

Linear peristaltic pumps transport fluid through a flexible duct using traveling contraction waves. In a typical linear

peristaltic pump, discrete translational elements rhythmically compress a straight section of flexible tube, moving fluid volumes. In contrast to rotary peristaltic pumps, linear peristaltic pumps usually do not use rollers or sliding contact elements. Because a moving boundary displaces fluid and induces the flow, linear peristaltic pumps are an example of positive-displacement pumps.

High pressure liquid chromatography (HPLC)

Definition

Liquid chromatography is a method for separating molecules dissolved in a liquid mobile phase. A pressure gradient drives the mobile phase through the stationary solid phase. Thermodynamic partitioning of the analytes between the liquid phase and stationary phase causes differential transport and spatial separation of different molecular species.

Overview

Molecular separations are used to reduce the complexity of a mixture of compounds. While complete separation of two or more compounds is typically desired, complete separation is theoretically impossible. In practice, the separation of a purified sample can appear to be complete, if the contamination is below the limits of detection. While the concepts discussed pertain to chromatography in general, the terminology and details will specifically address bonded phase column chromatography.

Theory

A sample mixture is composed of different molecular components that have different chemical structures, and to be detectable each component must have a population of molecules. All of the molecules of a single component have the same chemical structure, and this population of molecules is referred to as the sample or analyte band as it moves through the column. The chemical structure of each component determines the strength and type(s) of intermolecular forces it has with the mobile phase and the stationary phase. These intermolecular forces govern the relative strength of analyte-mobile phase and analyte-stationary phase interactions, which determines the relative amounts of the analyte molecules in mobile and stationary phases. If the analyte interactions with the stationary phase are strong enough, the analyte molecules will bind or adsorb to the stationary phase. Stronger analyte interactions with the stationary phase increase the fraction of analyte adsorbed to the stationary phase and decrease the analyte velocity. The process of molecules leaving the stationary phase and becoming solvated in the mobile phase is referred to as desorption. This adsorption/desorption process or partitioning can be described by the reaction shown in Eq. (1), where $[A]_{mp}$ is equal to the concentration of the analyte A in the mobile phase and $[A]_{sp}$ is the concentration of the analyte A in the stationary phase.

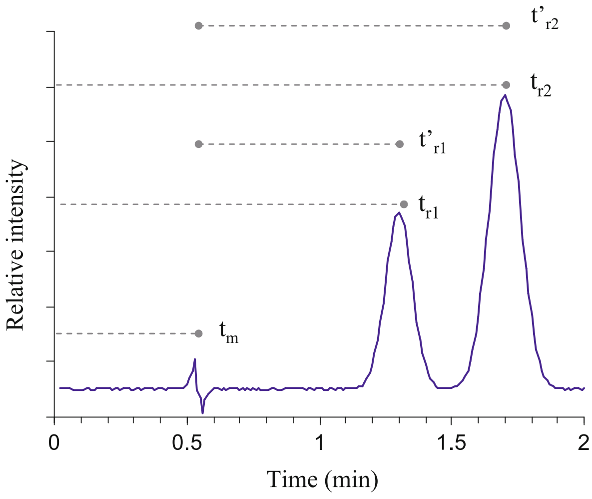
$$[A]_{mp} \leftrightarrow [A]_{sp} \tag{1}$$

The equilibrium constant, termed the partition coefficient (K), is the ratio of the analyte concentration in the stationary phase to the concentration in the mobile phase, as shown in Eq. (2).

$$K = \frac{[A]_{sp}}{[A]_{mp}} \tag{2}$$

The tendency of any chemical system to approach equilibrium drives adsorption and desorption of the sample band as it migrates through the column. Equilibrium cannot be reached, because the mobile phase is constantly moving and forcing the analyte concentration profile in the mobile phase ahead of the solid phase profile. Thus, the leading edge of the sample band has a solute concentration in the mobile phase above the equilibrium position, increasing the rate of adsorption above the equilibrium level, while the trailing edge solute concentration in the mobile phase is lower than the equilibrium position, increasing the rate of desorption in this zone above equilibrium levels. Analytes with larger K values will spend more time adsorbed to the stationary phase and will elute later than those that have smaller K values.

The separation is usually monitored by a detector that records the intensity at one fixed point at or near the end of the column. The intensity values are related to the analyte concentration and are plotted against time, where the



Liquid Chromatography, Figure 1 Measurement of the retention times (t_r), void time (t_m), and adjusted retention times (t_r') are shown. The void time is equal to the elution time of the un-retained substances, and it can be related by the flow-rate to the void volume, which is the volume of solution between the injector and detector. Two analyte peaks are shown with their corresponding retention times. The retention time of the first eluting analyte is t_{r1}, and the retention time of the second eluting analyte is t_{r2}. The void time is subtracted from the retention times to provide the corresponding adjusted retentions times (t_{r1}' and t_{r2}')

injection time is equal to zero. The time for the analyte to travel from the injector to the detector is referred to as the retention time, t_r, as shown in Fig. 1. The retention time is measured at the point of maximum intensity or peak maximum for the analyte band. The void time, t_m, describes the time required for a compound that does not interact with the stationary phase to travel from the injector to detector. By subtracting the dead time from the retention time, the adjusted retention time, t_r', is given as shown in Eq. (3).

$$t_r' = (t_r - t_m) \tag{3}$$

Another important parameter for characterizing the retention of a compound is the capacity factor, k', which is defined as the mass of solute in the stationary phase divided by the mass of solute in the mobile phase as shown in Eq. (4). In contrast with partition coefficient, k' is not a state function and is dependent on the column's characteristic phase ratio, which is equal to the volume of the stationary phase (V_s) divided by the volume of the mobile phase (V_m). A greater stationary phase volume increases interactions with the stationary phase, thereby increasing the retention time and k'. It is important to note that the capacity factor is also equivalent to the adjusted retention time divided by the void time, which are obtained directly from the chromatogram. This important parameter can be intuitively described as a measure of the strength of an analyte's interaction with the stationary phase in a particular chromatographic system.

$$k' = \frac{\text{mass}_{sp}}{\text{mass}_{mp}} = \frac{(t_r - t_m)}{t_m} \tag{4}$$

The main objective of liquid chromatography is separation, and the quality of the separation of two analyte bands or peaks is measured by the resolution, R. The resolution is calculated by dividing the difference in retention times by their average base widths (w_b) as shown in Eq. (5).

$$R = \frac{t_{r2} - t_{r1}}{\frac{1}{2}(w_{b1} - w_{b2})} \tag{5}$$

It should be noted from Eq. (5) that there are two fundamental approaches to improving the resolution: increasing the separation between the two peaks or decreasing the peak width. The difference in retention time is determined by the selectivity of the chromatographic system for the two analytes. Manipulating the difference in retention times to improve the resolution is usually achieved by adjusting the mobile phase or the stationary phase, but the effects of such adjustments are difficult to predict. In samples with many components, improving the resolution of a single pair often results in a scrambling of retention times and in poor resolution of other analyte pairs.

For complex samples, the peak capacity is best for evaluating the separation power of a particular system. Peak capacity is calculated in Eq. (6) where L is the separation length in time, w is the peak width in time, and R is the specified resolution.

$$n = \frac{L}{wR} \tag{6}$$

This equation reveals the number of ideally spaced peaks of set width and set resolution that can be separated in the characteristic separation time. Clearly, in a real sample containing components with unrelated properties, the peak spacing will be random and the number of well resolved peaks will be much less than the peak capacity. Although the calculated peak capacity is unobtainable in practice, it is well suited for comparing the effectiveness of different systems for separating complex mixtures.

The most direct and universal means of improving a separation is to decrease the peak width, which is typically described by separation efficiency. The separation efficiency is equal to the length of the separation squared divided by the peak variance (σ^2) and is dimensionless;

$$N = \frac{L^2}{\sigma^2} = \frac{t_r^2}{\sigma^2} = \frac{5.55 t_r^2}{{w_{1/2}}^2} = \frac{L}{H}, \tag{7}$$

L

where L represents the column length, $w_{1/2}$ is the peak width at half maximum, and σ the peak width measured as the standard deviation of a Gaussian peak. Therefore, the separation efficiency, N, can be thought of as the variance of peak width, normalized to the elution time. The quotient is inverted, so larger separation efficiencies represent better performance. The plate height, H, is also used to characterize the peak width and is inversely proportional to the separation efficiency as shown in Eq. (7).

A peak in a chromatogram represents the distribution of molecules in an analyte band. An analyte band is composed of many molecules that are identical in structure, but that experience different microenvironments as they travel through the column. As the analyte bands move through the column, band broadening increases the peak width and decreases the peak height. Therefore, the analyte band is both lengthened and the concentration is diluted as it moves through the column. Band broadening can be caused by many processes some of which are unavoidable and random in nature. Random processes give rise to analyte bands that have Gaussian concentration profiles, creating the symmetric peaks shown in good chromatograms. Other non-random processes can cause asymmetric peak shapes, but these can typically be eliminated with the proper mobile phase and stationary phase composition. Band broadening increases the peak width, and consequently it must be minimized for optimal performance.

Rate theory describes the contribution of different band broadening processes as a function of mobile phase flow rate, μ_x. The original rate theory developed by van Deemter in 1956 [1], relates the plate height to the three major band broadening terms. This theory is used to minimize peak width in terms of plate height (H), and was further refined to the Hawkes' equation, which is shown in Eq. (8).

$$H \approx \frac{B}{\mu_x} + C_s\mu_x + C_m\mu_x \tag{8}$$

This equation is defined by the parameters B, C_s, and C_m that are dependent on the column characteristics and mobile phase viscosity. These three band broadening components are: longitudinal diffusion, B, mass transfer in the stationary phase, C_s, and mass transfer in the mobile phase, C_m. The first term is longitudinal diffusion, which is the amount of band broadening along the length of the column that increases peak width directly. Higher flow rates μ_x minimize the B-term, by decreasing the time during which longitudinal diffusion can occur. For bonded phases, the stationary phase mass transfer is dependent on the capacity factor and the molecular adsorption and desorption kinetics. Increasing the homogeneity of the stationary phase functional groups and decreasing unwanted interactions with the solid support decreases band broadening.

To minimize band broadening in the mobile phase, the velocity distribution of the molecules in the sample band must be minimized. Contributing to the different mobile phase velocities are: the parabolic flow profile of pressure driven flow, variations in inter-particle flow path diameters, and stagnant mobile phase pools in pores. Thus band broadening is minimized by using smaller inner diameter columns that minimize the variation in flow paths. Additionally, performance increases as bead diameter, size distribution, and porosity decrease; performance also increases as the beads are packed in a more uniform manner. However, smaller bead sizes increase the backpressure requiring the use of higher pressures or shorter columns. While, decreasing the porosity decreases the capacity factor, which decreases resolution and sample loading capacity. Therefore, it is important to emphasize that miniaturization improves performance.

Basic Methodology

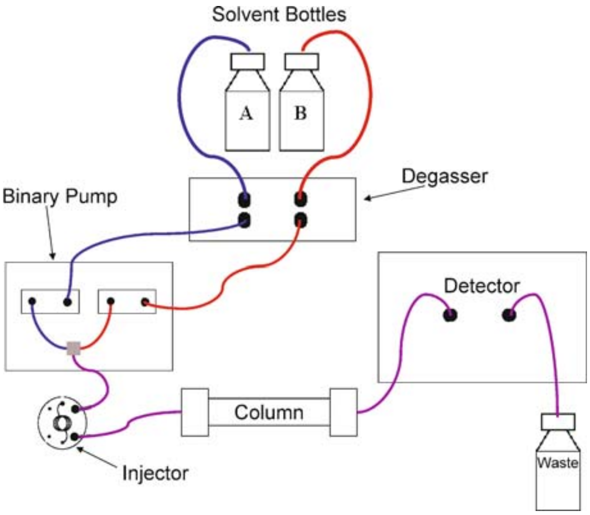
In liquid chromatography there are two primary methods of eluting analyte from a column, isocratic elution and gradient elution. Isocratic elution is characterized by using constant solvent composition. Gradient elution uses a mixture of two or more solvents that are mixed at different ratios during the run to change the solvent composition. Each of the two methods will be discussed in more detail below; in addition, the advantages and disadvantages of each method will be established.

Isocratic Elution

As mentioned above an isocratic elution is performed using a single solvent or a solvent mixture with a constant composition. Isocratic elution is best suited for separating analytes with similar capacity factors and provides the best resolution for these mixtures. Conversely, if the difference in capacity factors is large, the separation can be prohibitively long with no definite end. Additionally, as the retention time increases, band broadening can decrease the peak height and increase the peak width, making detection more difficult. Altering the column or mobile phase to decrease retention improves the detection of the latter eluting peaks and decreases the separation time, but worsens the separation of the early eluting peaks. On the other hand, increasing retention improves the separation of early eluting peaks, but makes the latter eluting peaks less detectable and increases the length of separation.

Gradient Elution

To improve separations of analytes with a wide range of capacity factors, gradient elution can be used to solve the general elution problem. Gradient elution is achieved by changing the solvent composition as a function of separation time. Typically, the solvent system is designed so that the initial k' values are very high, leading to complete adsorption of all of the analytes on the column. This initial adsorption process provides sample extraction and concentration, allowing the injection and cleaning of large sample volumes without an increase in peak width. After the separation is started, the solvent composition is changed to lower the k' values until the k' values of all of the analytes are low enough to allow their migration down the column. Because the solvent composition is continually being changed to lower the k' values, the analyte bands move quickly down the column after their desorption. The constant decrease in the k' values provide consistent peak widths throughout the separation, improving the detection of latter eluting compounds. With steeper gradients, the solvent strength at the trailing edge of the sample band is substantially greater than at the leading edge, causing the trailing edge to move faster than the leading edge. This difference in velocities provides focusing of the bands that can improve the detection limits up to a factor of 3. Gradient separations also have a well defined beginning and end, eliminating the indefinite end time encountered with isocratic separations. However, the same number of analyte peaks are compressed into a shorter separation time that is not compensated for by the reduction in peak width. This case leads to the only major drawback in performance encountered with gradient separations – a reduction in resolution and peak capacity.



Liquid Chromatography, Figure 2 A schematic showing the components of a typical HPLC system. Here a binary pump is shown, which can be used for gradient separations by utilizing two different solvents (A and B). The degasser removes dissolved gases from the solvents before the pumps and the high pressure mixing tee to prevent air bubbles from forming in the system. The solvent then flows to the injector and through the column before reaching the detector

Instrumentation

Most HPLC systems have a modular design that provides flexibility and allows for many different combinations. In Fig. 2, the basic components of an HPLC are shown. In most microfluidic HPLC systems, the column is miniaturized while the other components are from a typical benchtop HPLC.

Injectors

HPLC injectors serve two basic functions: to load a precise volume and to enable the use of high pressure. The small particle and column diameters used in analytical and microfluidic HPLC can cause large backpressures, requiring high pressure for moving the sample solution and mobile phase through the column. However, a specific design of a chromatography column can greatly affect the pressure needed for injection, and low back pressure columns do not require the use of an injection valve. For typical HPLC columns, an injector that can withstand high pressure consists of a sample injection loop and a multiport valve. The sample loop is made from a tube whose interior defines a precise volume. A sample injection valve is used to switch the sample loop between different ports that alternate between the sample injection port and HPLC pump on the inlet side. On the outlet side, the excess sample waste line and the column are connected. In the sample loading position, the valve connects the inlet port and the sample waste line. This configuration allows the sample to be injected into the loop with low backpressure. Following sample loading, the sample loop is connected with the HPLC pump and the column, beginning the separation. In this manner, the sample is easily injected using a syringe at low pressure, and the HPLC pump is used to inject the sample plug onto the column.

Pumps

There are multiple types of pumps utilized for HPLC; however, this discussion will focus on reciprocating pumps since most commercial instrumentation is equipped with this type of pump. Reciprocating pumps are widely used, because they have many qualities desirable for HPLC, including the ability to generate high pressures and reproducible gradients. This type of pump uses a piston to

L

draw solution into a chamber as the piston retracts. On the forward stroke, the check valve closes and the piston pushes the solution out of the chamber through the injector and column. To reduce pulsations, a dual piston design is used in which one piston retracts while the other advances. When this pump design is used in combination with a pulse dampener, the net result is a constant virtually pulse free solvent flow.

For microfluidic systems, the flow rate range of the pump is an important consideration. Most pumps are designed to work effectively for the 5 ml/min to 0.1 ml/min range, while microfluidic systems typically require flow rates in the 1 μl/min to 50 nl/min range. The flow with such pumps can be reduced easily with a flow splitter. However, the flow splitter should be upstream of the injector to avoid sample loss. Downstream of the injector the volume of the connective tubing used for sample delivery must be kept to a minimum. Many conventional auto-samplers have connective tubing volumes that are too large for the flow rates used by microfluidic systems causing excessive delay times.

Columns

The column is the key component of an LC system, because it is used to effect the separation and holds the stationary phase. The choice of stationary phase is of critical importance, because the stationary phase largely determines what molecular properties the separation will be based on. An appropriate stationary phase should interact with all the analytes, but have a wide range of interaction strength.

While there are many types of stationary phases to choose from, most are bonded phases in which the functional moieties are covalently linked to the surface of a solid support. The functional coating is usually considerably less than a monolayer and must have batch to batch reproducibility to provide consistent retention times. Ideally there is no interaction between the uncoated surface of the solid support and the analytes, which would result in irreproducible retention times.

After the type of functionality is chosen, the next two most important considerations are the particle size and porosity. For high efficiency separations, smaller particles usually in the 0.5 to 10 μm range with a narrow size distribution are used. Increasing bead porosity increases the surface area and sample capacity of the beads; however, if the porosity is too high it will lead to band broadening. Smaller pores work better for smaller analytes, while large pores work better for larger analytes. Commercial HPLC columns are common in lengths ranging from 10 to 30 cm with inner diameters ranging from 2 to 10 mm. For isocratic separations, increasing the column length (L) increases the resolution by the $\sqrt{L}$, while the increase in backpressure is directly proportional to L. For gradient separations, the column must be long enough to provide sufficient sample loading capacity, but has a reduced effect on resolution.

Detectors

There are many different detection methods that can be coupled to an HPLC system; however, this section will only discuss three methods of detection, namely UV-visible absorbance, fluorescence, and mass spectrometry (MS).

The most commonly used detection methods are the optical detection methods, UV-visible absorbance and fluorescence. Both are methods of molecular spectroscopy, and therefore the spectra contain broad bands that can not be used for structural characterization of unknowns, but can be used for identification by matching with standard spectra. UV-visible absorbance has relatively high detection limits, but its wide use stems from it being the most universal detector. The signal/noise (S/N) is path length dependent for absorbance, so decreasing the column diameter raises the detection limits. Fluorescence detection limits are not path length dependent and are the best of the methods discussed. In addition, it is also more selective than UV-visible absorbance. However, this selectivity can be a disadvantage since few analytes fluoresce natively, although it is possible to fluorescently derivatize analytes with a label such as fluorescein isothiocyanate (FITC).

Mass spectrometry provides an unparalleled combination of structural information and sensitivity. However, coupling a liquid phase separation to an analytical instrument that operates at high vacuum was not straightforward. In 1985, Fenn's lab developed an electrospray ionization (ESI) interface that provided soft ionization of molecules in solution making it well suited for coupling HPLC and MS [2]. ESI is concentration sensitive, so decreasing the eluted band volume by decreasing the column diameter and flow rate improves the detection limits for mass-limited samples. MS separates ions in the gas phase and measures the mass to charge ratio (m/z). Further structural information can be obtained by isolating an ion in the MS, fragmenting the ion, and measuring the m/z of the fragment ions through a process called tandem MS. Typically ions are fragmented individually and the fragmentation process requires a finite amount of time, so the analysis of complex samples with dilute components is aided greatly by coupling with an HPLC. The HPLC injects concentrated sample bands at different times improving sample utilization and MS sensitivity.

Key Research Findings

The field of liquid chromatography is well established and reliable methods have been developed for analytical and preparative separations. Column miniaturization improves performance for analytical separations. Numerous stationary phases have been developed to separate analytes based on a wide variety of molecular properties including hydrophobicity, ionic interactions, and molecular size. Mobile phase modifiers can be used to aid in the minimization of unwanted interactions with the solid support. Although the field is well established, current research continues to improve separations for both microscale analytical and larger preparative separations. Recent publications will be highlighted that demonstrate the developments toward integrating HPLC components and separation techniques onto microfabricated devices.

A major problem associated with performing HPLC on chips is the difficulty of making a column using traditional solid support in a microfluidic channel. The difficulty with creating a column on chip lies in trapping and packing the support. However, Regnier et al. [3] showed using microfabrication methods that an HPLC column could be made on a microfluidic device without using traditional media. In this work, a $5 \times 5 \times 10\,\mu m$ collocated monolith support structure was created by etching $1.5\,\mu m$ wide $\times$ $10\,\mu m$ deep channels in a crossed diagonal pattern on a quartz wafer. This microfluidic device demonstrated a separation efficiency of approximately 35,000 theoretical plates from a 4.5 cm length column, compared to 40,000 to 60,000 theoretical plates from a conventional 10 – 30 cm column.

In another publication also by Regnier and coworkers, a highly integrated microfluidic device was created [4]. In the first section of the device, a tryptic digest of FITC labeled bovine serum albumin was performed. Next, immobilized metal affinity chromatography (IMAC) was performed on the tryptic digest to extract histidine containing peptides, which were finally separated using the monolith support design discussed above. This publication is an excellent example of the integration that is possible in a microchip format.

Another strategy to avoid packing beads in a microfluidic device is in-situ polymerization of a porous monolithic stationary phase. Svec et al. [5] have formed monolithic columns in microfluidic chips by using methacrylate chemistry to form reversed-phase or ion exchange stationary phases. Preconcentration was used to increase the concentration of GFP by a factor of 10^3. Another advantage to this technique lies in the ability to control the porosity of the monolith. The ability to control the porosity decreased the backpressure allowing for flow rates as high as $10\,\mu l/min$.

An additional example of integration on a chip format was demonstrated by Thibault [6] using an Agilent chip after they launched a product for performing on-chip liquid chromatography. The chip is made of polyimide and is coupled to a typical injector as described in the instrumental section. However, a clamp to ensure proper alignment and sealing between the components of the injector and the chip was necessary. The Agilent chip also included an enrichment column with a 40 nl volume. The separation column was 4.5 cm in length and utilized $5\,\mu m$ reversed phase beads. The reported peak capacity was 141 for a separation of peptides.

To further integrate on-chip LC, it is necessary to miniaturize LC components. Terry Lee's group has worked to utilize the gas produced from hydrolysis to act as the pumping mechanism for on-chip chromatography [7]. In order to effectively develop this pumping mechanism, high backpressure needed to be considered when delivering the solvent for on-chip LC. Backpressure causes the flow rate to be inadequate to practically perform a separation. Their electrochemical pump was able to deliver 70 nl/min at a backpressure of 80 psi.

Two of these pumps have been successfully coupled to generate gradients that were used to perform a separation with $3\,\mu m$ beads, a 1.2 cm column, and 80 nl/min flow rate. The sample consisted of 600 femtomols of digested BSA, which was also separated on a commercial nanoLC system for comparison. The resolution was superior for the commercial system. Although the commercial system demonstrated better resolution, it could be attributed to the 15 cm column.

Future Directions for Research

Future research will continue to improve the fabrication of liquid chromatography columns on microfluidic chips. The high porosity and high surface area of in-situ polymerized monolithic columns makes this approach most promising. Implementation of comprehensive analytical methods for characterization of biological systems in fields such as proteomics and metabolomics require large improvements allowing for more complex samples to be analyzed while reducing the amount of sample needed. Such developments should include integrated microfluidic devices capable of performing multidimensional separations that can analyze complex biological samples. Although miniaturization increases resolving power, it also decreases the loading capacity making it more difficult to detect components of low relative abundance. Therefore, many challenges remain in improving the detection limits, particularly for the analysis of

complex, mass limited samples. In addition, further developments need to include miniaturized integrated components, such as miniaturized pumps capable of higher pressures.

Synonyms

Thermochromic liquid crystals; TLCs

Definition

Thermochromic liquid crystals (TLCs) are a mixture of organic chemicals which have an optical active twisted molecular structure. Within a certain range of temperature they react to changes in temperature by changing color, when illuminated with white light. These temperature-dependent reflections (of a narrow band of wavelengths) are often called *color play*. The color play is reversible and can be calibrated accurately enough for measuring temperature fields with high resolution.

Overview

In the course of the fast growing development of microfluidic devices like ▶ Lab-on-a-Chip, ▶ microreactors, and ▶ micro heat pipes it is essential to develop effective systems for measuring the temperature distribution in the microscale. For example, for observing the ▶ heat transfer in microchannel flows it is a matter of particular interest to know both the temperature distribution along the wall and the temperature distribution in the fluid flow. Conventional ▶ methods for temperature measurements are based on ▶ thermocouples and ▶ resistance thermometers which have a minimum size of about 10 μm and which always interfere with the system to be measured. Contactless methods for measuring temperature, e. g. ▶ infrared thermography, have many advantages. But, according to the fundamental laws of optics, there is a maximum possible limit for spatial resolution in thermal imaging, which lies in the micrometer range for thermal infrared radiation. But it is not possible with infrared thermography to measure the temperature profile of a fluid flow. ▶ Fluorescent thermometry might be a solution for this case. With a system based on thermochromic liquid crystals (TLCs) both options are possible: measuring temperature fields in flows and on solid surfaces. Furthermore the velocity field can be acquired with TLC ▶ tracers and ▶ particle image velocimetry (PIV).
When illuminated, the TLCs reflect the light in a special way: an opalescent color play occurs, strongly dependent on temperature. These light reflections, a narrow band of wavelengths, can be recorded with the usual ▶ color cameras and ▶ microscopic lenses. With a special calibration technique the *RGB* information of the color images is converted into the scalar *hue-value* and from that into a temperature value for each pixel of the frame. Thus, it is possible to determine entire temperature fields with high spatial resolution.

Liquid Crystal Technique for Measuring Temperature, Figure 1 Overview of different TLC packing forms and applications

Researchers operating with the TLC technique have some general options, shown in Fig. 1. The pure (unencapsulated) TLC substance applied in very thin films onto a flat surface offers temperature field measurements with a spatial resolution of about 800 nm. But, unencapsulated TLCs require sophisticated application techniques and the pure TLC substance is very sensitive to UV light and contaminations, particularly oxygen from the air. More common are ► micro-encapsulated TLCs which are stable and easier to handle. They are available as complete foils, in binder mixtures for spray applications and as *tracers*. With the latter it is possible to acquire the temperature distribution in liquid flows.

The activity range of the TLC color play is limited to a certain bandwidth of 0.5 to 30 K. The start temperature of the color play varies from −30 to 120 °C.

Basic Methodology

Temperature measurements using TLCs are based on certain physical properties of the liquid crystal molecules. The technique requires a general experimental setup with illumination and camera and particularly a sophisticated image processing procedure.

Physical Background of Thermochromic Liquid Crystals

Molecular Structure

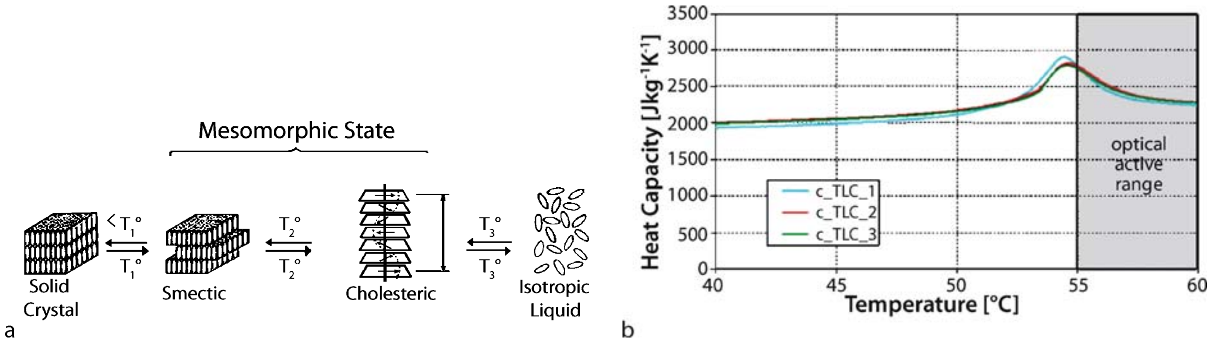
TLCs are optically active mixtures of organic molecules. The correct name for TLCs used for temperature measurements is ► chiral nematic or ► cholesteric liquid crystals. TLCs are characterized by well-analyzed reflections of visible light (color play) within a definite bandwidth of temperature. A certain temperature leads to reflections of an explicit spectrum of wavelengths, with a local maximum and a narrow bandwidth. Below the start temperature of the color play, called red-start temperature, the TLCs are transparent, when applied in thin layers; the bulk looks milky and white. In this state the molecules, which are elongated like a cigar, have a typical size of about 2 – 5 nm [1], are well ordered and close to each other like in a solid crystal (see Fig. 2a). When the temperature increases the arrangement passes through the ► mesomorphic state, which characterizes the TLCs. The crystals are still optically inactive or transparent, but the molecules are separated in layers.

Above the red-start temperature the molecules are in the cholesteric phase: they are optically active and reflect light selectively and strongly depending on temperature. With increasing temperature the reflected light changes from red to orange, to yellow, green and blue. The molecules are now arranged in layers, within the alignment is identical. In between two layers the molecule orientation is twisted by a certain angle. Cumulatively, an overall helicoidal architecture is formed, whereas the molecular director traces out a helix in space [2]. The degree of twist is defined by the pitch length L_0, which is the height of the helical structure after one 360° rotation and which is proportional to the wavelength λ_0 of the selective reflected light. This relationship can be described by the ► Bragg diffraction equation:

$$\lambda_0 = L_0 \cdot \bar{n} \cdot \sin\varphi\,, \qquad (1)$$

where $\bar{n}$ is the mean refraction index and φ is the angle of the incident light beam normal to the surface [2].

If the temperature continues to increase, the molecular structure of the helix disbands and the molecules are uniformly distributed like in an isotropic liquid. Above this so-called clearing point the crystals are optical inactive



Liquid Crystal Technique for Measuring Temperature, Figure 2 (**a**) Different states of the TLC molecule structure with increasing temperature [2]. (**b**) Heat capacity of pure TLC substance R55C5W as a function of temperature (three different samples)

again. Exceeding this temperature might lead to a permanent damage of the TLCs, depending on time and extent of the overheating.

In Fig. 2b the ▶ heat capacity of a pure TLC substance is plotted as a function of temperature. There is a noticeable peak of the heat capacity just before the red-start temperature caused by the heat of fusion. When numerical modeling of the TLC layer is required, this dependency on temperature has to be taken into account.

Temperature Range and Bandwidth

Red-start temperature and bandwidth of TLCs are important criteria when designing a TLC application of temperature measurements. As a manufacturer of TLCs, the Hallcrest Company provides a large assortment of mixtures with red-start temperatures between 12 and 120 °C and with bandwidth between 1 and 20 K. The designation R50C10W, for example, classifies a TLC mixture with a red-start temperature of 50 °C and a bandwidth of 10 K.

Encapsulation and Application Techniques

According to the requirements of the experiment, different TLC applications can be chosen, depending on lateral or temporal resolution and suitability of the technique. High lateral resolution of about 800 nm can be achieved when the pure TLC substance is applied as a thin film directly onto the surface to be observed.

However, the pure TLC substance is very sensitive to UV light and contamination with air and other substances. Without protection the pure substance undergoes fast ▶ aging and will be unusable after some hours. Therefore, TLCs are most commonly used within ▶ micro-encapsulation. Mixed with a binder the TLC capsules can be applied onto a surface via an airbrush. Complete adhesive foils produced with micro-encapsulated TLCs are available for measuring the surface temperature with reduced lateral resolution. Another different technique is accessible when micro-encapsulated TLCs are dissolved in a liquid. Thus, it is possible to determine the temperature field within a fluid. In general the capsules reduce the lateral resolution; tracers in liquids for example have a minimum resolution of about 100 μm.

Hardware and Experimental Setup

When designing an experiment for measuring temperature fields with TLCs, a basic hardware setup is needed which is exemplarily shown in Fig. 3. In general two different setups are possible. On the left side of Fig. 3 a thin metallic ▶ heating foil is used for observing the heat transfer from a hot wall to cold liquid. On the back side of the heating foil a thin layer of TLCs is applied which displays a temperature-dependent color play. On the right side of Fig. 3 small TLC capsules are dissolved in the liquid. Here the TLCs respond to the temperature of the liquid. Every particle displays a certain color which is a function of the temperature at the particular position and time.

In both cases the TLCs require bright illumination of white light, while the system should be shielded from unwanted heat input. ▶ Cold light sources with ▶ fiber optic cables are a common possibility. To ensure high lateral resolution of the temperature field the color play can be recorded with modern color cameras through microscopic lenses. Thus, the lateral resolution of the surface temperature measurements depends on the magnification of the optics and on the capsule size of the TLCs. When TLCs are used for temperature measurement in liquids, the magnification and the density of the TLC capsule seeding determine the lateral resolution. The temporal resolution depends on the camera speed and on the thermal inertia of the TLC assembly.

Application Techniques of TLCs

The application techniques of TLC films and tracers are some of the most important criteria when designing an experiment. Often much experience is required, especially when using unencapsulated TLCs.

TLC Films

The left side of Fig. 3 shows a TLC layer composition for observing the temperature distribution from the back side of a thin heating foil. The thickness of the heating foil determines when microscale effects should be observed, due to lateral heat conduction. Since metal foils have a very high ► reflective index it is hard to filter out the light reflections from the TLCs – when no background is used. The Hallcrest Company provides a black lacquer which can be applied via an airbrush to avoid light reflections. Another very thin and absolute homogenous layer of black paint can be applied by rubbing of graphic stripes from the Alfac Company. The TLC layer itself can also be applied via an airbrush when micro-encapsulated TLCs are used in combination with a binder. The technique requires some experience since the capsules tend to form porous structures within relatively thick layers. The lateral resolution is therefore reduced. However, the TLC layer is stable, and the TLCs are protected against contamination from the environment. Complete TLC sheets with black background, protective foil and adhesive for binding onto surfaces are available from different distributors. These foils are the first choice, if high lateral resolution is not needed. If very high lateral resolution in the sub-micrometer range is required, accurate measurements are possible with a thin layer of unencapsulated TLCs. The technique is quite sophisticated and requires some experience.
In the following a special technique is described, which was developed in the authors' institute and was applied in [3] and [4]. For realizing a thin film, the surface is previously heated up above the red-start temperature of the TLC substance. Then a small droplet of the substance is placed and distributed with a paintbrush while controlling the homogeneity of the color play with the naked eye. After this, a 12 μm thin polyester sheet is placed to cover the TLCs and to ensure an almost homogenous thickness due to capillary forces. While doing so, the polyester sheet must be *rolled* over the TLCs to avoid any air bubbles inside the TLCs. The TLCs have to be applied and calibrated for every experiment due to effects of aging, contamination and flowing of the film.
The group of David Kenning also did extensive studies in the 1990s using a thin film of pure TLC substance applied with a paintbrush on the back side of a 100 μm thick stainless steel foil [5].

TLC Tracers

When used in encapsulated form, TLCs can be applied as tracer particles. By means of the reflected wavelength it is possible to obtain the temperature of the particles. This method is called *PIT* (► particle image thermometry) and was first implemented by Rhee et al. [6] in the form of expertise through the human eye. Quantitative temperature measurements with TLCs in liquids were first performed by Dabiri and Gharib [7].
There are several things which should be borne in mind before using encapsulated TLCs. It is important to choose a working liquid which has a density close to that of the TLCs (1.1 – 1.2 g/ml) and does not chemically attack the polymer shell of the TLCs. Water or a mixture of water and glycerin are often used as a working liquids. The ideal concentration of TLCs in a liquid depends on the kind of illumination, the measurement depth and other factors. When ► volume illumination is used as shown in Fig. 3, an excess concentration leads to a low signal-to-noise ratio due to disturbing reflections of TLCs which are out of the camera focus, while a concentration which is too low results in a decrease of the spatial resolution. The chosen particle diameter depends on the magnification, the optical resolution of the camera and the size of the ► FOV (field of view). Note that TLCs with small diameter offer better thermal response character while bigger TLCs reflect more light. The diameter of the TLC should be approximately 3 – 4 pixels of the investigated digital image.
In the main, flow visualization with TLCs offers some elementary advantages. It is a non-intrusive measurement technique, the TLCs are easy to handle, the measurement is nearly instantaneous and the TLCs can also be used as tracers for 2D and 3D micro PIV to determine the velocity profile.

Illumination

Most suitable for the illumination of the TLCs is white light, while infrared and ultraviolet radiation should be avoided. The effect of different light sources on the calibration curves was analyzed in [8]. Especially in micro applications with high temporal resolution a strong light source is needed which might lead to photon absorption through the background and thus to unwanted heat input. A pulsed light source without infrared and ultraviolet radiation minimizes this effect. It is well known that the angle between the camera and the illumination axis has an influence of the reflection properties (e. g. [9]). Furthermore it is important to avoid non-uniform illumination; otherwise the color play of the TLCs also depends on their location within the *FOV*.

Liquid Crystal Technique for Measuring Temperature, Figure 4 Temperature-hue calibration curve for R55C5W, applied as a thin layer of pure TLC substance

Generally there are two possibilities for the illumination of flows whereby the most common is the illumination with a ▶ light sheet perpendicular to the camera axis. Especially in micro applications it is often not possible to generate a light sheet with a thickness of a few micrometers or there is no optical access. For that reason the whole volume is illuminated and the ▶ measurement depth is defined by the ▶ depth of field of the optical setup.

General Experimental Procedure

After setting up the experimental assembly a typical procedure has to be undertaken which leads to sequences of temperature fields.

Calibration

Qualitative observations of the TLC color play are possible with the naked eye. But for precise temperature field analysis an optical–electronic calibration process is required where the TLC color play has to be analyzed at a series of different temperatures. This procedure should be carried out by slow heating of the system, to ensure a homogeneous temperature distribution inside the *FOV*. At various temperature levels single pictures are recorded and saved in connection with the actual temperature recorded by thermocouples e. g.

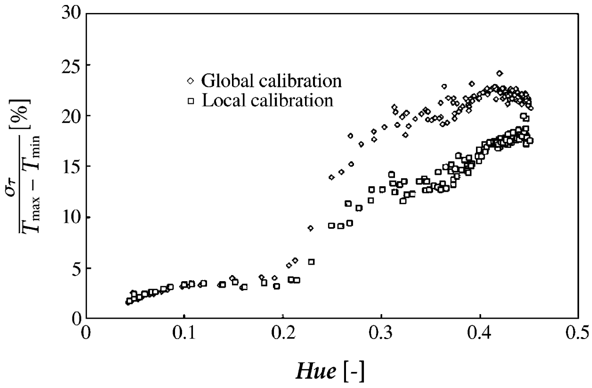
It has to be noted that in situ calibration is absolutely necessary for every experimental setup. If pure TLC substance is used, it must be applied fresh by taking into account the purity of all substances and materials. The light source intensity, the angle of illumination and all camera parameters must be set before the calibration procedure. This is important, since small variations of these parameters can falsify the measurement results in a wide range.

Image Processing

Since all recorded frames from the color camera are saved to hard disk, the color information is available in ▶ RGB matrixes (red, green, blue). A common way of color analysis is available by the use of the ▶ HSV color space. For this, a color is given by the hue (H), the saturation (S) and the value of the brightness (V). The hue value can be interpreted as an angle in the HSV color space. The corresponding colors vary from red through yellow, green, cyan, blue, magenta, and back to red. The *RGB* information can be converted into hue with a certain formula in such a way that the color information is available in the form of a scalar:

$$hue = \arctan \frac{\sqrt{3}(G-B)}{2R-G-B} \qquad (2)$$

Other equations for transformation of the *RGB* values to the *HSV* values are available and their influences on the measurement accuracy are discussed by Hay et al. [10]. In Fig. 4 the hue values are plotted versus the corresponding temperatures for TLCs with an activity range from 55 to 60 °C. A polynomial is fitted through the measurement points and finally describes the dependence of the hue values on the temperature.



Liquid Crystal Technique for Measuring Temperature, Figure 5 Normalized standard deviation of temperatures calculated with local and global calibration curves under isothermal properties for encapsulated TLCs in liquid

A problem occurring is the deviation of the reflected hue values at isothermal conditions which is caused by several factors (see Sect. *measurement accuracy*). To decrease the position-dependent errors like illumination or image acquisition, a local calibration can be done. Hereby the *FOV* is divided in ►interrogation areas and a temperature–hue calibration curve is generated for every interrogation area. The improvement of the measurement signal for encapsulated TLCs suspended in water is shown in Fig. 5. The deviation of the indicated temperatures under isothermal conditions can be reduced.

Special Image Processing for Encapsulated TLC Tracers in Liquids

The potential of the simultaneous estimation of the temperature and the velocity distribution in a liquid is a big advantage of the TLC measurement technique. The procedure is shown in Fig. 6.

PIT – Particle Image Thermometry

The acquired *RGB* images are transformed into ►HSV images and the intensity information is taken for the detection of the particles. Before that, the intensity image is pre-processed by classic image operations such as ►background subtraction and ►low-pass filtering. Particle detection can be done by a ►threshold filter or by the estimation of local maxima. With the location of the particles and their corresponding hue values from the HSV image, a location-dependent temperature is calculated with the according (local) calibration polynomial(s). Generally the hue values of the TLCs and thus the calculated temperatures are afflicted with errors (see Sect. *measurement accuracy*). To enhance the measurement results, the hue values have to be post-processed. One possibility is ►temporal averaging where several pictures of the same area are taken at different times. Hence the investigated flow has to be time independent. Another possibility to decrease the deviation of the hue values is ►local filtering of the image. Common filters for this purpose are ►mean filter, ►Gaussian filter and ►median filters. Note that filtering always leads to loss of resolution.

PIV – Particle Image Velocimetry

To obtain the velocity field with the *PIV* method (see also ►Micro-PIV-Based Diffusometry) two images with a short time interval Δt are applied. It is possible to use the same images for the estimation of the temperature and the velocity fields (see Fig. 6). Therefore intensity images are created of the RGB images, which are pre-processed as described above and divided into interrogation areas. The two-dimensional cross correlation of related interrogation areas leads to the pixel displacement in the measurement plane direction s, and with the length of a square pixel d_r and time interval Δt the velocity vector can be calculated with the formula:

$$v = s \cdot \frac{d_r}{\Delta t} \tag{3}$$

Measurement Accuracy

In [3] the maximum occurring ►standard deviation of the hue values is estimated to 5% of the activity range. This has been conducted for a thin film of unencapsulated TLCs on a flat surface.

Park [11] found a standard deviation of up to 20% of the activity range for encapsulated suspended TLCs. This relatively high deviation can be minimized with the above mentioned image processing techniques to maximum of 10%.

The deviation of the reflected hue values of the TLCs at isothermal conditions and therefore the uncertainty of the temperature measurement is caused by several factors, as discussed below.

Non-Uniformity of the Manufactured Encapsulated TLC Particles

This occurs due to variations in the chemical composition, variation of the thickness of the polymer shell, and ►residual stress due to the encapsulation process and results in different reflective properties [11].

L

Illumination and Viewing Angles

The angle between the optical and the illumination axes affects the color response of the TLCs. This has been observed by several authors (e. g. [9]). Furthermore a non-uniform illumination results in position-dependent deviation of the hue values.

Thermochromic Liquid Film Thickness

When thin films of TLCs are used the thickness is a deciding factor for the quality of the color play. Layers greater than 100 μm appear misty due to reflections from deeper molecules, and very thin layers (less than 10 μm) display too low an intensity of the color information. Around 20 μm is an ideal thickness for unencapsulated TLCs and around 50 μm for encapsulated layers.

TLC Concentration in Liquids

If the concentration of the TLCs in the suspension is too low, a loss in spatial resolution occurs while a suspension with too many TLCs leads to a high noise.

Response Time

While the response of the TLCs themselves lies in the range of about a millisecond [12, 13] most of the signal attenuation and phase shift is caused by heat conduction and by the capacity of the TLC and capsule material. Kobayashi and Saga [14] performed numerical calculations of the dynamical heating of the TLCs.

Hysteresis and Aging

If the particles are heated above their maximum activity temperature, they are damaged and a ►hysteresis of the temperature–hue values of the heating and cooling gradient appears (e. g. [15, 16]). In [3] calibration curves were recorded for the same layer of unencapsulated TLCs after 1, 10, and 20 days, which led to a temperature uncertainty of around 40% of the activity range.

Digital Resolution

Since the R, B, and G values are digitized by the image acquisition, they have a restricted resolution of 8 bits (for most digital cameras). Therefore the hue value, which is a function of the R, B, G values (Eq. 2), has a definite uncertainty. Wiberg and Lior [16] and Behle et al. [9] stated a resulting temperature uncertainty of 1% of the activity range due to the digital resolution. Limitation of this uncertainty can be achieved through illumination with a wide color spectrum [8] and proper adjustments of the camera.

Key Research Findings

In this article applications with TLCs for high temporal and spatial resolution are presented for thin TLC films and for TLC tracers.

Surface Temperature Measurements with TLCs

Lateral Resolution

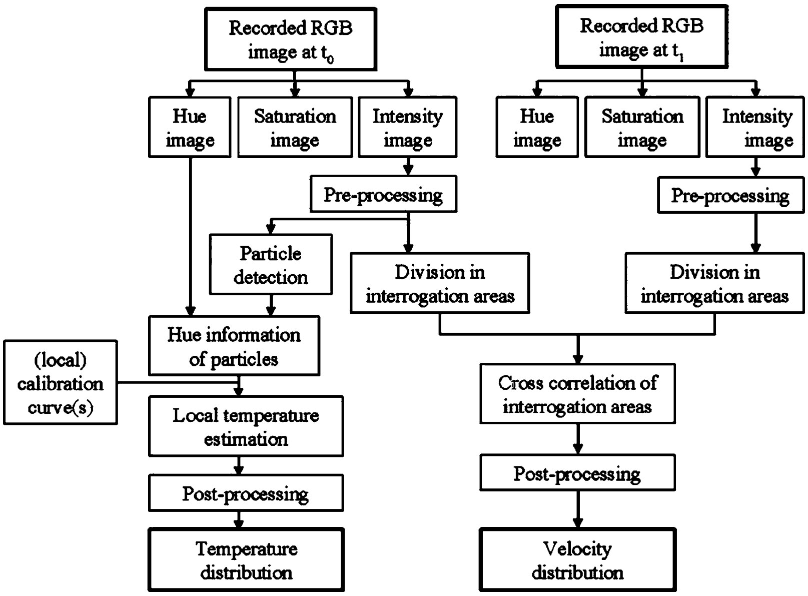
Very high lateral resolution is one of the most important criteria when using unencapsulated TLC films. To the authors' knowledge there is no other technique which provides higher lateral resolution in the sub-micrometer range.

Figure 7 shows the hue value frequency of an unencapsulated TLC layer in comparison to a more common layer with micro-encapsulated TLCs (►micro-encapsulation). While unencapsulated TLCs display a clear-cut signal for a homogenous temperature distribution, micro-encapsulated TLCs show a much more attenuated and blurred signal. This is due to the empty space between the capsules which displays no color information and due to the reflections on the capsule surface.

With unencapsulated TLCs in [3] the microscale cooling effect of an evaporating liquid meniscus could be visualized. Within a width of about 40 μm a distinctive temperature drop of about 0.2 K could be observed (see Fig. 8). The lateral resolution in this experiment was 800 nm.

Temporal Resolution

At present it is important to know if the TLC technique is also suitable for observing dynamic processes with high frequencies, e. g. nucleate boiling. In this case the thermal inertia of all substances and materials close to the nucleation site plays an important role. The composition of the heated wall consisting of a thin metallic foil, a black background color, the TLC layer and a transparent covering obviously has an influence on the time response of the entire system. Kenning did extensive studies of nucleate boiling on electrically heated thin metallic foils [5]. He used unencapsulated TLCs to observe the temperature field on the back side of these foils and found that the maximum bubble departure frequency, which can be followed by TLCs, lies between 0 and 20 Hz. Ireland and Jones determined a time delay of the TLC color play appearance during heating rates of 2000 K/s and more [12]. They used a blackened aluminum foil which was electrically heated and laminated with a mixture of 10 μm TLC capsules and PVA binder. They found that the measured time delay of about 3 ms must be a consequence of both conduction as well as an intrinsic physical lag. In [13] the ►frequency response of a pure TLC film was inves-



Liquid Crystal Technique for Measuring Temperature, Figure 6 Flow chart of simultaneous measuring of temperature and velocity

Liquid Crystal Technique for Measuring Temperature, Figure 8 Local cooling effect of an evaporating liquid meniscus [3]

tigated using an electric resistance heater with harmonic oscillations within a frequency band of 3 to 70 Hz. It was found that for frequencies above 1 Hz the TLCs do not display the actual heater temperature due to amplitude attenuation and phase shift; a maximum frequency of 70 Hz could be analyzed. In Fig. 9 the temperature time progression simulated with a numerical approach is displayed for different positions along the thickness of the layer assembly.

While the highest amplitude is computed in the centre of the heating foil (rectangle label), the amplitude decreases rapidly with increasing distance from the heater plate: in the centre of the TLC layer, where the measurement fits best with the numeric result, the amplitude is only about 60% of the heating foil amplitude.

Summarizing these results, it can be said that the dominating effect of amplitude attenuation and phase shift is a problem of heat conduction inside the TLC system. The

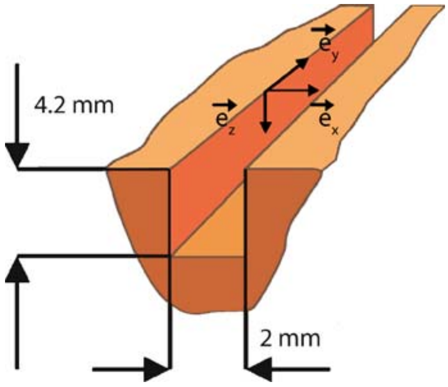
Simulated temperature progression inside a 20 μm thick TLC [4]



Liquid Crystal Technique for Measuring Temperature, Figure 10
Sketch of the mini channel

problem can be simulated by simple models of heat conduction. A residual time shift between the numeric and experimental results of about 1 ms might be caused by the averaging process over the TLC layer thickness or by an intrinsic physical lag of the TLC molecule orientation.

Flow Visualization with Encapsulated TLCs

The application of TLCs in liquids is well known for bigger fields of view and slower flow rates and was employed by Dabiri and Gharib [7]. Typical investigated processes are free convection in a tube or crystallization of water (e. g. [6]). Only a few experiments have taken place with a high lateral resolution. Richards and Richards [17] put TLCs in a water droplet which was cooled by an air flow. The diameter of the droplet was less than 1 mm and they investigated the temperature profile with a spatial resolution of 100 μm. They used volume illumination and a *CCD camera* with a depth of field of 100 μm.

The free convection of water with suspended TLCs in a small vertical gap with dimensions of $1.1\times 10\times 10\ \text{mm}^3$ $(b\times d\times h)$ is considered by Heiland et al. [18]. Heating of one side wall and cooling of the other led to a convective flow of the liquid. Heiland et al. [18] used a ► light sheet with a thickness of 1 mm for illumination and a ► CCD camera for image acquisition. The temperature and the velocity field were investigated with TLCs as tracer particles with a spatial resolution of approximately 150 μm for temperature and 80 μm for velocity field. The maximal measured velocity was 0.1 mm/s.

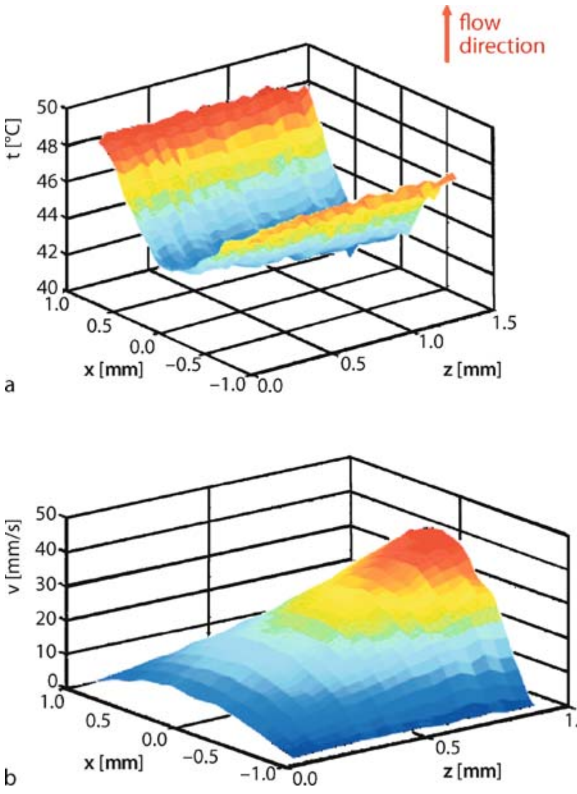
Liquid flows with higher velocities were investigated by Park [11]. He used two xenon flash lamps which were fired at 15 Hz each. The flash lamps were synchronized with a CCD RGB camera. Park was able to measure the temperature and the velocity field of a wake behind a cylinder with a spatial resolution of 280 μm and a measurement frequency of 30 Hz.

The group of Rudolf von Rohr [19, 20] used encapsulated TLCs to investigate a liquid flow over a wavy bottom wall. For the *PIV* measurements a Nd:YAG laser as pulsed light source and a 12 bit monochrome camera were used. Within the same *FOV* ($35\times 45\ \text{mm}^2$), a *CCD* color camera acquired the color distribution of the TLCs illuminated by a stroboscope. Both the laser light and the white light were focused with lenses to *light sheets* and triggered so that the *FOV* was illuminated alternately. The images were acquired with a frequency of 15 Hz [20].

In the laboratories of the authors simultaneous PIT/PIV measurements with TLCs are performed and a flow in a mini channel is investigated (Fig. 10). The illumination is done by two 250 W halogen ► cold light sources and the images are acquired by a high-speed color ► CMOS camera with a long-distance microscope. With this measurement setup, measurements with a frequency of 1000 Hz are possible. The camera can be moved perpendicular to the streaming direction in micrometer steps whereby it is possible to measure on different layers and 3D temperature fields can be obtained (Fig. 11a) under steady flow conditions. The velocity fields (Fig. 11b) are estimated simultaneously and a spatial resolution of 100 μm is achieved for both the velocity and the temperature fields.

Future Directions for Research

Particularly the temperature measurement with encapsulated TLCs shows extensive deviation in the reflected wave length. To minimize this, the illumination technique should be enhanced to receive a uniform illuminated ► FOV. Furthermore strong illumination is needed for applications with high lateral and temporal resolution. Another problem is the heat introduced by the illumination especially when continuous volume illumination is used. A pulsed illumination decreases this effect.



Liquid Crystal Technique for Measuring Temperature, Figure 11 (**a**) Temperature profiles on several *z*-positions. (**b**) Velocity profiles on several *z*-positions

When encapsulated TLCs are used in flows with high temperature gradients, a fast thermal response time is needed. To study the possible use of encapsulated TLCs, their thermal response time should be investigated.

The resolvable spatial resolution of temperature measurements in liquids mainly depends on the concentration of the TLCs in the suspension, the size of the averaging area (interrogation area) and the size of the TLC particles. To decrease the size of the averaging area, a better hue response of the temperature of the TLCs is needed. Since the concentration of the *encapsulated* TLCs in the suspension is restricted by the signal-to-noise ratio, only a smaller diameter of the particles can improve the resolvable spatial resolution.

Two-fluid stratified flow

Definition

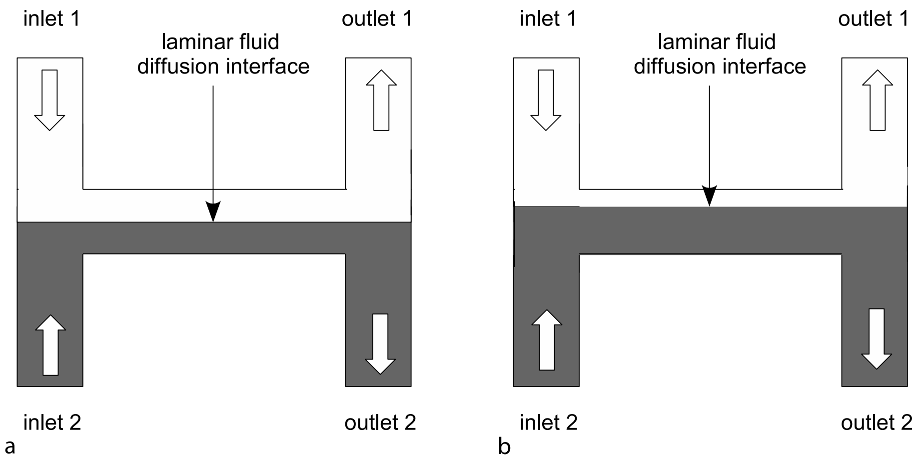
When two liquids co-flow in a microchannel, an interface forms between them due to the low Reynolds number. This is known as liquid–liquid stratified flow.

Overview

Liquid–liquid stratified flow in microchannels is often used in biological analysis, such as during ion exchange or solvent extraction from one phase to another phase [1]. For liquid flow in microfluidics, the Reynolds number is small and the flows are always laminar. Laminar fluid diffusion interfaces (LFDIs) are generated when two or more streams flow in parallel within a single microstructure [2], as shown in Fig. 1a. For laminar streams flowing side by side, diffusion is the only mechanism by which molecules can pass from one phase to another. The diffusion through the phases is a function of diffusion coefficient and distance. The mixing time is proportional to the square of the distance traveled. The mixing time can be reduced effectively by decreasing the diffusion distance. Much research has studied ways to promote mixing at the small scale [3]. However, non-mixing in microchannels can be very useful as well. Because only diffusion occurs between different streams of flow, it is used for extraction or separation in biological analysis. Diffusion-based microfluidic devices, such as the T-sensor® and the H-filter®, have been developed for commercial use by Micronics, Inc.

In an extraction or separation of biological analysis, the two liquids used are biological liquid and aqueous reagent [4]. These two liquids are very different in properties such as density, surface tension and viscosity. The mismatch of the viscosity of the two liquids can be problematic in diffusion-based applications. The liquid with higher viscosity will spread more widely in the channel while having a smaller velocity; the liquid with lower viscosity flows at a larger velocity with a smaller fraction of the channel volume. Consequently, the resulting liquid–liquid interface deviates from the central position, shown in Fig. 1b. This applies when the two flows have the same volumetric flow rate. The unmatched viscosity also affects the diffusion in terms of the residence time. The average residence time of the more viscous liquid increases, while that of the less viscous liquid decreases. To overcome this problem, one method is to measure the viscosity of one liquid, then add viscosity-enhancing solute to the less viscous liquid so as to match the viscosity. Another method, the *flow-rate-ratio* method, is used to control the ratio of the volumetric flow rate of the two liquids. Hydrodynamic spreading and narrowing can be controlled by adjusting the flow rates of the two co-flowing liquids. However, the unmatched average residence time problem still remains unsolved, because the less viscous fluid flows faster and has a shorter average residence time within the channel.

As dimension shrinks, the surface area to volume ratio increases by orders of magnitude. Many forces or fields, which are not significant in macroscale fluid flow, become important in manipulating and controlling fluids in microfluidics. These effects include the thermal capillary effect, electroosmosis, surface tension and magnetohydrodynamics. These forces or fields provide us with alternative means to control the microfluidic flow behaviors. In this article, we propose a theoretical model to predict the interface position of two liquids flowing through a rectangular cross-section microchannel, as shown in Fig. 2. One liquid is a conducting liquid with high electroosmotic mobility and the other is a nonconducting liquid with low electroosmotic mobility. When an external



Liquid–Liquid Stratified Flow in Microchannels, Figure 1 Schematic of liquid–liquid interface in an H-shaped microchannel: (**a**) the laminar fluid diffusion interface (LFDI) at the center of the microchannel; (**b**) LFDI deviating from the center

electric field is applied across the conducting liquid, electroosmotic forces will be generated and the velocity of the conducting liquid can be regulated depending on the direction and strength of the applied electric field. We will show that by adjusting the applied electric field, the interface position can be precisely controlled. Analytical formulas are presented for the interface position as a function of the ratio of the input flow rates, the ratio of the shear viscosities, the aspect ratio of the channel, the applied electric field and concentration of the conducting liquid. Predictions from the mathematical model are validated by experimental results.

Basic Methodology

Theory

Consider a two-liquid system, in which one is a conducting liquid containing ionic charges in contact with a charged smooth solid wall and the other is a nonconducting liquid. It is assumed that the two liquids are immiscible. A planer interface shape is assumed. Due to the symmetry, only half of the cross-section of the rectangular channel is considered. The half-width of the channel is taken as w. The height is taken as h and the heights of the conducting and nonconducting liquids are denoted by h_1 and h_2, respectively. To analyze this system, a Cartesian coordinate system is used where the origin point is at the intersection of the interface and the symmetric line as shown in Fig. 2.

Electrical Double Layer in the Conducting Liquid

The two liquids move due to both pressure gradient and electroosmotic body force. When the flow is fully developed, at position r, the velocities of two liquids, u_1 or u_2, along the channel are independent of the x-coordinate. The subscripts 1 and 2 denote the conducting and nonconducting liquids, respectively. Provided that the aspect ratio $\chi = h/2w$ is large, the pressure gradient at the fully developed region is uniform across the channel. Symmetric electrolyte is considered as the conducting liquid. The electric potential in the conducting liquid due to a charged channel wall is taken as ψ and the net volume charge density in the conducting liquid as ρ_q. The length scale and velocity scale of the flow are taken as L and V, respectively. The independent variable r and dependent variables u, p, ψ and ρ_q are expressed in terms of the corresponding dimensionless quantities (shown with an overbar) by

$$\begin{cases} r = L\bar{r} & \\ u = V\bar{u} & p = \rho_1 V^2 \bar{p} \\ \psi = \dfrac{k_B T \bar{\psi}}{(z_0 e)} & \rho_q = 2 n_0 z_0 e \bar{\rho}_q \end{cases} \tag{1}$$

where ρ is the liquid density, k_B is Boltzmann's constant, T is the absolute temperature, z_0 is the valence of ions, e is the elementary charge and n_0 is the reference value of the ion concentration.

First we consider the electric potential in the conducting liquid. It is assumed that the electric charge density is not affected by the external electric field due to the thin electrical double layers (EDLs) and small fluid velocity; therefore the charge convection can be ignored and the electric field equation and the fluid flow equation are decoupled [5]. Based on the assumption of local thermodynamic equilibrium, for small zeta potential, the electric potential due to the charged wall is described by the lin-

ear Poisson–Boltzmann equation which can be written in terms of dimensionless variables as

$$\nabla^2 \bar{\psi} = K^2 \bar{\psi} \tag{2}$$

where $K = L\kappa$ is the ratio of the length scale L to the characteristic double-layer thickness $1/\kappa$. Here κ is the Debye–Hückel parameter:

$$\frac{1}{\kappa} = \left(\frac{\varepsilon \mathrm{k_B} T}{2 z_0^2 e^2 n_0} \right)^{1/2} \tag{3}$$

where ε is the relative permittivity of the conducting liquid.

As the channel walls are made of different materials, we specify the zeta potential at the bottom wall is ζ_1, at the sidewall is ζ_2 and at the interface is ζ_3. At the mid-plane $z = 0$, a symmetric condition, $\partial\psi/\partial z = 0$ holds. The solution to the Poisson–Boltzmann equation subjected to the above boundary conditions is obtained as

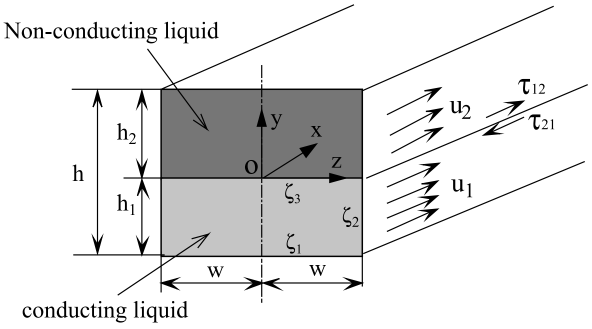
$$\begin{aligned} \bar{\psi}(\bar{y}, \bar{z}) = \sum_{j=1}^{\infty} \Bigg\{ & \left[\bar{\zeta}_1 \sinh\left(B_j \bar{y}\right) + \bar{\zeta}_3 \sinh\left(B_j \bar{h}_1 - B_j \bar{y}\right) \right] \\ & \times \frac{4(-1)^{j+1} \cos\left(\lambda_j \bar{z}\right)}{(2j-1)\pi \sinh\left(B_j \bar{h}_1\right)} \Bigg\} \\ & + \sum_{p=1}^{\infty} \Bigg\{ 2\bar{\zeta}_2 \left[1 + (-1)^{p+1} \right] \\ & \times \frac{\cosh\left(A_p \bar{z}\right)}{p\pi \cosh\left(A_p \bar{w}\right)} \sin\left(\frac{p\pi}{\bar{h}_1} \bar{y} \right) \Bigg\} \end{aligned} \tag{4}$$

where

$$\begin{cases} B_j = \sqrt{K^2 + \dfrac{(2j-1)^2 \pi^2}{4\bar{w}^2}} \\ \lambda_j = \dfrac{(2j-1)\pi}{2\bar{w}} \\ A_p = \sqrt{K^2 + \dfrac{p^2 \pi^2}{\bar{h}_1^2}} \end{cases}$$

From electrostatics, the normal component of the gradient of the electric potential, ψ, jumps by an amount proportional to the surface charge density, ρ_q^s, that is

$$\rho_q^s = -\varepsilon \frac{\partial \psi}{\partial y} \tag{5}$$



Liquid–Liquid Stratified Flow in Microchannels, Figure 2 Schematic representation of the coordinate system

It is assumed that the gradient of electric potential in the nonconducting liquid vanishes. Using the reference surface charge density as $(\varepsilon \mathrm{k_B} T)/(z_0 e L)$, one obtaines the dimensionless surface charge density at the two-liquid interface as

$$\begin{aligned} \bar{\rho}_q^s(\bar{z}) = & \sum_{j=0}^{\infty} \frac{4(-1)^{j+1} B_j}{(2j-1)\pi} \left[\frac{\bar{\zeta}_3}{\tanh\left(B_j \bar{h}_1\right)} - \frac{\bar{\zeta}_1}{\sinh\left(B_j \bar{h}_1\right)} \right] \\ & \times \cos\left(\lambda_j \bar{z}\right) - \sum_{p=1}^{\infty} \frac{2\bar{\zeta}_2 \left[(-1)^{p+1} + 1 \right] \cosh\left(A_p \bar{z}\right)}{\bar{h}_1 \cosh\left(A_p \bar{w}\right)} \end{aligned} \tag{6}$$

It should be mentioned that the surface charge at the interface, ρ_q^s, is opposite in sign to the volumetric net charge in the EDL region at the vicinity of the interface. From Eq. (6), it can be seen that the contribution of zeta potential at the bottom wall, ζ_1, is relatively small and the contribution of the sidewalls, ζ_2, is also relatively small except when z approaches w. Once the electric potential distribution is known, the volumetric net charge density can be obtained through the relationship

$$\bar{\rho}_q = -\bar{\psi}(\bar{y}, \bar{z}) \tag{7}$$

This volumetric net charge density, Eq. (7), and the interface charge density, Eq. (6), are required to determine the electrostatic force caused by the presence of zeta potential. The bulk electrostatic force is considered as an additional body force exerted on the conducting solution to modify the conventional Navier–Stokes equation. The nonconducting liquid is dragged by the viscous forces from the conducting liquid and the external electrostatic force (E_x) due to the electrokinetic charge density at the interface. If the external electric field varies, such applied electroosmotic body forces will be changed correspondingly. As a result, for a given inlet flow rate, the velocities of the

two liquid depend on the applied electroosmotic force; hence the interface position between the two liquids can be controlled.

Momentum Equation of Two-Liquid Flow

We assume that the two liquids are Newtonian and incompressible and that the Reynolds number ($\mathrm{Re} = \rho_1 LV/\mu_1$, where μ is the liquid viscosity) of the flow is much smaller than unity so that inertia effects on the liquid flow may be neglected. For a fully developed flow, the momentum equation for the conducting liquid becomes

$$\nabla^2 \bar{u}_1 = \mathrm{Re}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}} - \mathrm{Re} G_x \bar{\rho}_{\mathrm{q}} \tag{8}$$

where $\mathrm{d}\bar{p}/\mathrm{d}\bar{x}$ is a constant dimensionless pressure gradient. For a fully developed flow, the pressure gradients of the two liquids are equal and G_x is the parameter given as

$$G_x = \frac{2 z_0 e n_0 L E_x}{\rho V^2} \tag{9}$$

For the nonconducting liquid, the momentum equation gives

$$\nabla^2 \bar{u}_2 = \frac{\mathrm{Re}}{\beta}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}} \tag{10}$$

where $\beta = \mu_2/\mu_1$ is the dynamic viscosity ratio. The velocities of the two liquids vanish at the lower ($y = -h_1$), upper ($y = h_2$) and side ($z = w$) boundaries. Additionally, at the interface ($y = 0$), matching conditions have to be obeyed. These are the continuities of velocity and shear stress balance, which jump abruptly at the interface due to the presence of surface charge:

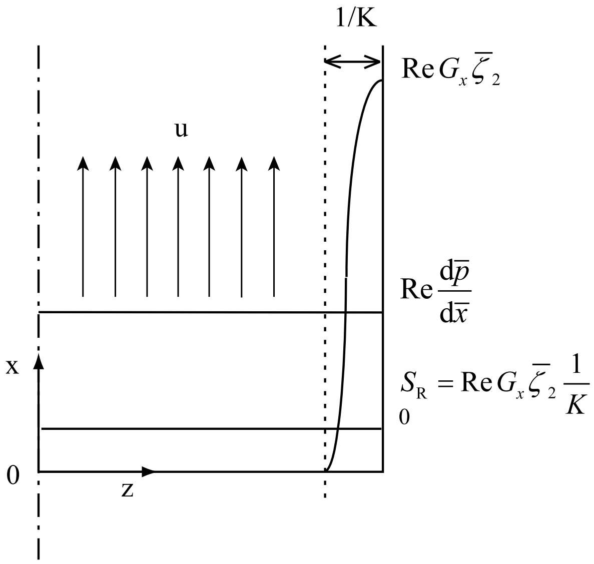
$$\begin{cases} \bar{u}_1 = \bar{u}_2 \\ \dfrac{\partial \bar{u}_1}{\partial \bar{y}} = \beta \dfrac{\partial \bar{u}_2}{\partial \bar{y}} - M \bar{\rho}_{\mathrm{q}}^{\mathrm{s}} \end{cases} \tag{11}$$

where

$$M = \frac{\varepsilon k_{\mathrm{B}} T E_x}{z_0 e V \mu}\,.$$

Because of linearity, the velocity of the conducting liquid in Eq. (8) can be decomposed into two parts:

$$\bar{u}_1 = \bar{u}_1^{\mathrm{E}} + \bar{u}_1^{\mathrm{P}} \tag{12a}$$



Liquid–Liquid Stratified Flow in Microchannels, Figure 3 Schematic of the meaning of S_{R}

where $\bar{u}_1^{\mathrm{E}}$ corresponds to the velocity component driven by the electroosmotic forces and $\bar{u}_1^{\mathrm{P}}$ corresponds to the velocity component driven by the pressure gradient. Consequently, the velocity of the nonconducting liquid is decomposed as

$$\bar{u}_2 = \bar{u}_2^{\mathrm{E}} + \bar{u}_2^{\mathrm{P}} \tag{12b}$$

where $\bar{u}_2^{\mathrm{E}}$ corresponds to the velocity component influenced by the electroosmotic flow in the conducting liquid and $\bar{u}_2^{\mathrm{P}}$ corresponds to the velocity component influenced by the pressure gradient.

Using the separation of variables method, the analytical velocity components corresponding to the electroosmotic force are obtained as

$$\begin{aligned} \bar{u}_1^{\mathrm{E}}(\bar{y},\bar{z}) = \sum_{j=1}^{\infty} \cos(\lambda_j \bar{z}) \Big\{ b1_j^{\mathrm{E}} \big[\sinh(\lambda_j \bar{y}) \\ - \tanh(\lambda_j \bar{h}_1)\cosh(\lambda_j \bar{y}) \big] \\ - \frac{\Phi_j(\bar{h}_1)\cosh(\lambda_j \bar{y})}{\cosh(\lambda_j \bar{h}_1)} + \Phi_j(\bar{y}) \Big\} \end{aligned} \tag{13a}$$

$$\begin{aligned} \bar{u}_2^{\mathrm{E}}(\bar{y},\bar{z}) = \sum_{j=1}^{\infty} \cos(\lambda_j \bar{z}) \Big\{ b2_j^{\mathrm{E}} \big[\sinh(\lambda_j \bar{y}) \\ - \tanh(\lambda_j \bar{h}_2)\cosh(\lambda_j \bar{y}) \big] \Big\} \end{aligned} \tag{13b}$$

$$\Phi_j(\bar{y}) = -\frac{4\mathrm{Re}G_x\bar{\zeta}_1(-1)^{j+1}\sinh(B_j\bar{y})}{(2j-1)\pi\left(\lambda_j^2-B_j^2\right)\sinh(B_j\bar{h}_1)} + \frac{4\mathrm{Re}G_x\bar{\zeta}_3(-1)^{j+1}\sinh\left(B_j\left(\bar{h}_1-\bar{y}\right)\right)}{(2j-1)\pi\left(\lambda_j^2-B_j^2\right)\sinh(B_j\bar{h}_1)} - \sum_{p=1}^{\infty}\left\{4\mathrm{Re}G_x\bar{\zeta}_2\left[1+(-1)^{p+1}\right] \times \frac{\lambda_j(-1)^{j+1}\sin(p\pi\bar{y}/\bar{h}_1)}{p\pi\bar{w}\left(\lambda_j^2+A_p^2\right)\left[(p\pi/\bar{h}_1)^2+\lambda_j^2\right]}\right\}$$

$$\Phi'_j(\bar{y}) = \frac{-4\mathrm{Re}G_x\bar{\zeta}_1(-1)^{j+1}B_j\cosh(B_j\bar{y})}{(2j-1)\pi\left(\lambda_j^2-B_j^2\right)\sinh(B_j\bar{h}_1)} + \frac{4\mathrm{Re}G_x\bar{\zeta}_3(-1)^{j+1}B_j\cosh\left[B_j\left(\bar{h}_1-\bar{y}\right)\right]}{(2j-1)\pi\left(\lambda_j^2-B_j^2\right)\sinh(B_j\bar{h}_1)} - \sum_{p=1}^{\infty}\left\{4\mathrm{Re}G_x\bar{\zeta}_2\left[1+(-1)^{p+1}\right] \times \frac{\lambda_j(-1)^{j+1}\cos(p\pi\bar{y}/\bar{h}_1)}{\bar{h}_1\bar{w}\left(\lambda_j^2+A_p^2\right)\left[(p\pi/\bar{h}_1)^2+\lambda_j^2\right]}\right\}$$

The velocity components corresponding to the pressure gradient are

$$\bar{u}_1^{\mathrm{P}}(\bar{y},\bar{z}) = \cos(\lambda_j\bar{z}) \sum_{j=1}^{\infty}\left\{\frac{4\mathrm{Re}(-1)^{j+1}}{(2j-1)\pi\lambda_j^2}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\left[\frac{\cosh(\lambda_j\bar{y})}{\cosh(\lambda_j\bar{h}_1)}-1\right] + b1_j^{\mathrm{P}}\left[\sinh(\lambda_j\bar{y}) - \tanh(\lambda_j\bar{h}_1)\cosh(\lambda_j\bar{y})\right]\right\} \tag{14a}$$

$$\bar{u}_2^{\mathrm{P}}(\bar{y},\bar{z}) = \cos(\lambda_j\bar{z}) \sum_{j=1}^{\infty}\left\{\frac{4\mathrm{Re}(-1)^{j+1}}{\beta(2j-1)\pi\lambda_j^2}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\left[\frac{\cosh(\lambda_j\bar{y})}{\cosh(\lambda_j\bar{h}_2)}-1\right] + b2_j^{\mathrm{P}}\left[\sinh(\lambda_j\bar{y}) - \tanh(\lambda_j\bar{h}_2)\cosh(\lambda_j\bar{y})\right]\right\} \tag{14b}$$

From the matching condition Eq. (11), the following constants can be obtained:

$$b1_j^{\mathrm{E}} = \beta b2_j^{\mathrm{E}} + \frac{M}{\lambda_j}\bar{\rho}_{\mathrm{q}j}^{\mathrm{s}} - \frac{\Phi'_j(0)}{\lambda_j} \tag{15a}$$

$$b2_j^{\mathrm{E}} = \frac{\frac{M}{\lambda_j}\bar{\rho}_{\mathrm{q}j}^{\mathrm{s}}\tanh(\lambda_j\bar{h}_1) + \frac{\Phi_j(\bar{h}_1)}{\cosh(\lambda_j\bar{h}_1)}}{\tanh(\lambda_j\bar{h}_2) - \beta\tanh(\lambda_j\bar{h}_1)} - \frac{\frac{\Phi'_j(0)}{\lambda_j}\tanh(\lambda_j\bar{h}_1) - \Phi_j(0)}{\tanh(\lambda_j\bar{h}_2) - \beta\tanh(\lambda_j\bar{h}_1)} \tag{15b}$$

$$b1_j^{\mathrm{P}} = \beta b2_j^{\mathrm{P}} \tag{15c}$$

$$b2_j^{\mathrm{P}} = \frac{\frac{4\mathrm{Re}(-1)^{j+1}}{(2j-1)\pi\lambda_j^2}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\left[\frac{1}{\cosh(\lambda_j\bar{h}_1)} - 1 - \frac{1}{\cosh(\lambda_j\bar{h}_2)\beta} + \frac{1}{\beta}\right]}{\beta\tanh(\lambda_j\bar{h}_1) - \tanh(\lambda_j\bar{h}_2)} \tag{15d}$$

The dimensionless volumetric flow rates through the rectangular channel can be defined by $\bar{q}_1 = \bar{q}_1^{\mathrm{E}} + \bar{q}_1^{\mathrm{P}} = q_1/\left(L^2V\right)$ and $\bar{q}_2 = \bar{q}_2^{\mathrm{E}} + \bar{q}_2^{\mathrm{P}} = q_2/\left(L^2V\right)$. The dimensionless flow rates are given by

$$\bar{q}_1^{\mathrm{E}} = 2\int_{-\bar{h}_1}^{0}\int_0^{\bar{w}}\bar{u}_1^{\mathrm{E}}(\bar{y},\bar{z})\,\mathrm{d}\bar{y}\,\mathrm{d}\bar{z} = 2\sum_{j=1}^{\infty}\left\{\left[1-\frac{1}{\cosh(\lambda_j\bar{h}_1)}\right]\frac{b1_j^{\mathrm{E}}}{\lambda_j} + \frac{\Phi_j(\bar{h}_1)}{\lambda_j}\tanh(\lambda_j\bar{h}_1) + \Phi_j^I(0) - \Phi_j^I(\bar{h}_1)\right\}\frac{\sin(\lambda_j\bar{w})}{\lambda_j} \tag{16a}$$

$$\bar{q}_2^{\mathrm{E}} = 2\int_0^{\bar{h}_2}\int_0^{\bar{w}}\bar{u}_2^{\mathrm{E}}(\bar{y},\bar{z})\,\mathrm{d}\bar{y}\,\mathrm{d}\bar{z} = 2\sum_{j=1}^{\infty}\left[\frac{1}{\cosh(\lambda_j\bar{h}_2)}-1\right]\frac{b2_j^{\mathrm{E}}}{\lambda_j^2}\sin(\lambda_j\bar{w}) \tag{16b}$$

$$\bar{q}_1^{\mathrm{P}} = 2\int_{-\bar{h}_1}^{0}\int_0^{\bar{w}}\bar{u}_1^{\mathrm{P}}(\bar{y},\bar{z})\,\mathrm{d}\bar{y}\,\mathrm{d}\bar{z} = 2\sum_{j=1}^{\infty}\left\{\left[1-\frac{1}{\cosh(\lambda_j\bar{h}_1)}\right]\frac{b1_j^{\mathrm{P}}}{\lambda_j} + \frac{4\mathrm{Re}(-1)^{j+1}}{(2j-1)\pi\lambda_j^2}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\left(\frac{1}{\lambda_j}-\bar{h}_1\right)\right\}\frac{\sin(\lambda_j\bar{w})}{\lambda_j} \tag{16c}$$

$$\bar{q}_2^{\mathrm{P}} = 2\int_0^{\bar{h}_2}\int_0^{\bar{w}}\bar{u}_2^{\mathrm{P}}(\bar{y},\bar{z})\,\mathrm{d}\bar{y}\,\mathrm{d}\bar{z} = 2\sum_{j=1}^{\infty}\left\{\left[1-\frac{1}{\cosh(\lambda_j\bar{h}_2)}\right]\frac{b2_j^{\mathrm{P}}}{\lambda_j} + \frac{4\mathrm{Re}(-1)^{j+1}}{(2j-1)\beta\pi\lambda_j^2}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\left(\frac{1}{\lambda_j}-\bar{h}_2\right)\right\}\frac{\sin(\lambda_j\bar{w})}{\lambda_j} \tag{16d}$$

where

$$
\begin{aligned}
\Phi_j^I(\bar{y}) = &\frac{-4\mathrm{Re}G_x\bar{\zeta}_1(-1)^{j+1}\cosh\left(B_j\bar{y}\right)}{(2j-1)\pi\left(\lambda_j^2-B_j^2\right)\sinh\left(B_j\bar{h}_1\right)B_j} \\
&+\frac{4\mathrm{Re}G_x\bar{\zeta}_3(-1)^{j+1}\cosh\left[B_j\left(\bar{h}_1-\bar{y}\right)\right]}{(2j-1)\pi\left(\lambda_j^2-B_j^2\right)\sinh\left(B_j\bar{h}_1\right)} \\
&+\sum_{p=1}^{\infty}\left\{4\mathrm{Re}G_x\bar{\zeta}_2\left[1+(-1)^{p+1}\right]\right. \\
&\left.\times\frac{\lambda_j\bar{h}_1(-1)^{j+1}\cos\left(p\pi\bar{y}/\bar{h}_1\right)}{p^2\pi^2\bar{w}\left(\lambda_j^2+A_p^2\right)\left[\left(p\pi/\bar{h}_1\right)^2+\lambda_j^2\right]}\right\}
\end{aligned}
$$

We define the holdup of the conducting fluid, α, as the ratio of the area occupied by the conducting fluid to the whole area of the cross-section of the channel. As a planar interface between the two liquids is assumed, the holdup is given by $\alpha = |h_1| / \left(|h_1| + |h_2|\right)$. Furthermore, if a reference length scale L is taken as the height of the channel, holdup α is the absolute value of h_1. From Eq. (16) the flow rates of the two liquids are a function of the holdup and the pressure gradient:

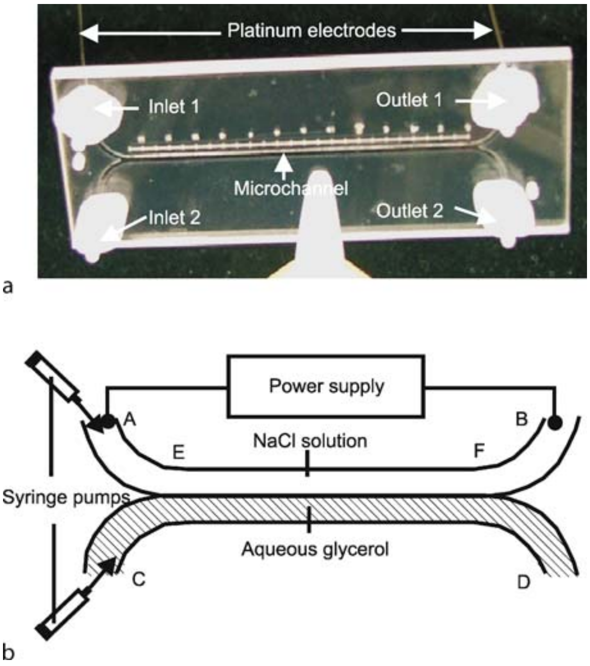
$$
\begin{cases}
\bar{q}_1 = q_1\left(\alpha, \dfrac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\right) \\
\bar{q}_2 = q_2\left(\alpha, \dfrac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}}\right) .
\end{cases}
\tag{17}
$$

If the flow rate conditions are specified, the system of equations can be solved. In this work, the holdup and pressure gradient are obtained by the Newton–Raphson method.

To investigate the relative importance of the electric force to the pressure gradient on the liquids, a new parameter S_R is defined as $S_\mathrm{R} = \mathrm{Re}G_x\bar{\zeta}_2/K$. Substituting Eq. (7) into Eq. (8) yields

$$
\nabla^2\bar{u}_1 = \mathrm{Re}\frac{\mathrm{d}\bar{p}}{\mathrm{d}\bar{x}} + \mathrm{Re}G_x\bar{\psi}\left(\bar{z},\bar{y}\right) \tag{18}
$$

In Eq. (18) the pressure gradient is uniform across the channel while the electroosmotic force is concentrated in the EDL regions close to the walls of the channel. $1/K$ is the dimensionless thickness of the EDL region. Figure 3 shows the meaning of S_R. The parameter S_R appears as apparent uniform forces acting on the liquid across the channel.

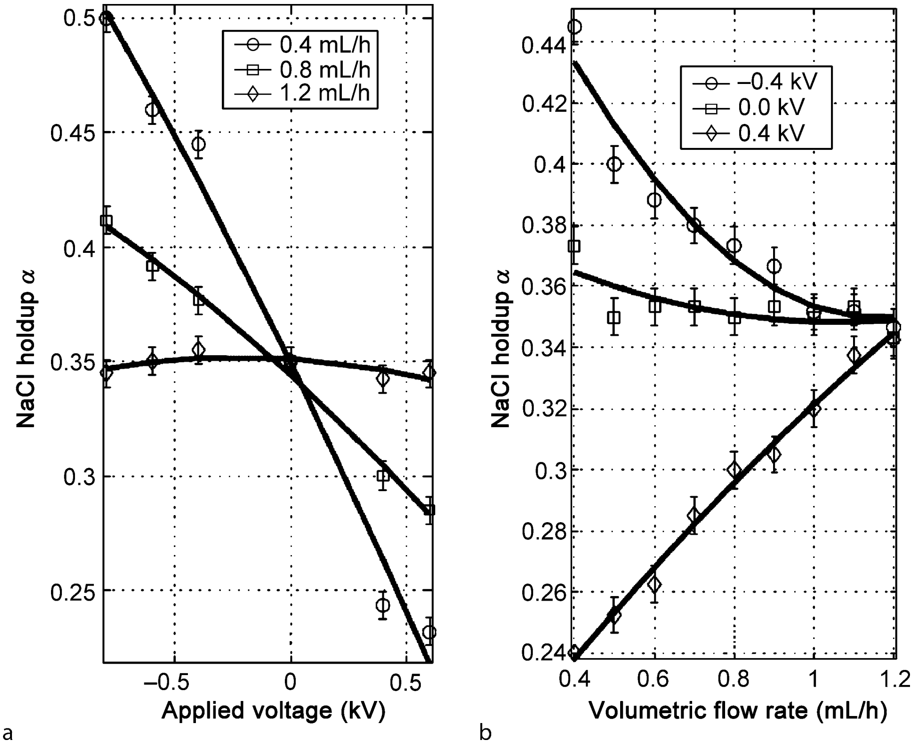


Liquid–Liquid Stratified Flow in Microchannels, Figure 4 The fabricated H-shaped microfluidic device used in the experiment

Experiment

The H-shaped microchannel used in the experiments is shown in Fig. 4. The fabrication is based on the adhesive lamination techniques. In this method, two polymethylmethacrylate (PMMA) plates ($75\,\mathrm{mm} \times 25\,\mathrm{mm}$) were bonded by a layer or layers of double-sided adhesive tapes to form a closed microfluidic channel with inlet and outlet holes. The channel structure was cut through the adhesive tape (Arclad 8102 transfer adhesive, Adhesives Research Inc.). Thus the adhesive tapes define the depth of the channel. The two liquids flow side by side in the straight microchannel in the direction from left to right from the syringe pump. The two liquids are introduced from inlet 1 and inlet 2; outlet 1 and outlet 2 are for collection of the products or wastes. Across the microchannel, platinum electrodes (Aldrich-Sigma, Singapore) were inserted for the application of the electric field.

The measurement setup can be used for both fluorescence imaging and microparticle image velocimetry (micro-PIV) measurements [6]. It consists of four main components: an illumination system, an optical system, a charge coupled device (CCD) camera and a control system. The control system, consisting of a peripheral component interface (PCI) card and its corresponding software, is implemented in a personal computer (PC). The PC can control and synchronize all actions related to illumination and



a b

Liquid–Liquid Stratified Flow in Microchannels, Figure 5 Relationship between NaCl solution holdup and (**a**) different applied voltage for the same volumetric flow rates of the two liquids or (**b**) volumetric flow rate under the same applied voltage

image recording. Two different light sources were used for the two measurements. For the fluorescence imaging measurements, a single mercury lamp was used for illumination. Because of the ability of precise timing and intensity control, a double-pulsed Q-switched (quality switched) Nd:YAG laser beam was used for the micro-PIV measurements. The optical system was a Nikon inverted microscope (model ECLIPSE TE2000-S) with a set of epifluorescent attachments. There are three optical elements in a filter cube: excitation filter, dichroic mirror and emission filter. Emission filters are used in both measurements to select more specifically the emission wavelength of the sample and to remove traces of excitation light. An interline transfer CCD camera (Sony ICX 084) was used for recording of the images.

Aqueous NaCl solution (concentration 7×10^{-4} M) and aqueous glycerol (volume concentration 14%) were introduced at inlets A and C through syringes (500 μl gastight, Hamilton) and syringe pump (Cole-Parmer, 74900-05, 0.2 to 500 μl/h, accuracy of 0.5%) system. The same volumetric flow rates of the two inlet flows were ensured by using two identical syringes driven by the syringe pump. Fluorescent dye (fluorescein disodium salt $C_{20}H_{10}Na_2O_5$, also called Acid Yellow 73) was added in the NaCl solution in the fluorescence imaging experiment to determine the interface location. In the micro-PIV measurement, the seeding particles used were Duke red particles (Duke Scientific Co.). The particles have a maximum excitation wavelength of 540 nm (green, very close to the characteristic wavelength of Nd:YAG laser) and a maximum emission wavelength of 610 nm (red). The diameter of the particles can be chosen from several hundreds of nanometers to several micrometers. The PIV measurement uses an epifluorescent attachment of type Nikon G-2E/C (excitation filter for 540 nm, dichroic mirror for 565 nm and an emission filter for 605 nm). Both filters in the attachment have a bandwidth of 25 nm.

Key Research Findings

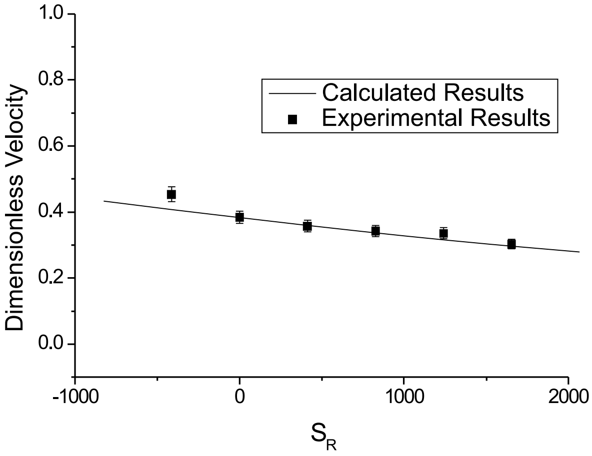
Liquid–Liquid Interface Position

As shown in Fig. 5a, as the electric field changes in magnitude and direction, the holdup of NaCl solution changes accordingly. When no voltage is applied across the microchannel, the flow is simply a pressure-driven two-fluid flow. The aqueous glycerol used is more viscous than NaCl solution, by about 1.5 times. The less viscous NaCl solution occupies a smaller portion of the chan-

nel under pressure-driven condition. The holdup value is about 0.35 when no externally applied voltage is present, as shown in Fig. 5a. When a negative electric field is applied across the microchannel (A is negative, B is positive), the holdup of NaCl solution increases. The electroosmotic flow is against the pressure-driven flow under a negative electric field. More resistance force will be encountered to drive the NaCl solution. Apparently, the NaCl solution becomes more "viscous" due to the electroosmotic effect, thus occupying a larger channel width. The holdup of NaCl solution increases with the increase of negative electric field. Due to the same pressure drop across the microchannel, in order to achieve the same volumetric flow rates, the more viscous fluid has to spread to a larger width, i. e. a higher liquid holdup. In another case where the positive electric field is applied (A is positive, B is negative), the NaCl electrolyte solution apparently possesses a lower "viscosity", since the electroosmotic flow is in the same direction as the pressure-driven flow. In other words, the electroosmotic effect aids the flow of the NaCl solution.

Figure 5a also shows that, as the inlet volumetric flow rates of the two liquids increase, the electroosmotic flow effect on the pressure-driven flow becomes weaker. At a flow rate of 1.2 ml/h, it seems that the holdup, α, of NaCl remains constant, although the voltage varies from -0.8 to 0.6 kV. For a typical electroosmotic flow, in which an electric field of hundreds of volts per centimeter is applied, the resulting velocity is of the order of 0.1 to a few millimeters per second. But for the pressure-driven flow in microchannels, the velocity can be controlled in a wider range. In this experiment, when the flow rate is at 0.4 ml/h, the average velocity of NaCl through the channel is 3.48 mm/s with no external applied electric field, the magnitude of which is comparable with that from the electroosmotic flow. Figure 5a shows that, by adjusting the electric field, the interface position between the two liquids, i. e. variation of the NaCl holdup, α, from 0.25 to 0.50, has been successfully controlled.

The relationship between the NaCl holdup, α, at different flow rates under the fixed electric field is shown in Fig. 5b. The NaCl holdup remains the same (0.35) for different volumetric flow rates in the absence of an externally applied electric field. This is because the volumetric flow rate ratio between the two liquids is kept unchanged at 1 : 1. This agrees very well with the previous theoretical and numerical study reported in the literature. From Fig. 5b, it can be seen that, as the flow rate increases, holdup α converges to a constant value, 0.35; that is, the value without the externally applied electric field. The reason is that larger pressure-driven flow velocity makes the electroosmotic flow effect almost insignificant.



Liquid–Liquid Stratified Flow in Microchannels, Figure 6 Comparison of the holdup of the conducting liquid between calculated and experimental results; $q_1 = q_2 = 0.05$ ml/h

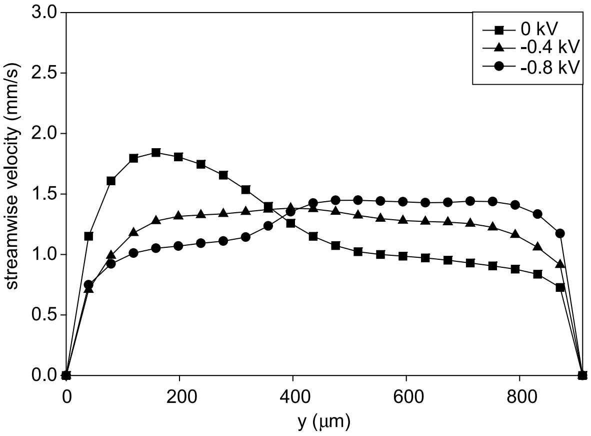
Figure 6 shows a comparison between the analytical results and the experimental results of the interface positions for different applied electric fields. In calculations, the reference velocity $V = 1.13 \times 10^{-3}$ m/s and the reference length $L = 910$ µm. The viscosity of NaCl solution and aqueous glycerol is 1.12 and 1.8 Ns/m^2, respectively. Under these conditions, the dimensionless flow rate is 0.0148 for 0.05 ml/h.

Velocity Profile

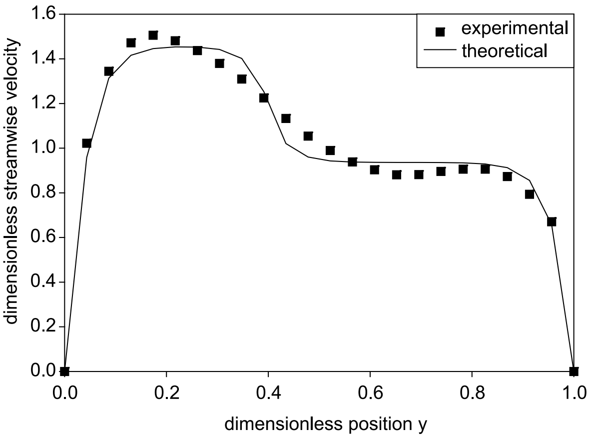
The micro-PIV measurement reported in this experiment was carried out with a ×4 objective lens. With a CCD sensor size of 6.3 mm × 4.8 mm, the size of an image pixel is 2.475 µm and the size of the measured area is 1584 µm × 1188 µm. Fluorescent particles with a diameter of 3 µm were used to trace the flow. A microchannel with cross-section of 910 µm × 50 µm and length of 5 mm was used. The liquids used in the experiment were aqueous NaCl solution (concentration 10^{-4} M) and aqueous glycerol (volume concentration 24%). The integration area was 32 px × 32 px. Previous studies show that the entry length of two-liquid flow in a microchannel is very short [7]. The measurement was taken at 1 mm downstream of the entrance; thus a stable velocity field was obtained.

The total measured velocity of the fluorescent tracing particles is a superposition of the electroosmotic, pressure-driven and electrophoretic and Brownian motion velocity components [8]. It can be expressed as

$$u_{\text{particle}} = u_{\text{eof}} + u_{\text{pressure}} + u_{\text{eph}} + u_{\text{b}} \tag{19}$$



Liquid–Liquid Stratified Flow in Microchannels, Figure 7 Velocity profile under different applied voltage (flow rate = 0.1 ml/h; NaCl on left side, glycerol on right side)



Liquid–Liquid Stratified Flow in Microchannels, Figure 8 Comparison between PIV measurement and theoretical analysis at flow rate of 0.1 ml/h, under applied electric voltage of − 0.2 kV

where u_{eph} is the electrophoresis velocity of the tracing particle and u_{b} is the velocity due to Brownian motion of the particle. The electrophoresis velocity is a function of the particle's surface zeta potential in the solution [5], expressed as

$$u_{\mathrm{eph}} = \frac{\varepsilon E_x \zeta_{\mathrm{p}}}{\mu} \tag{20}$$

where ζ_{p} is the particle's surface zeta potential, and ε and μ are the permittivity and the dynamic viscosity of the fluid. In this experiment, the particle's zeta potential was measured as $-25.2\,\mathrm{mV}$. From Einstein's Brownian movement equation, the average Brownian velocity during the time elapsed between two subsequent images can be estimated as

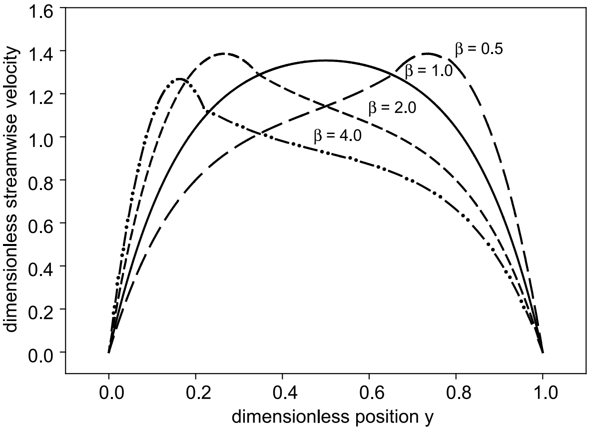
$$u_{\mathrm{b}} = \sqrt{\frac{2D}{\Delta t}} \tag{21}$$

where Δt is the elapsed time duration and D is the diffusivity of the particles. The diffusivity is given by

$$D = \frac{\mathrm{k_B} T}{3\pi \mu d_{\mathrm{p}}} \tag{22}$$

where T is the absolute temperature, $\mathrm{k_B}$ is Boltzmann's constant and d_{p} is the particle diameter.

The effect of the applied voltage on the velocity profile is shown in Fig. 7. Without the externally applied voltage, the NaCl (on the left side in Fig. 7) flows faster. When a negative electric field is present, the velocity of NaCl decreases whereas the velocity of aqueous glycerol increases. It is noted that as the applied voltage is set to $-0.4\,\mathrm{kV}$, both liquids achieve about the same velocity,

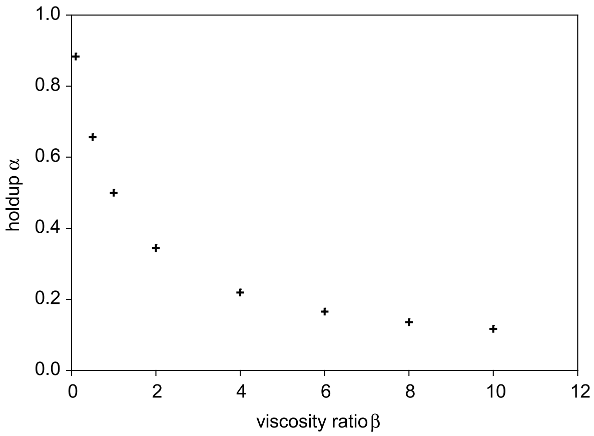


Liquid–Liquid Stratified Flow in Microchannels, Figure 9 Dimensionless velocity profile for different viscosity ratios

and hence the same average residence time. If the applied voltage continues to increase to $-0.8\,\mathrm{kV}$, the NaCl flows at smaller velocity and spreads more in the channel. As the magnitude of the applied voltage increases, the interface position shift increases. This is in agreement with the fluorescent experiment observation.

A comparison between experiment and theoretical analysis under an applied electric field of $-0.2\,\mathrm{kV}$ is shown in Fig 8. Reasonable agreement is obtained. In the theoretical prediction, a relatively sharp transverse velocity gradient occurs at the interface as the model assumes two immiscible liquids. In fact, glycerol is miscible in water; therefore, there exists an interfacial region in the measured velocity profiles.

Our theoretical model considers both the pressure gradient and electroosmosis. If there is no electroosmosis effect



Liquid–Liquid Stratified Flow in Microchannels, Figure 10 Holdup for different viscosity ratios

involved, such as in the case where no external electric field is applied, the theoretical model reduces to a simple pressure-driven flow. In Fig. 9, the dimensionless velocity profile for different liquid viscosity ratios is shown. When the viscosity ratio equals 1, the two-liquid flow is in fact a pressure-driven flow of a single liquid, showing a parabolic velocity profile. The holdup for different viscosity ratios is shown in Fig. 10. The values of viscosity ratio in the figure are 0.1, 0.5, 1.0, 2.0, 4.0, 6.0, 8.0 and 10.0. We note that for two-liquid flow under only pressured gradient the holdup does not depend on the flow rate. It only depends on the viscosity ratio between the two liquids.

Future Directions for Research

The interface position and velocity profile of liquid–liquid stratified flow in microchannels can be controlled using the electroosmosis effect, which can retard or aid the flow of one liquid. The experiment demonstrated a new method to solve the unmatched viscosity problem of liquid–liquid flow in diffusion-based microfluidic applications. Other potential uses include development of flow switching or flow focusing for multi-liquid flow in microfluidics.

Local Filtering

Definition

In image processing local filtering is used to increase the quality of an image. As a wanted result the image is smoothed and noise is removed. Typical local filters are ►mean filter, ►low-pass filter, ►Gaussian filter, and ►median filter. Local averaging causes loss of spatial information.

Low-Frequency Capacitance

► Shunt Capacitance

Low-Pass Filtering

Definition

When a low-pass filter is used high frequencies are attenuated while low frequencies pass through. An image which is low-pass filtered appears smoothed.

Ludwig–Soret Effect

► Thermophoresis

Luminescence

Definition

Luminescence is the emission of light from any substance occurring when an electron returns from an electronically excited state to ground state. Luminescence can be caused by a number of factors, most commonly chemical or biochemical changes, electrical energy or subatomic motions. There are two main categories of luminescence, fluorescence and phosphorescence and these are dependent on the nature of the excited state.

Definition

Magnetic fields are used to manipulate or organize magnetic materials for Lab-on-Chip applications.

Overview

The use of ►magnetic fields for Lab-on-Chip applications has become very common over the past few years. Indeed, a great deal of research in microfluidics has been focused on developing not only magnetic-field based Lab-on-chips for biological or chemical applications, but also microfluidic actuators. The first class of these Lab-on-chips, as is often the case in microfluidics, consisted of a direct downscaling of existing methods for biological or chemical sample handling through the use of ►magnetic microbeads. More recently, the use of magnetic fields in microfluidics has been extended to devise mixers, sorters

or on-chip detection systems. Magnets and magnetic coils can now be fabricated on the micrometer scale and be directly integrated in the chip. Therefore, this makes magnetic-field based Lab-on-Chip an exciting topic that we will review in this entry.

Generalities on Magnetism

Magnetic fields can be created by permanent ▶magnets or ▶magnetic coils and be used to apply global forces or organize different materials. The magnetic properties of a material are characterized by its ▶magnetic susceptibility χ. It represents the degree of magnetization M of a material in response to an applied magnetic field $\boldsymbol{B}$:

$$\boldsymbol{M} = \chi \boldsymbol{B} \tag{1}$$

The magnetic susceptibility can be negative, in which case the field will repel the material; a positive χ stands for a material that is attracted by the field. As summarized in Table 1, among the values of χ, three main classes of magnetism are distinguished:

- Diamagnetic materials have a very weak susceptibility and are thus often simply considered as non-magnetic.
- Paramagnetic materials become magnetic under an external field and are then attracted by the field. This mechanism is reversible, meaning that when the external field is turned off, the material loses its magnetic properties.
- Finally, ferromagnetic materials become magnetic under an external field, identical to paramagnetic materials, but with a much higher susceptibility. Also, when the field is turned off, the material remains magnetic and produces a magnetic field called remanence.

Upon the application of an external magnetic field $\boldsymbol{B}$ a magnetic particle gets magnetized and is submitted to a force $\boldsymbol{F}$:

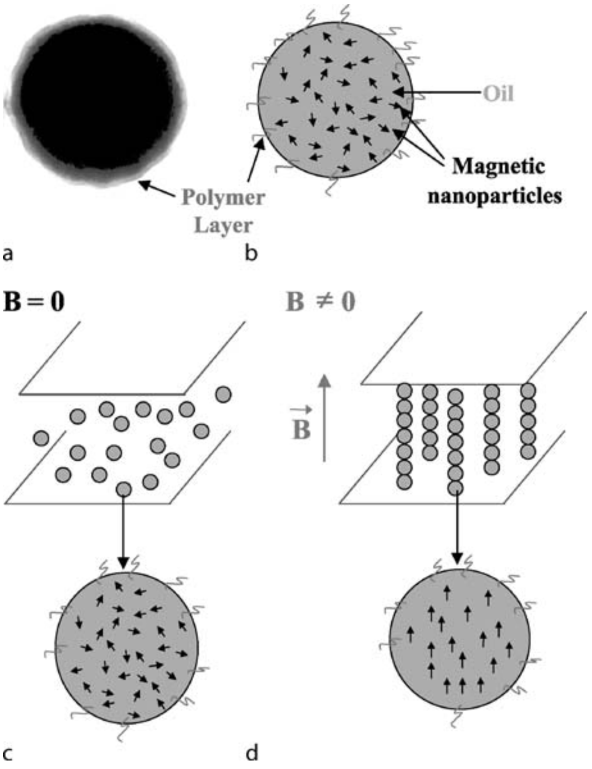
$$\boldsymbol{F} = \frac{V(\chi - \chi_{\mathrm{m}})}{\mu_0}(\boldsymbol{B}.\nabla)\boldsymbol{B} \tag{2}$$

In this equation, V represents the volume of the particle, χ its magnetic susceptibility, χ_{m} the susceptibility of the surrounding medium and μ_0 the magnetic permeability of the vacuum. Following formula (2), one may notice that in a homogeneous field the particle is magnetized, but the force is zero. Only a magnetic field gradient produces a force on the particle, and it results in a translational movement of the particle toward the maxima of the field.

Magnetic Beads

Magnetic particles are certainly the most useful tools of magnetic fields for Lab-on-Chip applications. They have embedded magnetic entities and thus can be manipulated at relatively long distances using permanent magnets or electromagnets. The effort that has been put into the development of these particles has turned them into a very strong tool for biomedical applications. Mainly any biological component (cell, DNA, proteins, antibody, etc…) or chemical can be very specifically attached to the particles. They can scale from 100 nm up to 100 μm and can be fabricated in a highly monodisperse manner. They are now used in numerous biomedical applications and provide a day-to-day tool for biologists.

As illustrated in Fig. 1b, these beads are suspensions of ferrofluids embedded in a polymer shell. The ferrofluid is made of nanometric particles of magnetic oxide (usually magnemite Fe_3O_4 or maghemite γ-Fe_2O_3) dispersed in organic oil. The concentration of magnetic entities in each bead is very high and thus they have magnetic susceptibilities typical of ferromagnetism [1–10]. Nevertheless, when the external field is turned off, the strong thermal agitation at the level of the nanoparticle redistributes the direction of the magnetic moments of these particles and the global magnetization of the bead returns to 0. Thus, the



Magnetic Field-Based Lab-on-Chip Devices, Figure 1 Magnetic beads: (**a**) Electron micrograph of a magnetic bead. (**b**) Schematic representation of a magnetic bead. (**c**) and (**d**) Self-organization of magnetic beads in a confined space

Magnetic Field-Based Lab-on-Chip Devices, Table 1 Classification of the magnetism of matter

Type of Magnetism	Examples of materials	Sign of χ	Typical values of χ
Diamagnetism	Water, DNA, cells, plastic, gold	$-$	-10^{-6} to -10^{-4}
Paramagnetism	Aluminium, platinium, oxygen, calcium	+	10^{-5} to 10^{-3}
Ferromagnetism	Iron, Nickel, Magnetite (Fe_3O_4)	+	1 to 10^5

bead, whilst being strongly magnetic, conserves the property of reversibility of the paramagnetism. This particular and valuable property is called ► superparamagnetism.

Another remarkable property of magnetic particles is their ability to self-organize under an external magnetic field. As mentioned above, when a magnetic field is applied, each bead becomes magnetized and behaves as a magnetic dipole pointing in the direction of the field. The resulting dipole–dipole attraction between beads will lead to the formation of chains parallel to the field. Furthermore, when the suspension is confined in the direction of the field (in a microchannel, for example) the chains have a size equal to the height of the channel. Lateral dipolar isotropic repulsions between chains lead to the formation of a hexagonal array of these chains in the plane perpendicular to the field (see Figs. 2c and 2d). When the concentration of beads is too high, the order is lost and the array adopts a "labyrinth-like" structure. These structures are generally called supra-particle structures (SPS).

Basic Methodology

Applying a Magnetic Field in a Microfluidic Channel

Depending on the type of application, one may choose to use either permanent magnets or magnetic coils to apply the magnetic field. They can consist of conventional large-scale objects simply placed in the vicinity of the microchannels or be microfabricated and directly integrated in the chip.

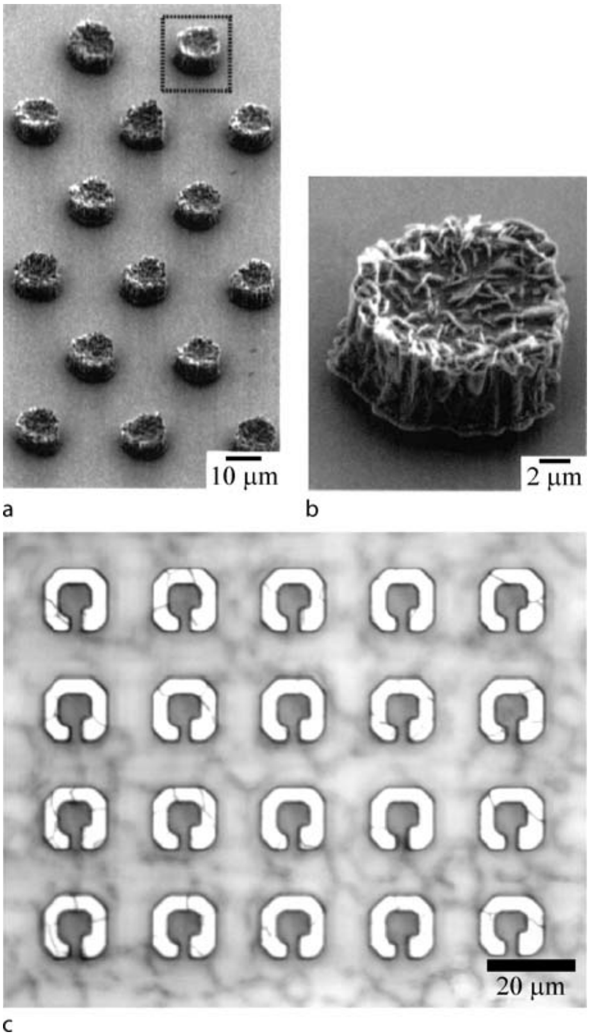
Permanent magnets would preferably be used for creating strong local gradients (and thus apply a force) in order to attract and/or immobilize magnetic material to one side of a channel. Combinations of magnets placed in certain geometries can also create precise gradients across or along a microchannel. These magnets are usually made of rare-earth alloys, the most common being the Neodymium iron boron (NdFeB) magnets. They are relatively affordable and can be fabricated in a wide variety of shapes (down to sizes of a fraction of a millimeter) and produce fields ranging from 0.1 T to 1 T at their surfaces. The use of magnetic coils, less popular than permanent magnets, allows for the creation of very uniform fields at the scale of the channel. They can also be used for the creation of a local gradient when combined with tapered magnetic cores. The field can easily be switched on and off, tuned in strength or even alternated through the control of the current in the coil. Compared to permanent magnets, they are much more expensive and the magnitude of the field they produce is limited by Joule heating, hardly reaching 50 mT.

At the microscale level, permanent magnets can be fabricated using standard lithography methods. Briefly, layers of magnetic metals are first deposited on a substrate by either sputtering, electroplating or vapor deposition. Then, lithography followed by etching and lift-off techniques allow for the creation of the desired patterns [1]. This has, for example, been used to design magnetic posts (see Figs. 2a and 2b) [2] or stripes in a microfluidic channel [3]. As an innovative alternative, Psychari et al. stamped ferrofluid spots on the surface of a microchannel. When an external uniform field is applied they behave as micromagnets [4]. A more complex process allows for the creation of miniaturized electromagnets: Microwires made of a conductive metal such as copper or gold are first patterned in spiral-like shapes on the substrate. Then, one has to address both the proper insulation of the wires and connection to an external control of the current. This method has recently been used to devise an array of magnetic microcoils (see Fig. 2c) [5]. Each microcoil has a width of 10 μm, produces a field of 1.5 mT and can be independently manipulated using an integrated circuit. Finally, devising microcoils also allows for the conception of micro NMR spectroscopy systems that permit the elucidation of chemical molecular structures while consuming a small amount of the chemical.

Use of Magnetic Beads as Solid Phases in Heterogeneous Assays

The most straightforward application of magnetic fields for microfluidics is the use of magnetic beads as a solid phase in a heterogeneous assay. This method is in fact a direct downscaling of a technique used very commonly in biology laboratories. In the first step, chemicals or

M



Magnetic Field-Based Lab-on-Chip Devices, Figure 2 Microfabricated magnets and magnetic coils: (**a**) Array of paramagnetic posts made in Ni in a microchannel. (**b**) Same post at a higher magnification [2]. (**c**) Array of micro-magnetic coils in a microchannel [5]

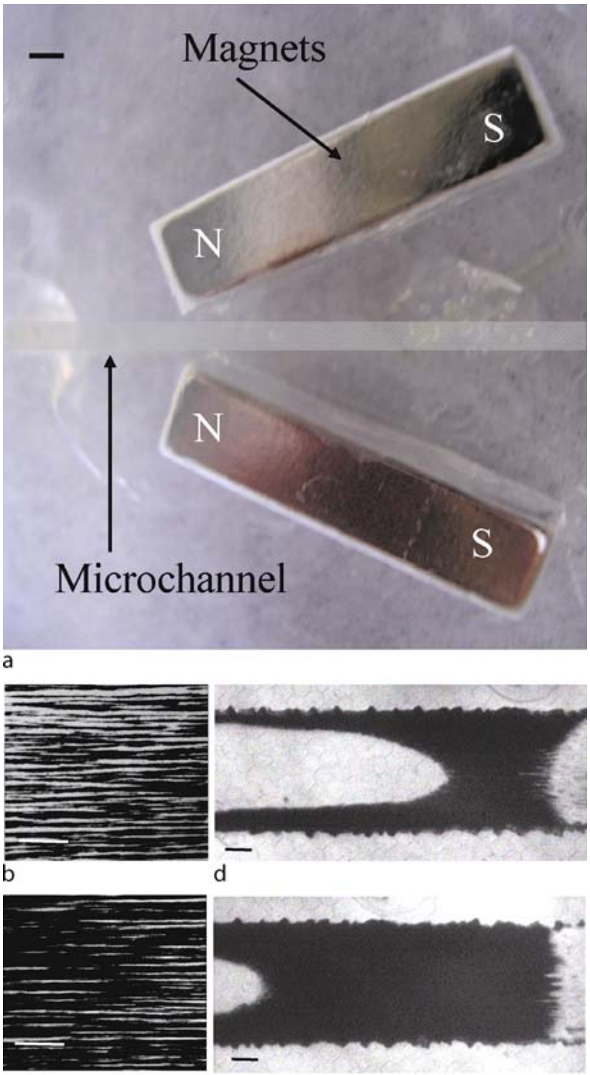
biomolecules are grafted onto magnetic beads. Then the beads are introduced into a microchannel and immobilized by one magnet, a pair of magnets or a magnetic coil placed in the vicinity of the channel [6]. The reactants (the mobile phase) are flowed through the immobilized plug of beads (the solid or stationary phase) and reaction occurs between the two phases. The high surface to volume ratio of the beads leads to a high density of binding sites and the compaction of the beads in the plug strongly decreases the diffusion time for the reactants to react with the solid phase. In addition to the reduction of the reaction time, this method keeps the two phases separated and thus avoids contamination from one phase to the other. Finally, by turning off the field, the beads can be washed out of the channel and stored for further use.

The high compaction of the beads in the plug gives rise to a pressure increase in the microchannel. This often leads to local breakage of the magnetic structure and opens large channels in the plug. In those apertures, the biological substance in the mobile phase can travel fast without having the time to diffuse to the surface of the beads. One idea to overcome this problem is to self-organize the beads in the plug [7]. To that aim, the authors used a longitudinal magnetic field created by two magnets pointing in the same direction and making a small angle (20°) with the channel (see Fig. 3a). At the beginning of the immobilization, magnetic particles self-organize in chain-like columns along the channel direction (Figs. 3b and 3c). When the concentration of beads increases, the plug becomes opaque, probably due to the formation of a "labyrinth-like" structure made of tortuous and ramified "walls" with one direction colinear to the field (Figs. 3d and 3e). The distance between the walls is maintained by dipole–dipole repulsion, keeping in the bulk of the plug channels colinear to the flow, with a thickness of a few micrometers. This structure has a low-hydrodynamic resistance and maintains an appropriate pore size well adapted for most biological molecules.

The use of magnetic beads as solid phases for bioassay has been widely used, and examples of biological applications include immunoassays, DNA or RNA hybridization, protein digestion or cell analysis [1]. As a typical example, Fig. 4 depicts a micro-immunoassay based on this method [8]. An immunoassay is a biochemical test that measures the level of a substance (virus, protein, etc...) in a biological liquid, using the reaction of an antibody to the substance also called antigen. In this example, a plug of beads coated with an antibody is immobilized on the side of a microchannel. A corresponding antigen is subsequently flowed through the channel and the small diffusion time allows for a fast and efficient binding of the antigen to the antibody attached on the bead. A second, fluorescently labeled antibody is then injected and binds to the antigen immobilized in the plug. A calibrated fluorescent detection finally allows for the precise measurement of very small concentrations of the antigen (down to 1 μg/l).

Application of Self-Organized Supraparticle Structures

The self-organization of magnetic beads introduced earlier has also been used for Lab-on-Chip application. The perhaps most well-known sets of experiments use an array of self-organized magnetic columns identical to the one represented in Fig. 2d as a matrix of obstacles for DNA electrophoresis [9]. DNA electrophoresis allows for separat-



Magnetic Field-Based Lab-on-Chip Devices, Figure 3 Use of self-organization for a heterogeneous bioassay. (**a**) Microchannels with magnets on the side (the bar is 1mm long). (**b**)-(**e**) Resulting self-organization of magnetic chains parallel to the flow direction (bars are 100 μm long)

(**a**) Molecules successively attached to the beads: Grafting of the first antibody; antigen attached to this antibody; second labeled antibody attached to the antigen. (**b**) Magnets on the side of the channel and complete set-up for observation. (**c**) At a relative slow flow-rate molecule can diffuse to the beads

ing DNA fragments by size. Its use is ubiquitous in many types of biological analysis. DNA (charged molecule) is mobilized by an applied electric field into a matrix of obstacles (most commonly an agarose gel). Basically, the bigger the DNA, the longer it takes for it to go through the maze of obstacles. This process gives rise to separation. In this example, the self-organized columns of magnetic beads serve as posts on which the DNA molecules will collide and remain stuck for a certain time that scales with the size of the fragment. Therefore, the array serves as the matrix to achieve the separation. The properties of the array can be tuned by changing the concentration of the beads allowing for optimization of the separation device. By stamping spots of ferrofluids on the channel surface, the same group recently demonstrated the possibility of guiding the self-organization of the matrix onto these spots [4]. This has been used to create a very dilute array of large columns strongly anchored to the magnetic spots and has been applied to the sorting of rare cells in a heterogeneous population. To that aim, antibodies specific to surface proteins of one cell kind are first grafted onto the beads. When a mixture of cells is then flowed through the array of columns, the specific cells remain stuck on the columns while the rest flow through the array.

Mixing Enhancement

Mixing (or lack thereof) is often crucial to the effective functioning of microfluidic devices and hence a lot of innovative systems have been developed for this technique. Magnetic fields can also be employed for these applications [1]. Most of the devices consist of a direct downscaling of the conventional bench magnetic stirrer. Some groups microfabricated magnetic rotors and directly integrated them in a microchannel. The rotors were simply actuated by a bench stirrer plate. Another group used assembled chains of magnetic beads as micro-stirrers in the channel. Finally, the alternated self-organization

and disorganization of magnetic supra-particle structures appeared to be a very efficient way of mixing in the microchannels [6].

Sorting with Magnetic Fields

As mentioned previously, when submitted to a field gradient, magnetic beads are submitted to a force (see Eq. (2)). They thus move in the direction of the field maxima and are submitted to the viscous drag:

$$\boldsymbol{F}_{\mathrm{d}} = 6\pi\eta r\boldsymbol{v} \tag{3}$$

In this expression, η represents the viscosity of water, r the radius of the particle and $\boldsymbol{v}$ its velocity. Combining Eqs. (2) and (3), we define and calculate the magnetophoretic mobility ξ as follows:

$$\xi = \frac{\|\boldsymbol{v}\|}{\|(\boldsymbol{B}.\nabla)\boldsymbol{B}\|} = \frac{2r^2\chi}{9\eta} \tag{4}$$

This quantity represents how easily the particle can be magnetically mobilized. According to this expression, at fixed susceptibility and field, bigger beads will move faster than smaller beads, and this allows for separating either magnetic beads or biological samples attached to beads. This phenomenon, called magnetophoresis, has for example been used in a microfluidic device for sorting cells among their size [10]. As represented in Fig. 5a, the device is composed of 2 series of 16 channels converging into a separation chamber. A magnet is placed on one side of this chamber and deflects the trajectory of the beads exiting one of the channels. The deflection of the trajectory relies on Eq. (4), and the biggest magnetic particles are strongly deflected, exiting in one of the top channels. Alternatively, cells of different sizes are attached onto the same beads and sorted by the same principle (see Figs. 5b and 5c). However, in this case, the viscous drag is imposed by the cell and the bigger cells will be less deflected than the smaller ones.

In a second example, Inglis and coworkers developed a magnetic cell sorter based on an array of microfabricated magnetic stripes [3]. In this device, non-labeled cells and cells labeled with magnetic beads are mixed together and injected into the channel. The direction of the flow makes an angle of about 10° with the array of parallel stripes thus deflecting the labeled cells and giving rise to separation (see Fig. 6).

Magnetic Beads for Detection

Magnetic beads can also be used as labels for detection. This method involves the use of precise magnetic field detectors such as Giant magnetic resistance (GMR) or spin-valve sensors. Basically, these sensors are made of alternating layers of magnetic and non-magnetic conductive materials. When an external magnetic field (produced by beads for example) is applied, it induces a change in the resistance of the conductive layer that can be detected. These sensors are commonly used as read-heads in hard-disk drives. For Lab-on-Chip application, this process can again be used to detect biomolecules grafted on the beads. Some examples including DNA hybridization detection have been developed, but the technique has a limited resolution and no one has yet reported the detection of a single bead.

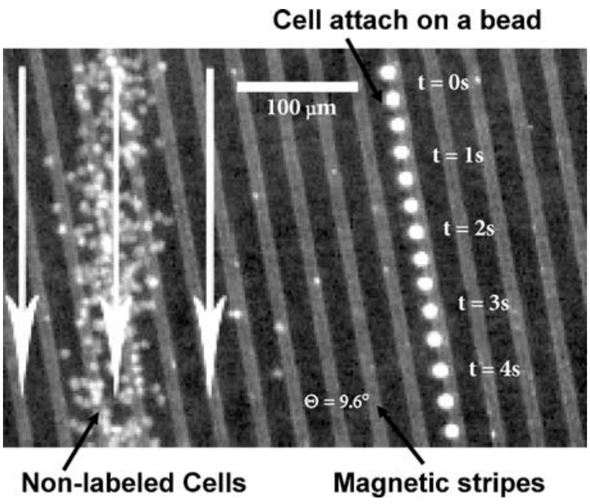
Key Research Findings

Interest in using magnetic fields for Lab-on-Chip applications has widely grown over the past decade. This has given rise to a large number of interesting devices that sometimes offer a lot of advantages as compared to their conventional counterparts.



Magnetic Field-Based Lab-on-Chip Devices, Figure 6 Magnetic fields for applications in sorting (based on [3]): Continuous cell sorting using magnetic stripes

One typical example stands in the heterogeneous bioassays. Miniaturizing this method offers many advantages and thus the optimization of the technique is crucial for further commercialization. Prior to using magnetic beads, several groups used non-magnetic glass beads immobilized between weirs in microchannels to create the solid phase of the assay. The use of magnetic beads, even if quite straightforward, appeared later. This has perhaps been a consequence of the aforementioned inhomogeneities in the immobilized structure created by the pressure drop. However, recent work improved the method and showed that a good reproducibility was achievable [7]. The miniaturization of the magnets and their direct integration in the chip should also offer new possibilities for improving those types of applications. Also, some devices are now appearing where several plugs of beads would allow for realizing more complex biological analysis.

Even if the mixing devices afford a convenient and efficient alternative, there is little chance that they will replace their conventional counterpart in the future. One of the main reasons is that, to date, they all involve the presence of stirrers (magnetic chains, magnetic sheets or microfabricated rotors) in the channel. Also, for the moment, the use of magnetic beads as labels for detection will not replace the use of fluorescent labels. On the other hand, the magnetic-based sorting systems are very competitive and should become an important tool in this field. The self-organization of beads has offered a great advantage in numerous applications. The ability to tune the order of the structure makes them a strong tool and further improvement and new applications should soon appear.

Finally, the use of magnetic fields has also been integrated in more complex Lab-on-Chip system to fulfill one of the steps of a complete biological analysis. Beads are, for example, used to trap and immobilize cells at the beginning of a complete genetic analysis that requires several steps (polymerase chain reaction, electrophoresis, etc. . .).

Future Directions for Research

Magnetic fields will take a growing place in the future of microfluidics. The miniaturization of the magnets and magnetic coils will soon replace the use of their large-scale counterparts, and most of the devices should soon have them integrated in the chip. The specific grafting of biomolecules onto magnetic beads still suffers from a great variability depending on the molecule. An effort in research has to be made to provide new methods or new beads that will facilitate this process. Finally, most of the work presented in this entry is still at the level of proof of principle. The reproducibility and reliability of these devices must be addressed before we see them integrated in commercial Lab-on-Chip.

Definition

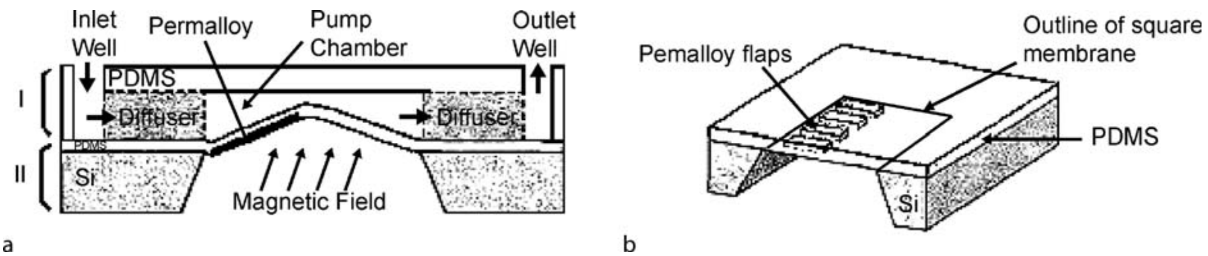
Magnetic pumps are pumps using electromagnetic or magnetic fields to actuate or to control the fluid motion in microchannels. The application of electromagnetic or magnetic forces is a flexible way of manipulating fluids in lab-on-a-chip devices.

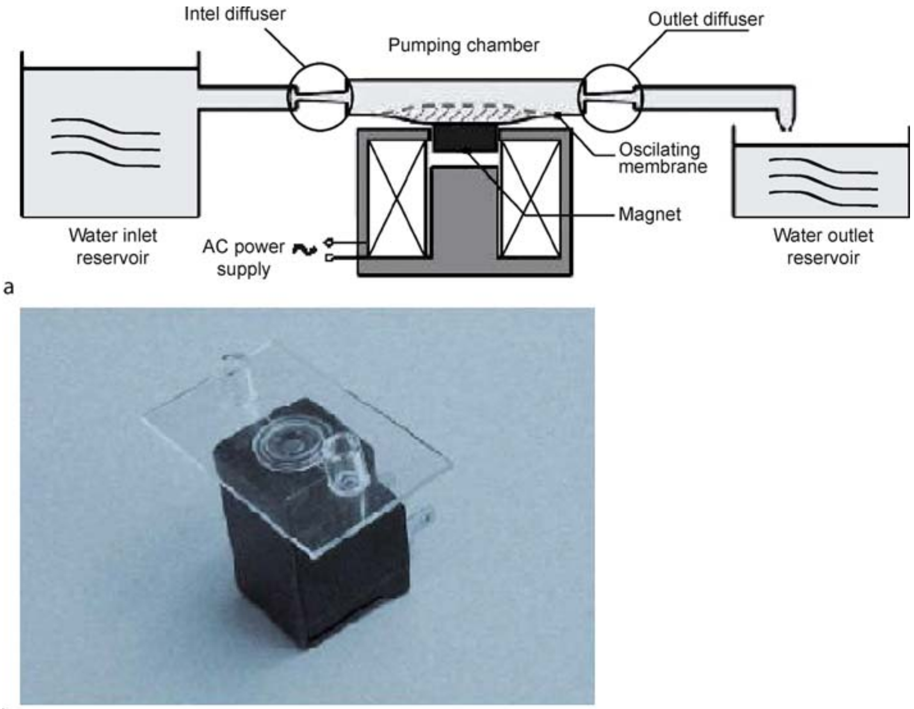
Overview

Micropumps can be classified into two general categories: mechanical and non-mechanical micropumps (an excellent review on micropumps can be found elsewhere [1]). In most mechanical pumps, a membrane is used to produce the pumping action. Non-mechanical micropumps on the other hand generally have no moving parts. Magnetic pumps can be found in both categories in the literature.

Khoo and Liu [2] presented results on the design, fabrication and testing of a novel, micromachined magnetic membrane microfluidic pump. Their pump was composed of a magnetic microactuator, which is based on a thin polydimethylsiloxane (PDMS) membrane, and two polymer-based one-way diffuser valves. Membrane displacement was achieved by the interaction of an external magnet (Fig. 1) with ferromagnetic materials which are embedded within the membrane. It was indicated that the flow rate of the micropump can be controlled by controlling the magnetic field strength and the actuation frequency of the membrane.



Magnetic Pumps, Figure 1 (**a**) Cross-section of assembled micropump and (**b**) schematic cut-out of membrane actuator. Reprinted from [2] with permission from Dr. Liu

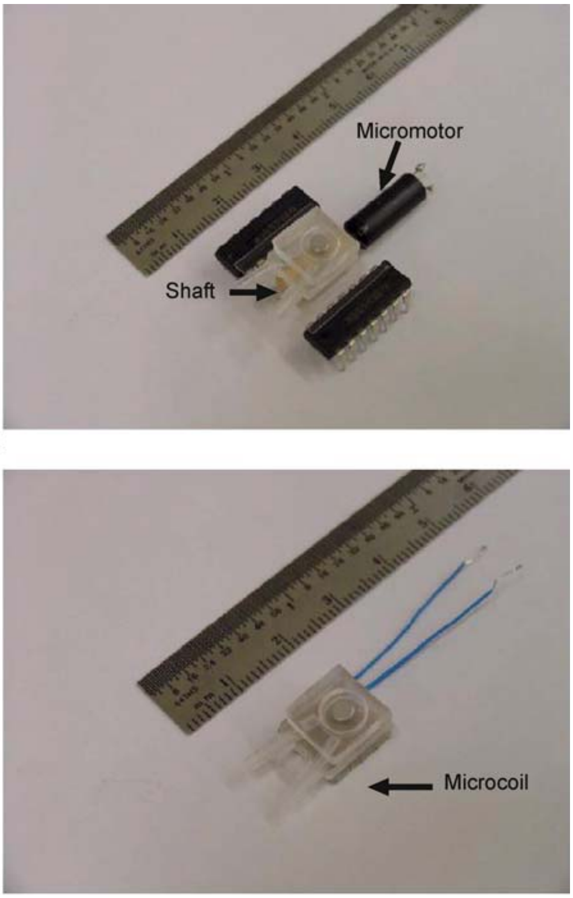


Magnetic Pumps, Figure 2 (**a**) Schematic and (**b**) photograph of micropump system of [4]. Reprinted from [4] with permission from Dr. Yamahata

Yamahata et al. [3] fabricated and characterized a poly(methyl methacrylate) (PMMA) valveless micropump which was actuated magnetically using an external electromagnet. The pump consisted of two diffuser elements and a PDMS membrane with an integrated composite magnet made of magnetic powder. They tested the setup with water and air. They relate the flow rate with the actuation frequency, and showed that frequency near to the natural frequency of the membrane generates higher flow rates due to the larger amplitude membrane vibrations. In their following study [4] (Fig. 2), they used glass instead of PMMA, and used a newly designed membrane, an improved actuation coil and a solid magnet rather than a polymer-bound powder magnet. They achieved four times larger pumping pressures compared to their PMMA-based pump.

Pan et al. [5] studied a magnetically driven PDMS membrane micropump with two ball check-valves (Fig. 3). Two driving mechanisms to generate the external magnetic force for the membrane were used: one used a permanent magnet with a small direct current (DC) motor and the other an integrated coil. They obtained higher flow rates with the latter mechanism but lower power consumption with the former mechanism.

Non-mechanical micropumps using the principle of magnetohydrodynamics (MHD) for fluid motion have also been studied in the literature. If an electrical field, $\boldsymbol{E}$, and



Magnetic Pumps, Figure 3 Test and measurement setup for two micropumps of different driving mechanisms: (**a**) permanent magnet with a small DC motor; (**b**) integrated coil. Reprinted from [5] with permission from Dr. Ziaie

a magnetic field, $\boldsymbol{B}$, are applied perpendicular each other they create a Lorenz force in the direction of $\boldsymbol{J} \times \boldsymbol{B}$, where $\boldsymbol{J}$ is the electrical current density. Since the mean free path of ions in a liquid is extremely small, momentum is transferred from the ions to the solvent molecules rapidly by collisions. Therefore, the sum of the Lorentz forces on all of the ions inside the liquid is just the net driving force causing the bulk liquid motion in MHD pumps. Jang and Lee [6] (Fig. 4), Huang et al. [7] and Zhong et al. [8] successfully applied the MHD principle for the development of micropumps using DC. The pressure head generated by MHD pumps can be controlled by adjusting the intensity of the magnetic field, the magnitude of the applied voltage across the electrodes and the length of the actuation section, which makes the usage of MHD pumps very flexible. However, all these micropumps suffer from bubble generation at certain voltage values at the electrodes that are used to generate the electrical field. Lemoff and Lee [9] used alternating current (AC) in their MHD micropump and eliminated bubble generation (Fig. 5). They used an electromagnet to generate the magnetic field. They showed that by using an electromagnet, multiple pumps can be driven independently by varying the amplitude and phase of the currents of electrodes and electromagnet.

Definition

Magnetophoresis, a nondestructive method for selectively collecting or separating magnetic particles, is the process of magnetic particle motion in a viscous medium under the influence of the magnetic field; the viscous medium may

be a magnetic or immunomagnetic liquid and the magnetic field should be in a gradient format.

Chemical and Physical Principles

The operating principle of the magnetophoresis is that the direction and velocity of the particle movement in a gradient magnetic field are determined by magnetic ($\boldsymbol{F}_{\mathrm{m}}$), gravitational ($\boldsymbol{F}_{\mathrm{g}}$), and drag ($\boldsymbol{F}_{\mathrm{d}}$) forces. By selectively controlling these forces, it is possible to control the mobility of the different species and, therefore, magnetically fractionate mixtures of them into discrete groups. If the analysis is limited to the motion of small particles, the inertial force can be neglected and the force balance equation is written as

$$\boldsymbol{F}_{\mathrm{m}} + \boldsymbol{F}_{\mathrm{g}} + \boldsymbol{F}_{\mathrm{d}} = 0 \tag{1}$$

Where (1)

$$\boldsymbol{F}_{\mathrm{m}} = \frac{4}{3\mu_0}\pi r^3 \Delta x\, |B|\, \nabla\, |\boldsymbol{B}| \tag{2a}$$

$$\boldsymbol{F}_{\mathrm{g}} = \frac{4}{3}\pi r^3 \left(\rho_{\mathrm{P}} - \rho_{\mathrm{f}}\right) \boldsymbol{g} \tag{2b}$$

$$\boldsymbol{F}_{\mathrm{d}} = 6\pi \eta r \boldsymbol{U} \tag{2c}$$

In Eqs. (2a)–(2c), r is the particle radius (m); Δx is the difference between the volume magnetic susceptibility of the particle and separation fluid; B is magnetic induction (Tesla); μ_0 ($= 4\pi \times 10^{-7}$ H/m) is the permeability of free space; ρ_{p} and ρ_{f} are the density of the particle and separation fluid, respectively (kg/m^3); η is the dynamic viscosity of separation fluid (kg/ms); and $\boldsymbol{U}$ is the particle migration velocity (m/s).
Inserting Eqs. (2a)–(2c) into Eq. (1), the migration velocity can be obtained

$$\boldsymbol{U} = \frac{2r^2 \Delta x |B| \nabla |\boldsymbol{B}|}{9\eta\mu_0} + \frac{2r^2 \left(\rho_{\mathrm{P}} - \rho_{\mathrm{f}}\right) \boldsymbol{g}}{9\eta} \tag{3}$$

Equation (3) considers the magnetic field and field gradient generated by the magnet only, and the interactions between particles are not included. Equation (3) shows that the migration velocity is strongly dependent on particle size.

Key Research Findings

Free-Flow Magnetophoresis of Continuous Flow Separation of Magnetic Particles

In continuous flow, magnetic particles were deflected from the direction of laminar flow by a perpendicular magnetic field depending on their magnetic susceptibility and size and on the flow rate. The particles with the larger susceptibility were deflected further from the direction of laminar flow than the other magnetic particles. Nonmagnetic beads, however, were not deflected at all. Magnetic particles could thus be separated from each other and from nonmagnetic materials. The applied flow rate and the strength and gradient of the applied magnetic field were the key parameters in controlling the deflection.
The central component is a rectangular flat separation chamber over which a laminar flow is generated in the x-direction by a number of inlet and outlet channels (Fig. 1). Magnetophoretic separation is based on deflection of the particles into the y-direction. Perpendicular to the direction of laminar flow, i. e., in the y-direction, an inhomogeneous magnetic field is applied, which forms a magnetic field gradient over the separation chamber. A mixture of particles can be injected continuously into the system through the sample inlet channel. The nonmagnetic particles are not influenced by the magnetic field and leave the chamber at the exit opposite the sample inlet. Superparamagnetic particles, however, become magnetized and are hence dragged into the inhomogeneous magnetic field. The deflection of the magnetic particles, $\boldsymbol{U}_{\mathrm{defl}}(\mathrm{ms}^{-1})$ can be described as the sum of two vectors: the vector for the magnetically induced flow velocity on the particle, $\boldsymbol{U}_{\mathrm{mag}}(\mathrm{ms}^{-1})$, and the vector for the velocity of the hydrodynamic flow $\boldsymbol{U}_{\mathrm{hyd}}(\mathrm{ms}^{-1})$:

$$\boldsymbol{U}_{\mathrm{defl}} = \boldsymbol{U}_{\mathrm{mag}} + \boldsymbol{U}_{\mathrm{hyd}} \tag{4}$$

The magnetically induced flow, $\boldsymbol{U}_{\mathrm{mag}}$, is the ratio of the magnetic force, $\boldsymbol{F}_{\mathrm{mag}}(\boldsymbol{N})$, exerted on the particle by the magnetic field to the viscous drag force:

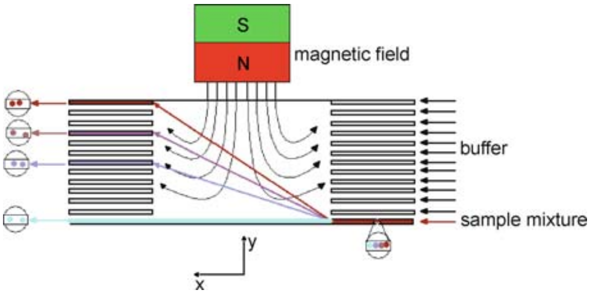
$$\boldsymbol{U}_{\mathrm{mag}} = \frac{\boldsymbol{F}_{\mathrm{mag}}}{\boldsymbol{F}_{\mathrm{drag}}} = \frac{\boldsymbol{F}_{\mathrm{mag}}}{6\pi\eta r} \tag{5}$$

where η is the viscosity of the medium ($\mathrm{kgm}^{-1}\mathrm{s}^{-1}$) and r the particle radius (m).
The magnetic force, $\boldsymbol{F}_{\mathrm{mag}}$, is:

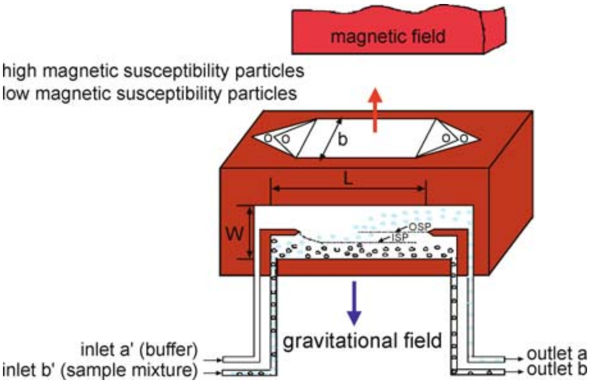
$$\boldsymbol{F}_{\mathrm{mag}} = \frac{\Delta x \cdot V_{\mathrm{p}}}{\mu_0} \cdot (\nabla \cdot B) \cdot \boldsymbol{B} \tag{6}$$

When inserting Eq. (6) into Eq. (5), it can be seen that, for a given magnetic field and a given viscosity, the magnetic velocity, $\boldsymbol{U}_{\mathrm{mag}}$, is dependent on the size and the magnetic characteristics of the particle. It is proportional to the square of the particle radius and to the magnetic susceptibility of the particle:

$$\boldsymbol{U}_{\mathrm{mag}} \propto r^2 \Delta x \tag{7}$$



Magnetophoresis, Figure 1 Concept of free-flow magnetophoresis. Magnetic particles are pumped into a laminar flow chamber; a magnetic field is applied perpendicular to the direction of flow. Particles deviate from the direction of laminar flow according to their size and magnetic susceptibility and are thus separated from each other and from nonmagnetic material



Magnetophoresis, Figure 2 Diagram of magnetic separator. Magnetic force is applied upward and gravitational force downward. The flow-rate conditions: $\boldsymbol{U}(a') > \boldsymbol{U}(b')$, $\boldsymbol{U}(a) = \boldsymbol{U}(b)$, $\boldsymbol{U}(b) > \boldsymbol{U}(b')$

Hence, particles that are either different in size, r, or different in their magnetic susceptibility, x_{p}, will be deflected from the direction of laminar flow to a different degree.

Free-flow magnetophoretic separations could be hyphenated with other microfluidic devices for reaction and analysis steps to form a micro total analysis system, i. e. on-chip free-flow magnetophoresis.

Magnetic Split-Flow Thin (SPLITT) Fractionation

A magnetic field was utilized as a driving force for split-flow thin (SPLITT) fractionation by Fuh and co-workers. This technique allowed the complete separation of paramagnetic ion-labeled particles from non-labeled particles. Zborowski et al. constructed a cylindrically-symmetric SPLITT fractionation channel that used a quadrupole magnetic field. In SPLITT fractionation the separation axis is the thin dimension of the channel.

The system set-up is shown in Fig. 2. The system had two inlets, two outlets, an inlet and an outlet splitter. The theory of operation of system is that magnetic force and gravitational force were applied in opposite direction on the channel to facilitate separation by the set-up. The sample mixture with carriers was introduced into inlet b' and the sample-free buffer (separation medium) was introduced into inlet a' to confine the samples into a small zone close to the bottom wall of the channel. Magnetic force drove the particles with high magnetic susceptibility upward toward the top wall, while particles with low magnetic susceptibility or nonmagnetic settled toward the bottom wall due to gravitational force. Particles with high magnetic susceptibility came out at outlet a, and particles with low magnetic susceptibility or nonmagnetic came out at outlet b.

For a species to be transported across a lamina of flow-rate $\boldsymbol{U}_i$, the field-induced flow-rate ($bL\boldsymbol{U}$) must be larger than or equal to $\boldsymbol{U}_i$, as shown in the following equation [8]:

$$bL\boldsymbol{U} \geq \boldsymbol{U}_i \tag{8}$$

where b is the channel breadth, L is the channel length, and $\boldsymbol{U}$ is the field-induced velocity. All particles with high magnetic susceptibility exit at outlet a when Eq. (8) is satisfied. This means that the net flow-rate resulting from subtracting the magnetically-induced flow-rate ($bL\boldsymbol{U}_{\mathrm{m}}$) from the gravitationally-induced flow-rate ($bL\boldsymbol{U}_{\mathrm{g}}$) was higher than the flow-rate at outlet b. Similarly all particles with low magnetic susceptibilities exit at outlet b when Eq. (9) is satisfied. The requirement that particles with very low magnetic susceptibility are fully retrieved at outlet b is quite straightforward from Eq. (9) when $\boldsymbol{U}(b) > \boldsymbol{U}(b')$ (i. e., the volumetric flow-rate at outlet b is higher than that at inlet b'). The gravitationally-induced flow-rate does not play an important role for particles with very low magnetic susceptibilities as shown in Eq. (9). The conditions of flow-rate used in this study keep $\boldsymbol{U}(b) > \boldsymbol{U}(b')$ valid. In order to achieve complete separation, Eqs. (8) and (9) must both be satisfied by particles with high and low magnetic susceptibilities

$$bL\boldsymbol{U}_{\mathrm{mh}} - bL\boldsymbol{U}_{\mathrm{g}} \geq \boldsymbol{U}(b) \tag{9}$$

$$bL\boldsymbol{U}_{\mathrm{ml}} - bL\boldsymbol{U}_{\mathrm{g}} < \boldsymbol{U}(b) - \boldsymbol{U}(b') \tag{10}$$

All particles with high magnetic susceptibilities exit at outlet a when Eq. (8) is satisfied. All particles with low magnetic susceptibilities exit at outlet b when Eq. (9) is satisfied.

Where $\boldsymbol{U}_{\mathrm{m}}$ is the magnetically-induced velocity ($\boldsymbol{U}_{\mathrm{mh}}$ and $\boldsymbol{U}_{\mathrm{ml}}$ are used for magnetically-induced velocities of particles with high and low magnetic susceptibilities, respectively), $\boldsymbol{U}_{\mathrm{g}}$ is the g gravitationally-induced velocity, $\boldsymbol{U}(b)$

is the volumetric flow-rate at outlet b, and $\boldsymbol{U}(b')$ is the volumetric flow-rate at inlet b'. Magnetically-induced velocity, $\boldsymbol{U}_{\mathrm{m}}$, can be calculated using

$$\boldsymbol{U}_{\mathrm{m}} = \frac{\Delta x \Delta H^2 d}{48\eta} \tag{11}$$

where $\Delta x = x_{\mathrm{p}} - x_{\mathrm{f}}$. x_{p} and x_{f} are the respective magnetic susceptibilities of particles and separation fluid, η is the fluid viscosity, d is the spherical particle diameter or the effective spherical diameter, and symbol ΔH is the drop in magnetic field strength. Gravitationally-induced velocity, U_{g}, can be calculated using

$$\boldsymbol{U}_{\mathrm{g}} = \frac{\Delta\rho d^2 g}{18\eta} \tag{12}$$

where η is the fluid viscosity, $\Delta\rho$ is the particle density minus the carrier fluid density, g is gravitational acceleration, and d is the spherical particle diameter or the effective spherical diameter. For particles with magnetically-induced velocity $\boldsymbol{U}_{\mathrm{m}}$ is between $\boldsymbol{U}_{\mathrm{mh}}$ and $\boldsymbol{U}_{\mathrm{ml}}$, the fraction of particles exiting at outlet a could be calculated using:

$$\frac{bL\boldsymbol{U}_{\mathrm{m}} - bL\boldsymbol{U}_{\mathrm{g}} - \boldsymbol{U}(b) + \boldsymbol{U}(b')}{\boldsymbol{U}(b')} \tag{13}$$

Capillary Magnetophoresis

The configuration of the magnets shown in Fig. 3 generated a large magnetic field gradient along the x-axis and enabled the magnetophoresis. The edge of the iron tips was defined as $x = 0$ and the direction toward the interior of the gap between the tips as $x > 0$.

In an inhomogeneous magnetic field, a particle in a solution experiences two types of forces. One is the magnetic force working on the particle itself, $\boldsymbol{F}_{\mathrm{p}}$, and the other is the magnetic buoyancy, $\boldsymbol{F}_{\mathrm{f}}$, exerted by the paramagnetic medium, with a direction opposite to $\boldsymbol{F}_{\mathrm{p}}$. The net force working on a particle, $\boldsymbol{F}_{\mathrm{m}}$, can be described as follows

$$\boldsymbol{F}_{\mathrm{m}} = \boldsymbol{F}_{\mathrm{p}} - \boldsymbol{F}_{\mathrm{f}} = \frac{V\left(x_{\mathrm{p}} - x_{\mathrm{f}}\right)}{\mu_0}\left(B\frac{\mathrm{d}B}{\mathrm{d}x}\right) \tag{14}$$

where V is the volume of the spherical particle (m^3), x_{p} and x_{f} are the respective magnetic susceptibilities per unit volume of the particle and the medium, m is the vacuum magnetic permeability (NA^{-2}) and $\mathrm{d}B/\mathrm{d}x$ the gradient of magnetic flux density ($\mathrm{NA}^{-1}\mathrm{m}^{-2}$). Acceleration and mass of the particle are so small in our system that the particles can migrate with a constant velocity, $\boldsymbol{U}$, keeping balance between the net magnetophoretic force, $\boldsymbol{F}_{\mathrm{m}}$, and the viscous or m frictional force, $\boldsymbol{F}_{\mathrm{U}}$, which is expressed by Stokes' law

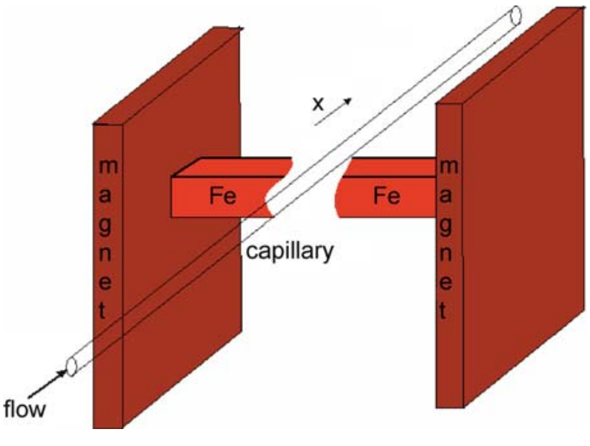
$$\boldsymbol{F}_{\mathrm{v}} = 6\pi\eta r v \tag{15}$$

where η is the fluid viscosity (Pas) and r the radius of the spherical particle (m).

From Eqs. (14) and (15), we can obtain the migration velocity v of a spherical particle as

$$\boldsymbol{U} = \frac{2}{9}\frac{\left(x_{\mathrm{p}} - x_{\mathrm{f}}\right) r^2}{\mu_0 \eta}\left(B\frac{\mathrm{d}B}{\mathrm{d}x}\right) \tag{16}$$

This equation can be used for the determination of $B(\mathrm{d}B/\mathrm{d}x)$ on the micrometer scale from the measurement of the velocity of a microparticle as a function of x. Also, at the point of minimum $B(\mathrm{d}B/\mathrm{d}x)$, a microparticle can be trapped in the capillary with the force of $\boldsymbol{F}_{\mathrm{m}}$. In addition, by controlling the rate of counter-current flow against the magnetophoretic buoyancy, differently sized microparticles can be segregated. If the flow-rate is lower than the velocity represented by Eq. (16), the particle cannot go through the minimum point and is trapped. When the flow-rate is the same as the velocity v, the probability of the particle passing through the minimum point is 50%. A flow-rate higher than $\boldsymbol{U}$ will result in complete passing.



Magnetophoresis, Figure 3 Enhanced of the magnetic field gradient by the pair of iron pieces

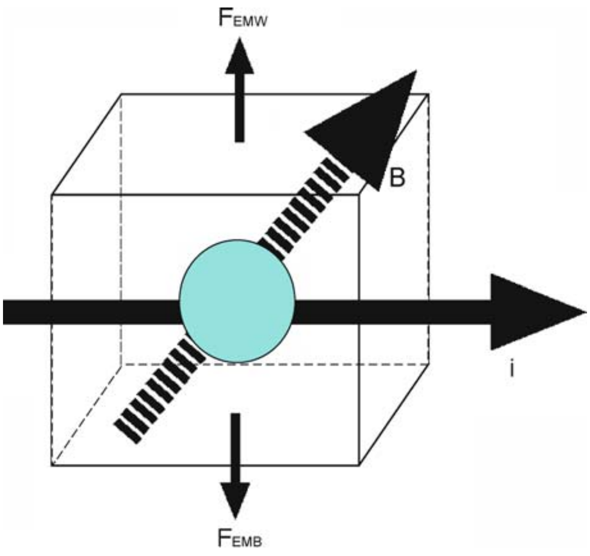
Electromagnetophoresis

The general concept of electromagnetophoresis (EMP) is the application of Lorentz force to migration analysis. The basic theory of electromagnetophoresis was proposed by Kolin in 1953. Electromagnetophoresis is a phenomenon where particles in an electrolyte solution migrate in the direction perpendicular to both a magnetic field and an electric current when the electric current is applied through the conductive fluid and the homogeneous magnetic field

is perpendicular to the current. When an electric current of density j (Am^{-2}) passes through a conductive fluid of volume V (m^3) perpendicular to a magnetic field, the fluid invariably experiences a force, the Lorentz force, expressed as

$$\boldsymbol{F} = \mu_0 \mu H \boldsymbol{j} \boldsymbol{V} \tag{17}$$

where μ_0 is the vacuum magnetic permeability (Ns^2C^{-2}), μ is the magnetic permeability of the conductor, and H is the magnetic field strength (Am^{-1}). As the current passes through the conductive fluid under a magnetic field, all of the fluid experiences the force and so a pressure gradient is produced inside. Figure 4 shows a schematic drawing of forces exerted on a particle in the fluid in this situation. When a current is applied through the enclosed conductive fluid in the homogeneous magnetic field, the force is exerted on both the fluid and the particles. If the force exerted on the fluid is equal to the one acting upon the particles, the particles dispersed in the fluid will be at rest. However, if the two forces are different, migration of the particles will be caused. The two forces acting on a particle in Fig. 4 are called the electromagnetic weight (EMW), $\boldsymbol{F}_{\mathrm{EMW}}$, and the electromagnetic buoyancy (EMB), $\boldsymbol{F}_{\mathrm{EMB}}$, acting opposite to $\boldsymbol{F}_{\mathrm{EMW}}$. The strength of FEMB is equivalent to the force working on the fluid whose volume is equal to that of the particle (V). The electromagnetophoretic force, $\boldsymbol{F}_{\mathrm{EMP}}$, exerted on a particle in a closed



Magnetophoresis, Figure 4 Schematic drawing of the electromagnetic weight, FEMW, and the electromagnetic buoyancy, FEMB, exerted on a particle. They are perpendicular to a homogeneous magnetic field is maintained at right angles to the current enhanced of the magnetic field gradient by the pair of iron pieces

cell which has an inner section of S (m^2) is expressed as the sum of $\boldsymbol{F}_{\mathrm{EMW}}$ and $\boldsymbol{F}_{\mathrm{EMB}}$:

$$\boldsymbol{F}_{\mathrm{EMP}} = \boldsymbol{F}_{\mathrm{EMW}} + \boldsymbol{F}_{\mathrm{EMB}} = 2BV\left(\frac{\sigma_{\mathrm{P}} - \sigma_{\mathrm{f}}}{2\sigma_{\mathrm{f}} + \sigma_{\mathrm{P}}}\right)\frac{i}{S} \tag{18}$$

where B is the magnetic flux density ($NA^{-1}m^{-1}$), σ_{p} is the electrial conductivity (Sm^{-1}) of the particle, σ_{f} is the electrical conductivity (Sm^{-1}) of the medium, and i is the current (A). The electromagnetophoretic velocity $\boldsymbol{U}_{\mathrm{EMP}}$ of a spherical particle in the fluid is expressed as

$$\boldsymbol{U}_{\mathrm{EMP}} = \frac{4}{9}\left(\frac{\sigma_{\mathrm{P}} - \sigma_{\mathrm{f}}}{2\sigma_{\mathrm{f}} + \sigma_{\mathrm{P}}}\right)\frac{iBr^2}{S\eta C_{\mathrm{W}}} \tag{19}$$

where η is the fluid viscosity (Pa s), r is the radius of the spherical particle (m), and C_{W} is the viscous drag coefficient due to the surface of the wall.

Examples of Application

Analogous to electrophoresis, magnetophoresis is a nondestructive method for selectively collecting or separating magnetic particles. Magnetophoresis applications involving the controlled movement of magnetic micro/nanoparticles in microfluidic systems are diverse and growing rapidly. Some of the most interesting of these are in the fields of microbiology and biomedicine where magnetic particles are used to target, label, manipulate and separate biomaterials such as cells, enzymes, antigens and DNA. The intense research in these areas is due primarily to advances in microfluidic technology, and progress in the development of surface-functionalized magnetic particles that can selectively transport a target biomaterial. Separating magnetic particles from each other as well as from nonmagnetic material in continuous flow on a microfluidic chip (on-chip free-flow magnetophoresis) is also very interesting. The device features a separation chamber over which a laminar flow was generated by a number of inlet and outlet channels. A magnetic field was applied perpendicular to the direction of flow. Magnetic particles were dragged into this field and thus deflected from the direction of laminar flow, depending on their size and magnetic susceptibility.

Cell handling

Definition

The collection of means for precise control of the static or dynamic position of individual biological cells with the purpose of observing, probing, and/or altering the cellular responses.

Overview

Different techniques for manipulating cells in microfluidic devices have been proposed for a wide variety of applications. The purpose of this essay is to systematize the techniques by the physical principles and forces used for controlling cell position. The reader is encouraged to follow the links to chapters describing in more detail how the interaction between cells and mechanical and biochemical entities, or with electrical, magnetic, or optical fields can be implemented at microscale for the handling of cells for various applications.

Several factors are usually considered for the choice of a cell manipulation method for a particular application. One important factor in the choice for a manipulation technique is the static or dynamic condition of the cell. In static conditions, cells are in a stationary phase and have to be actively moved to the desired location. In dynamic conditions, cells follow stream lines and the manipulation

Manipulating Cells, Techniques, Table 1 Classification of the techniques for manipulating cells by physical mechanisms employed

Physical Mechanism	Cell Condition	
	Static	Dynamic
Mechanical	Cell patterning	Sieves, posts, stagnation points
Biochemical	Chemical patterns	Antibody coated surfaces
Magnetic	Magnetic bead-mediated	Magnetic bead-mediated trapping
Electric	DEP traps	DEP barriers
Optical	Optical traps	Optical barriers

would either block cells in predetermined locations or only veer them into different stream lines. Some mechanisms are more appropriate for static conditions (e. g., cell patterning), while others benefit from the effects of the flow (e. g., sieves, light diffraction patterns). The choice of a manipulation mechanism is also related to the particular type of the cell to be manipulated. Bacteria cells are smaller (few microns) but more resistant to alterations of microenvironment around them, and thus are more difficult to manipulate mechanically and easier to handle using electric fields. Eukaryotic cells on the other hand are larger (10 – 20 μm diameter) but very sensitive to changes in the composition or temperature of their microenvironment, and thus mechanical methods are usually preferred. Finally, some of the manipulation mechanism can be made specific for a target cell type in a more complex sample, and differential handling and sorting of cells can be achieved by the use of particular manipulation mechanisms.

Basic Methodology, Key Research Findings

The implementation of physical mechanisms at the microscale for cell manipulation takes advantage of the scaling laws at sizes comparable to cells sizes. Some of the techniques are widely used and very well developed (see the chapters on ► cell patterning, ► dielectrophoretic motion, ► optical tweezers). Other techniques are still emerging and our understanding of the practical aspects of these is still evolving.

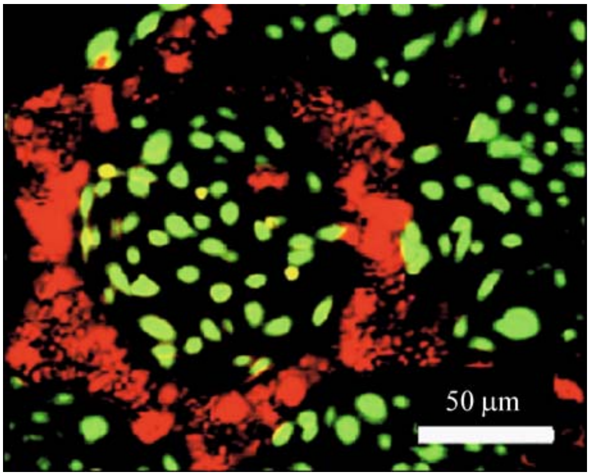
By far the easiest to implement at microscale are the mechanical features for patterning and trapping cells in precise locations. Microwells and microchannels can be used to pattern cells and allow them to grow in precise configurations inside microfluidic chips (see also: ► cell culture 2D and 3D on chip). Eukaryotic cells can be mechanically trapped from flowing solutions by using arrays of posts, weir type structures, or channels of size too small for the cells to go through. For higher throughput applications, methods based on pinched flow and deterministic lateral displacement [1] are usually preferred.

Biochemical methods can be tuned to achieve the highest selectivity for the manipulation of cells from complex cell suspensions. Cell patterning (see ► cell patterning on chip) is now a well-established method and homogeneous as well as heterogeneous patterns, with various numbers of cells, and in various configurations have been described [2]. Selective capture of cells under flow conditions, on surfaces or posts is emerging as a reliable method for isolating specific cells from clinical samples that could be as complex as blood [3] (see also: ► integrated microfluidic systems for medical diagnostics).

The use of magnetic beads for manipulating cells has originally been developed for bulk assays. Magnetic beads coated with antibodies against proteins on the surface of cells are used as *a handle* to manipulate specific cells from complex suspensions. The integration of these assays in microfluidic format takes advantage of the capability of producing high magnetic field gradients at the microscale, in the close proximity of microscopic magnetic features. This approach has been demonstrated both for trapping cells in precise locations as well as for the deviation of tagged cells across streamlines and cell sorting [4] (see also magnetic particle labeling).

Dielectrophoresis methods for manipulation use electric fields to induce electrical polarization of cells and induce translational motion or reorientation of the cells. Dielectrophoresis is extremely attractive at the microscale because it can be fine tuned to be selective to different characteristics of the cells, and because low voltages are usually enough to produce intense electric fields [5, 6]. This technique is widely applied for bacteria handling in microfluidic devices, and applications for mammalian cells are emerging, including both trapping and dynamic perturbation in cell suspensions (see also ► dielectrophoretic motion of particles and cells).

Last but not least, optical methods for trapping and separating cells can achieve the highest precision and spatial resolution while having minimal secondary effects on the manipulated cells. Large scale arrays of optical traps are being used to manipulate multiple cells and particles at the microscale [7] and the integration of dynamically reconfigurable optical lattices have been demonstrated for



Manipulating Cells, Techniques, Figure 2 Static manipulation of cells. Micropatterning techniques were employed to precisely position hepatocytes (light gray, red in the online version) and fibroblasts (darker gray, green in the online version) in a configuration comparable to the regular liver functional unit [2]

the separation of particles based on size and refractive index (see also ► optical tweezers for manipulating cells and particles, and optophoresis for cell sorting). Despite their unmatched precision, optical methods have been so far confined to research applications only, mainly because of the requirements for expensive optical instruments that could not be integrated on the microfluidic chips.

Future Directions for Research

The interest in manipulating cells in microfluidic devices is growing because of increasing interest in the development of devices that use cells for basic research and clinical diagnostic purposes [8]. High throughput methods for manipulation of cells that could be applied to complex cell mixtures are expected to have a great impact in the development of point of care devices. New capabilities for manipulation and subsequent comprehensive analysis of single cells would become valuable discovery tools pushing the frontiers of biological research to new limits.

Marangoni Convection

Charles N. Baroud
LadHyX and Departement de Mécanique, Ecole Polytechnique, Palaiseau, France
baroud@ladhyx.polytechnique.fr

Synonyms

Thermocapillary convection; Solutal marangoni

Definition

The Marangoni effect refers to the variation of surface tension of a liquid with temperature (thermocapillarity) or

with the concentration of a surfactant (solutal Marangoni effect). The variation of surface tension in turn leads to convective motion of the fluid: Marangoni convection. This motion along the surface of the liquid layer in turn leads to flow in the bulk and may be used to transport fluids in microfluidic devices.

Overview

Solutal Marangoni convection is caused by variations in the concentration of a surfactant at the interface between two liquids or a liquid and a gas. The surface tension being a function of the local surface concentration of surfactant, a variation in the latter will affect the value of surface tension locally and therefore give rise to stresses along the interface. The relation between the surface concentration of surfactant and the surface tension is a complex one which will be addressed first. Furthermore, three important dynamical phenomena need to be accounted for in order to compute the Marangoni flow for a moving interface:

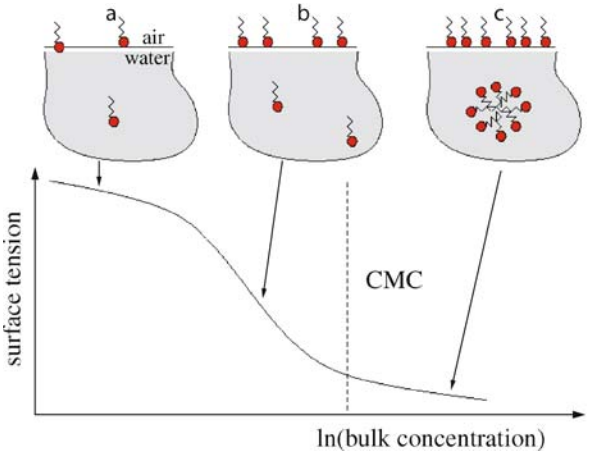
1. Adsorption of surfactant molecules to the surface
2. Transport of surfactant molecules in the bulk
3. Surface dilation or contraction

In the following, we start by describing the equilibrium relations that determine surface tension as a function of surfactant concentration. Then the mechanisms for dynamic variation are incorporated. Finally, the dynamic variations are related to the presence of Marangoni surface stresses and therefore Marangoni convection.

Surface Tension vs. Surface Concentration

Surfactants come in a very wide variety of sizes and compositions. What they have in common is their affinity for the surface of a liquid, which means that the free energy of the solvent/solute system is reduced when a surfactant molecule migrates to the surface, compared to when it is in the bulk of the fluid. As the concentration along the surface (Γ, in mol/m^2) increases, the original interface starts to give way to two new interfaces: solvent–surfactant and surfactant–air, with a lower global surface tension (γ, typically measured in mN/m or mJ/cm^2).

Surfactant molecules are typically composed of two parts: a hydrophilic head and a hydrophobic tail. Owing to this structure, a surfactant molecule will tend to adhere to the surface with a well determined orientation, for example with its hydrophobic part pointing out of the water phase. The final surface tension of the liquid–surfactant solution will therefore depend on the quality of the packing of surfactant molecules and their chemistry. They are termed 'soluble' if they can be dissolved in the bulk, even though they prefer to be on the interface. Common examples of soluble surfactants are soaps or other detergents.



Marangoni Convection, Figure 1 Schematic of surfactant surface concentration and the corresponding surface tension, as a function of bulk concentration of surfactant on a logarithmic scale. The dashed line corresponds to the critical micellar concentration, discussed in the text

The relation between the surface tension of the interface and the surfactant concentration can be understood by thinking of the molecules as rigid objects covering the surface (Fig. 1). At very low concentrations (Fig. 1a), the molecules sit on the surface, far from each other, and do not affect the surface energy (and therefore surface tension) very significantly. As the concentration is increased however (Fig. 1b), the molecules start to cover a more significant part of the surface and the surface tension starts to decrease significantly. Beyond a critical concentration of surfactant (Fig. 1c), a new state becomes thermodynamically available to molecules, that of forming micelles, which are groupings of surfactants whose heads are exposed to the liquid and whose tails are enclosed within the ball. Beyond this critical micellar concentration (CMC), the surface tension remains approximately constant in spite of increasing the surfactant concentration in the solution.

Around 1920, I. Langmuir formalized the first nonlinear model to describe the surface tension dependence on surface concentration (see Ref. [1] for a detailed description). Langmuir's model is based on a lattice description of the adsorption sites, making three assumptions about the lattice which we quote from Ref. [1]:

1. every adsorption site on the lattice is equivalent;
2. the probability for adsorption at an empty site is independent of the occupancy of neighbouring sites; and
3. there are no interactions between the surfactant molecules in the lattice, and no intermolecular forces act between them.

By accepting that there is a maximum surface concentration (Γ_∞) and given an equilibrium constant K_L which

relates the rates of adsorption vs. desorption, we may write the equilibrium surface concentration as

$$\Gamma = \Gamma_\infty \left(\frac{K_L c}{1 + K_L c} \right) , \tag{1}$$

with c being the bulk concentration of surfactant molecules. Equation (1) contains two independent free parameters, K_L and Γ_∞ which must be measured from experiments, in practice.

By using this so-called Langmuir isotherm, one may write the surface tension, as derived by Frumkin, as

$$\gamma = \gamma_0 + RT\Gamma_\infty \ln (1 - \Gamma/\Gamma_\infty) . \tag{2}$$

Though it does not account for molecule–molecule interactions, this Frumkin–Langmuir model accounts for the trends of Fig. 1. It is currently the most widely used model for modelling surface tension dependence on bulk concentration.

Dynamic Situations

The above discussion accounts for the equilibrium state of a surface. However, when a new surface is formed (e. g. during drop formation), this equilibrium state will be reached after a transient time which ranges from milliseconds to hours, depending on the surfactant. The transient time is determined by the mobility of the molecules and their adsorption dynamics on the interface, which we discuss below.

Adsorption Dynamics

As stated above, the adsorption and desorption of molecules on an interface must be accounted for in understanding the dynamic variations of surface tension. Let us consider a newly formed interface of a liquid which contains a bulk concentration c of surfactant. At the initial moments, the interface is almost free of surfactant molecules and may resemble the situation of Fig. 1a. In this case, any surfactant molecules which happen to be in the neighbourhood of the interface will stick to it, and the rate at which the molecules arrive at the interface will limit their adsorption. In the absence of other driving mechanisms, this rate will depend only on the diffusion of molecules to the surface, and is typically very short.

At later times, the interface will start to look more like Fig. 1b, and now a molecule will adsorb to the surface only if it reaches an empty site. Furthermore, the high concentration of molecules at the interface means that they may also diffuse away, and then their desorption must also be modelled.

A classic model for accounting for adsorption/desorption dynamics is the Ward and Tordai equation [2]. This model predicts the presence of a subsurface layer, a few molecular diameters in size. Molecules present in the subsurface immediately adsorb to the surface at early times, while at later times they might linger there or possibly diffuse back into the bulk. Therefore, transport from the bulk to the subsurface is purely diffusive, while the mechanism between the subsurface and the surface depends on time in a more complex manner. The Ward–Tordai equation may be written as

$$\Gamma(t) = 2c_0\sqrt{\frac{Dt}{\pi}} - \sqrt{\frac{D}{\pi}} \int_0^{\sqrt{t}} c_s \, \mathrm{d}\left(\sqrt{t-\tau}\right) , \tag{3}$$

where c_0 is the bulk surfactant concentration far from the subsurface, D is the diffusion coefficient of the surfactant molecule, c_s is the concentration in the subsurface and τ is a dummy integration variable. Note that Eq. (3) constitutes an equilibrium relation between the diffusion of molecules from the bulk (first term) and the diffusion that takes place in the subsurface, both treated using Fick's law.

At short times ($t \to 0$), the second term may be neglected and $\Gamma(t)$ increases simply by diffusion from the bulk. The surface tension variation at those times can be written as

$$\gamma_{t\to 0} = \gamma_0 - 2RTc_0\sqrt{\frac{Dt}{\pi}} . \tag{4}$$

At long times ($t \to \infty$), the first term of Eq. (3) tends to its equilibrium value, while the second term approaches zero as $t^{1/2}$. The surface tension in this case can be modelled as

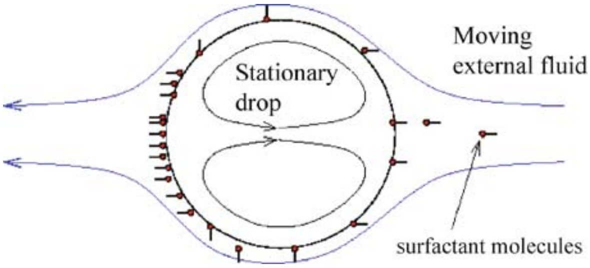
$$\gamma_{t\to\infty} = \gamma_{\mathrm{eq}} + \frac{RT\Gamma_{\mathrm{eq}}^2}{c}\sqrt{\frac{\pi}{4Dt}} . \tag{5}$$

However, there are no analytical solutions for Eq. (3) for intermediate times, although numerical solutions are easy to produce.

Transport in the Bulk

The model above assumed that the only transport mechanism in the bulk flow was through diffusion, which may not be true for many situations in microfluidics. For instance, Marangoni flows are of great importance in situations of bubble or drop formation when new interfaces are created. In microfluidics, droplets are often formed in a strong shear, which means that the fluid flow displays large velocity gradients present.

A classic situation of surfactant transport is the situation of a stationary drop in a moving fluid [3]. Indeed, this situation can be simply related to the situation of a moving drop



Marangoni Convection, Figure 2 Schematic of a stationary drop subjected to the flow of a surfactant-laden external fluid. The surfactant molecules which adsorb on the interface are transported by the flow on this surface towards the rear stagnation point. This leads to a strong concentration of surfactant molecules in the rear region

by a transformation of the reference frame. Let us consider the flow in the reference frame of the drop, as shown in Fig. 2. In this frame, the drop sees a surfactant-rich flow arriving from the right and this surfactant is adsorbed on the interface between the drop and the outer fluid. However, the outer flow also creates recirculation zones inside the drop which redistribute the surfactant molecules on the rear (left) end of the drop. This situation creates an imbalance in the surfactant concentration along the drop surface, which translates into a surface stress. This surface stress in turn creates a net force on the drop from the left side to the right side, which slows down the external flow.

The relative importance of the advective transport compared to diffusion is measured by calculating the Péclet number. This dimensionless number is defined as

$$\mathrm{Pe} = \frac{Ul}{D}\,, \tag{6}$$

where U is a typical flow velocity, l is a typical length scale over which molecules must diffuse and D is the diffusion constant of the surfactant molecule. For small Pe, the transport due to the mean flow is small and the diffusion dominates, while in the opposite case, transport by the mean flow is dominant and diffusion is not sufficiently fast to redistribute the surfactant molecules. While in large-scale industrial or geophysical flows the Péclet number is always large, the scale and velocities typical in microfluidics imply that one may observe both regimes of high and low Pe. This is especially true since different surfactants have widely varying diffusion coefficients, based for instance on the length of their hydrophobic chains.

Variations of Interface Surface Area

Marangoni effects may play a major role during the formation and detachment of a drop or bubble, since the formation of such a drop naturally involves the formation of a new surface which needs to be covered by surfactant. In this situation, surfactant coverage of the new interface occurs gradually as it is formed, and the rate at which the new surface is covered is limited by the transport mechanisms discussed above. In contrast, the rate at which the surface is created is independently determined by the dynamics of the fluid flow. For instance, the surface concentration Γ may decrease as the surface area is increased, even for a fixed number of surfactant molecules. The relative rates of surface dilation and surfactant transport give rise to several regimes, leading to drops which are subject to strong Marangoni stresses in the case of rapid surface variation, or drops with even distribution of surfactant in the slower cases.

However, drop formation is not the only situation during which a new surface is created. Indeed, while the volume of fluid inside a drop must be conserved, its shape may very well vary, leading to very different values of the surface area. For instance, a spherical drop (of minimal surface area) may be deformed by the external flow to form an oval or other shape. This creation of a new surface is coupled with the presence of Marangoni stresses: as we shall see below, the surface variation can create Marangoni stresses but it can also be caused by uneven distribution of surfactant.

M

Basic Methodology

Numerical simulations of Marangoni flows always have to deal with free interfaces and the associated difficulties. These difficulties are related to meshing, in order to account for large gradients (e. g. in surfactant concentration) near the interface, but also due to moving interfaces in the case of translating or deforming drops. Furthermore, the transport of surfactant in the bulk must also be modelled and coupled with the equations of state of the interface in order to obtain the surface stresses. The modelling of the transport depends strongly on the Péclet and Reynolds number regimes under consideration and will require different numerical techniques depending on the values of the dimensionless parameters.

Therefore the details of the numerical simulations will vary greatly depending on the regime under study. Typically, the flow field around the drop or bubble is computed, e. g. using finite volume methods. The flow field is then coupled with a transport equation for the surfactant which involves diffusion and/or advection. Similar techniques may be used for thermal Marangoni convection by replacing surfactant concentration with thermal energy. The computed surface tension, using for instance the Langmuir relation of Eq. (2), then provides the stress

boundary condition at the interface. This dynamic boundary condition is then used in the calculation of the next time step [4].

Boundary element methods are also used for the calculation of the flow field, since they automatically take into account the free surface. These methods are based on the reformulation of the flow as a potential field, which can be solved in terms of an integral equation on the field boundary, usually taken to be the free drop interface. This technique, which reduces the problem dimensionality by one, is well adapted for the solution of deformable drops since it does not require a mesh to be generated everywhere in the flow but only on the surface [5].

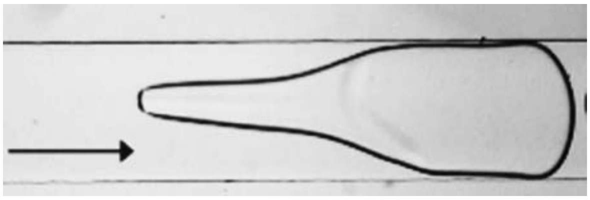
One model system has been at the centre of many studies on Marangoni effects, namely the flow in a gap of small thickness compared to the other typical scales. This system, known as a Hele–Shaw cell, significantly reduces the complexity of the problem, allowing a formulation as a two-dimensional potential flow which admits many elegant analytical solutions. Although the flow of a drop in a Hele–Shaw cell in the presence of surfactants does not have a single analytical solution, it does offer a simplified system which can be realized experimentally and numerically. Furthermore, the Hele–Shaw model is of great significance to microfluidic flows, where surface microfabrication techniques often lead to rectangular channels which may have a large width/height aspect ratio.

Key Research Findings

An initial and important result is that the accumulation of surfactant molecules at the rear stagnation point of a translating droplet imposes a surface stress which opposes the outer flow (see Fig. 2). A direct implication is that for a gas bubble rising in a quiescent liquid, the surface is immobilized and the rise velocity is more similar to the rise of a rigid disc than to an inviscid bubble.

Studies of bubble rise in Hele–Shaw cells demonstrated the production of an 'anomalous' wake structure which encircles the bubble completely and yields a larger effective size of the bubble. A systematic study found that the velocity of a bubble in the presence of surfactant could be almost an order of magnitude lower than the velocity expected in the case of a clean interface. More surprisingly, drops could take on complex shapes such as oval or dumbbell shapes, or even forming tails behind them [6]. Similar drop shapes may be obtained in microfluidic situations, as shown in Fig. 3 for the case of a droplet with a tail.

Further stresses on the liquid interface lead to the phenomenon of tip streaming. This phenomenon was first reported by G.I. Taylor in 1934 and involves the production of singular tips and tiny droplets from a larger drop. Tip streaming may be understood as a destabilization of drops with tails as follows [7]. A strong concentration of surfactant can build up at the tail of the drop, while the rest of the interface remains at low concentration. In this case, a very large difference of concentration occurs, giving rise to a pressure imbalance inside the drop. In order to balance the pressures, the drop shape must change locally and produce regions of high curvature where the surface tension is low, i. e. in the tail region. This process may cascade and lead to continually increased curvatures, which occur at the cost of elongating the tail. In turn, the elongated thin tail is destabilized by the Rayleigh Plateau instability and sheds droplets much smaller in size than the mother drop.



Marangoni Convection, Figure 3 A drop of water in oil, flowing in a microchannel in the presence of surfactant. The shear induced on the drop from the external flow produces the tail-shape discussed in [6]. (Photo: Charles Baroud, LadHyX, Ecole Polytechnique)

Microfluidic observations of this phenomenon were recently reported [8]. An external flow of oil and surfactant was used to focus a stream of water in a sheared geometry. The resulting concentration of surfactant on the tip of the water surface was shown, for sufficiently high shear rates, to produce drops that were much smaller than the typical length scale of the microchannels.

Marangoni convection has also been identified as a major driving mechanism in the spread of surfactant and other liquids lining the lung airways [9]. This layer lining the pulmonary airways is necessary for the proper inflation and deflation of the lung and for the transport of pollutants that may be inhaled. It may be damaged by disease or in premature births. Surfactant replacement therapy (SRT) is used in this case, and may consist of inducing the inhalation of a liquid plug, rich in surfactant, which must travel through the successive bifurcations in the airway tree. Although the transport of the surfactant in plug form is limited by the inhaled liquid volume, transport in the further reaches of the lung is enhanced by the presence of a surface tension gradient due to the variations in surfactant concentration. Therefore surfactant-rich liquid near the mouth is drawn deeper into the pulmonary tree by Marangoni convection, thus enhancing the success of SRT.

Future Directions for Research

Since surfactants are almost always present in droplet microfluidics, a further understanding of their dynamics and their effect on the formation and transport of drops is crucial. In particular, micro-droplet production is a mechanism which produces very large amounts of new surface area in a confined volume, i. e. with a limited amount of surfactant molecules. Although drops in microfluidics are typically produced in a periodic fashion, recent work has demonstrated that the number of drops produced per period varies as a function of forcing rates, up to several drops per period. This raises questions about the homogeneity of the surfactant coverage on the successive drops, which influences their later evolution.

Furthermore, the temporal evolution of a train of drops in the presence of surfactant will be influenced by Marangoni effects. Drops may catch up with their neighbours due to Marangoni retardation effects discussed above and this may lead to destabilization of a microemulsion, or variations of timing in situations where the droplets are used as microreactors in series.

The merging of drops in the presence of surfactants is also a major question. Surfactants have been demonstrated to retard droplet merging, thus stabilizing emulsions. However, drops offer great promise for use as microreactors since they may contain small volumes of reactants and transport them in a microfluidic lab-on-a-chip. Therefore, merging drops will be important in order to bring in contact the different chemical species and perform the desired reactions but the merging process will have to overcome the surfactant barrier. Moreover, the merging may produce Marangoni stresses on the resulting drop which may enhance or retard the mixing of the two reactants in the drop. Such questions have not yet been addressed.

More complex questions involving production or depletion of surfactant also will probably be important in the near future. Recent work has demonstrated complex Marangoni flows and tip streaming on a drop surface that underwent a chemical reaction which produced surfactant. The localized production of surfactant may therefore be considered in applications to microfluidic forcing. Furthermore, the depletion of surfactant through localized heating has been demonstrated to induce large forces on droplets which may be used as a forcing tool for droplet microfluidics. This combination of thermal and solutal Marangoni flows promises to be a rich field with a variety of phenomena and applications.

Definition

Mass spectrometry (MS) is a sizing technique that provides a mass to charge (m/z) ratio of target analyte ions.

Overview

MS has its origins in J.J. Thomson's vacuum tube where the existence of electrons and *positive rays* was demonstrated. Thomson observed that the new technique could be used by chemists to analyze chemicals. This was in the early part of the century, however it took decades for MS to be used as an effective analytical chemistry technique. Subsequently, advances in MS technology in concert with computational tools and separation methods, laid the foundation for the now extensive use of MS in biochemical research. MS is a powerful analytical technique that can identify and quantify compounds, and also elucidate the structure and chemical properties of molecules. Detection of compounds can be accomplished at extremely low concentrations and often very rapidly. The versatility of mass spectrometry is evident in the valuable information it provides to diverse applications such as detection of illegal drug use, composition of molecular species in a variety of samples, adulteration/contamination of food products etc. In the biological research setting, mass spectrometry is used to identify structures of biomolecules, sequence proteins and oligosaccharides and perform differential proteomic analysis. It may be argued that MS-based protein analysis has made the most significant impact on postgenomic science.

Working principle(s)

A mass spectrometer analyzes ions that are created from molecules. The overall working scheme can be viewed as a combination of three major processes: ionization, sorting and detection. **a)** The first step is introduction of sample into the instrument. Samples can be introduced as either a solid, liquid, or vapor into a vacuum chamber through an inlet. Depending on the type of inlet and ionization techniques used, the sample may already exist as preformed ions or it may be ionized in the ion source. Several ionization modes [1] are commercially available with electrospray ionization (ESI) [2] and Matrix Assisted Laser Desorption/Ionization (MALDI) [3, 4] being the most widely used nowadays. ESI uses an electric field to produce a droplet spray, the sample in this case is typically in a volatile solvent. Irrespective of the original sample source, the final sprayer is usually a fine metal needle that is maintained at high voltage. The solvent vaporizes as it leaves the spray needle and enters additional nebulizing chambers, resulting in positively (or negatively) charged ions that become smaller and more densely charged. This production of multiply charged ions makes ESI particularly useful to study molecules with larger masses, since the actual measurement in MS is the m/z. ESI is most typically used with liquid chromatography (LC) as the upstream separation but is also easily coupled with solution phase separation systems such as capillary electrophoresis (CE) [5]. MALDI differs in being able to desorb analyte ions from a solid phase. Here samples are mixed with an excess of a UV-absorbing matrix, typically small organic acids like sinapinic acid or 3-hydroxypicolinic acid. A small volume of this sample-matrix mixture is spotted on a probe and allowed to dry. Desorption-ionization is achieved by focusing a laser on the sample. **b)** Gas phase ions are sorted in a mass analyzer according to their mass-to-charge (m/z) ratios by one or more methods. Common sorting approaches are magnetic sector, drift tubes (**T**ime-**o**f-**F**light), electrical fields (quadrupole), used alone or often in combination, depending on the requirements of the experiment. MS/MS or tandem MS refers to multiple stages of mass analy-

sis interspersed by the fragmentation of parent ions into daughter ions. Such fragmentation, often induced by gas phase collisions, are critical to structural analysis by MS. **c)** Separated ions are detected by converting the sorted ion flux into a recordable (electrical) function of m/z. The output is displayed as a mass spectrum with relative intensity on the Y–axis and m/z on the X–axis. A typical MS data set can be rather large and complex, which explains the necessity of computers and sophisticated algorithms to analyze spectra.

Interfaces

Separation methods and MS analysis often go hand in hand. MS is a powerful downstream detection method for most separations. Conversely, good MS analysis of compounds depends on effective separation of the individual components. Separation is necessary for unambiguous identification because two compounds present in the source region simultaneously create an overlapping or mixed spectrum and even simple compounds can generate many fragment ions. Gas chromatography (GC) was the earliest separation technique coupled to mass spectrometry allowing compounds already in the vapor phase to enter the mass spectrometer separated in time. Presently, liquid chromatography and capillary electrophoresis are the primary separation systems interfaced to mass spectrometers and present a large opportunity to interface smaller scale separation devices. Effective interfacing of a separation system with MS analysis is critical and presents the biggest challenge to using MS with microfluidic separations. Thus, a significant level of effort is evident in the literature on developing suitable MS interfaces, some of which have already entered the market.

Mass analyser

Definition

A mass spectrometer is a vacuum analytical instrument that uses electric or magnetic fields or a mixture of the two to separate ions based on the ratio of their mass m to their charge q. A distinction is made between mass spectrometers, which produce a serially scanned output, and mass spectrographs, which produce a parallel (and sometimes graphical) output. The mass-to charge ratio is often written as m/z, where $q = ze$, $e = 1.6 \times 10^{-19}$ C is the electronic charge and z is the charge number. The ions are created from analyte molecules by processes that give rise to a characteristic pattern of fragments, in addition to the molecular ion itself, allowing a mass spectrometer to be used for chemical identification, compositional quantification and structural analysis. Performance is characterized in terms of the mass range (defined by the maximum mass $m_{\max}$ that can be measured), the mass resolution (defined as $m/\Delta m$, where Δm is the uncertainty in the mass being measured) and the sensitivity. Applications include analytical chemistry, process and pollution monitoring, forensic science, the detection of drugs, chemical and biochemical weapons, and space exploration. In some cases, high performance is essential, while in others, low cost, small size, and portability are more desirable. Increasingly, key components are being constructed on chip, to allow overall system miniaturization.

Overview

A complete mass spectrometer normally contains an ►ion source, a ►mass filter and one or more ►ion detectors. In addition, the system will require a vacuum chamber,

a method of sample introduction, vacuum pumps (usually a roughing pump and a main pump), a vacuum gauge, control electronics and a data acquisition, display and storage system.

A variety of different operating principles can be used for each component. The most common methods of ionization in miniaturised devices are:

- Electron impact ionization, for gaseous analytes
- Electrospray ionization, for liquid analytes

Similarly, the most common variants of miniaturised mass filter are:

- ►Time-of-flight filters
- ►Magnetic field and ►crossed-field filters
- Electrostatic ►quadrupole filters and quadrupole ion traps

Finally, ion detectors may be single elements or arrays of

- Faraday cup,
- Electron multiplier.

The main factor dominating the size, weight and the cost of the overall system is the pump set. Pumping requirements are largely determined by the size of the vacuum chamber, which is in turn controlled by the size of the components therein. Consequently, there is a drive to use planar processing or microelectromechanical systems (MEMS) technology to construct miniature ion sources, mass filters and detectors. Other drivers include the use of cold cathode field emission electron sources as low power ion sources (for example, for space applications), nanospray capillaries as low-flow-rate sources for liquid analytes (for example, in drug discovery) and arrayed detectors in high-resolution mass spectrographs.

Because of the reduced ion flight path, miniature mass spectrometers can operate at higher pressures than conventional systems. However, size-scaling laws and limitations on achievable features affect the performance of microfabricated devices. Although many MEMS mass spectrometers now exist, and are producing increasingly realistic data, their designs have not yet reached the sophistication of conventional systems, where cascaded or double-focusing analyzers are common.

Basic Methodology

The operation of all types of mass spectrometer is subject to simple size scaling laws, which become very significant as devices are miniaturized.

Mean Free Path

According to the kinetic theory of gases, the mean free path λ in a gas with a molecular collision diameter d at an absolute temperature T and pressure P is:

$$\lambda = \frac{kT}{(\sqrt{2}\pi d^2 P)} \tag{1}$$

Here, $k = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant. Since the overall flight path L in a mass spectrometer must be smaller than the mean free path if the ions are to transit successfully, the operating pressure must be:

$$P < \frac{kT}{(\sqrt{2}\pi d^2 L)} \tag{2}$$

This result implies that operating pressures can vary inversely with the dimensions of the system. Assuming the typical value of $d = 3.7 \times 10^{-10}$ m for the collision diameter (for N_2), at $T = 300$ K we obtain $P = 6.8 \times 10^{-1}/L\,\mathrm{N/m^2}$, where L is in cm. Since the dimensions of microengineered mass spectrometers are typically one or two orders of magnitude smaller than conventional systems, operating pressures can in principle be up to two orders higher. However, the need to avoid discharges often tends to negate this advantage.

Electron Impact Ionisation

Electron impact ionization (EI) is primarily suitable for gaseous analytes. In an EI source, electrons are produced by either thermionic emission from a hot filament or by field-induced tunneling from a cold surface. They are accelerated into an ionization region, where they encounter the analyte. At low energies (<20 eV), there is insufficient energy for ionization. At higher energies (in a broad range near 70 eV), the de Broglie wavelength of the electrons matches the length of typical molecular bonds, and ionization and molecular fragmentation rates are both maximised. At higher energies, the electron wavelength reduces and the ionization efficiency decreases. Typical ionization efficiencies (i. e., the number of ions produced per electron) are extremely low, around 1 in a 1000.

In thermionic emission, the current density J obtained from the electrically heated filament in the presence of an electric field E obeys the modified Richardson–Dushman equation:

$$J = AT^2 \exp\left(-\frac{\phi - \Delta\phi}{kT}\right) \tag{3}$$

Here ϕ is the work function of the filament material, and A is Richardson's constant, given by $A = 4\pi m_e k^2 e/h^3$, where m_e is the electron mass and $h = 6.62 \times 10^{-34}$ Js is Planck's constant. The field-induced term is $\Delta\phi = (eE/4\pi\varepsilon_0)^{1/2}$, where $\varepsilon_0 = 8.85 \times 10^{-12}$ F/m is the vacuum permittivity. Because of the exponential variation above, materials such as tungsten that can survive operation at very high temperatures are required. Difficulties

in fabrication and thermal management have hindered the development of integrated hot filament sources.

This drawback has led to a focus on cold-cathode sources, which operate by tunelling from a surface in the presence of a strong electric field. The current density obtained is given in this case by the Fowler–Nordheim equation:

$$J = AE^2 \exp\left(-\frac{B\phi^{3/2}}{E}\right) \tag{4}$$

Here A and B are different constants. In this case, the dominant factor is the electric field. Suitable fields can be obtained at voltages of $\approx 100\,\mathrm{V}$ from tips with radii of $\approx 1\,\mathrm{nm}$, which can be made by microfabrication. Since $\log_e(J/AE^2) = -B\phi^{3/2}/E$, a plot of $\log_e(I/V^2)$ versus $1/V$ (where I is the emission current and V is the voltage) should be a straight line with a negative slope. The reduction in operating temperature and the elimination of a heater current makes cold-cathode sources a strong candidate for low-power portable systems.

Electrospray Ionization

Electrospray ionization (ESI) is primarily suitable for liquid analytes. In ESI, a voltage is applied between an electrode and a capillary containing the analyte. Liquid is extracted from the tip and drawn into a Taylor cone, from which large charged droplets are emitted. The droplets are accelerated to supersonic speed, evaporating as they travel. Coulomb repulsion of the charges in the shrinking droplet results in fragmentation to ions when the Rayleigh stability limit is reached. The resulting ions can be multiply charged. In a conventional electrospray system, with capillaries of $\approx 100\,\mu\mathrm{m}$ internal diameter, flow rates are of the order of $1\,\mu\mathrm{lmin}^{-1}$, and extraction voltages lie in the range $2.5-4\,\mathrm{kV}$. Flow rates and voltages are reduced in so-called "nanospray systems", based on capillaries having internal diameters down to $\approx 10\,\mu\mathrm{m}$. Decreasing the capillary diameter and lowering the flow rate also tends to create ions with higher mass-to-charge ratio, extending the applicability further towards biomolecules.

Forces

An ion of mass m and charge q travelling with a velocity $\boldsymbol{v}$ in an electric field with strength $\boldsymbol{E}$ and a magnetic field with flux density $\boldsymbol{B}$ experiences a force $\boldsymbol{F}$ defined by the Lorentz force law. This equation can be combined with Newton's laws to yield the acceleration $\boldsymbol{a}$ as:

$$\boldsymbol{F} = q(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B}) = m\boldsymbol{a} \tag{5}$$

Many combinations of electric and magnetic field are exploited in mass spectrometry.

Ion Velocity

For example, in an electric field E that acts only in the x-direction, we obtain:

$$F = qE = m\frac{\mathrm{d}^2x}{\mathrm{d}t^2} \tag{6}$$

Here t is time, and $E = \mathrm{d}V/\mathrm{d}x$, where $V(x)$ is the potential variation that gives rise to the field. Integrating from zero potential at the origin to V_a at x we obtain the ion velocity v as:

$$\frac{1}{2}mv^2 = qV_\mathrm{a} \quad \text{so that} \quad v = \sqrt{\frac{2qV_\mathrm{a}}{m}} \tag{7}$$

This result implies that ions accelerated through a common potential will acquire a velocity that varies as the inverse square root of their mass.

M

Filtering by Time-of-Flight

A simple method of constructing a mass spectrometer is based on time-of-flight (TOF), first described by Cameron in 1948. A pulse of ions of mass m entering an analyser of length L at zero time will exit at time τ , given by:

$$\tau = \frac{L}{v} \quad \text{so that} \quad \frac{m}{q} = \frac{2V_\mathrm{a}\tau^2}{L^2} \tag{8}$$

This result implies that the time-of-flight τ is a direct measure of the mass-to-charge ratio m/q. However, the time-scale is non-linear, and flight times reduce linearly with the characteristic dimension L of the system. Consequently, very short ion pulses and fast detector electronics are required in miniaturised TOF-MS.

Magnetic Filtering

An alternative method of filtering is based on the use of a magnetic field. Magnetic mass spectrometers were developed and improved by the fathers of mass spectrometry, Thompson, Aston and Bainbridge, in the early part of the 20th century. An ion with velocity v travelling in a perpendicular magnetic field of flux density B will follow a circular trajectory of radius r, found from a balance between the magnetic and centrifugal forces as:

$$qvB = \frac{mv^2}{r} \quad \text{so that} \quad r = \frac{m}{q}\frac{v}{B} \tag{9}$$

This result may be combined with the earlier expression for velocity to obtain:

$$\frac{m}{q} = \frac{B^2 r^2}{2V_a} \tag{10}$$

These two results imply that a magnetic field will disperse ions into trajectories of different radius, depending on their mass. Greater dispersion can be obtained by reducing the ion energy V_a; however, V_a cannot be reduced arbitrarily, and must typically be significantly larger than the thermal energy of the ion. A small radius (and hence a compact instrument) is only obtained with a powerful magnet. Consequently, magnetic filtering is difficult to scale into the MEMS size domain.

Crossed Field Filtering

Consider now the case when an additional electrostatic field E is introduced, perpendicular to both the ion velocity and the magnetic field. This field will generate an additional force, which can compensate for the magnetic force, partially straightenening the ion trajectories in a magnetic mass spectrograph. The two forces can balance exactly if:

$$qvB = qE \quad \text{so that} \quad v = \frac{E}{B} \tag{11}$$

In this case, the trajectory is exactly a straight line. An arrangement of crossed fields, with a pair of co-linear apertures allowing only line-of-sight path, will therefore act as a filter (first demonstrated in 1898 by Wien) for ions with the velocity given above. If the exit aperture in a Wien filter is replaced with a detector array, ions will be dispersed across the array so that the device acts as a mass spectrograph. In this case, the mass resolution is:

$$\frac{m}{\Delta m} = \frac{EL^2}{2V_a \Delta w} \tag{12}$$

Here L is the length of the filter and Δw is the spacing of the detector array.

Quadrupole Filtering

Filtering may be carried out in an entirely different way using a method invented by Paul and Steinwedel in 1953 and based on a time-varying hyperbolic electrostatic field. Four parallel electrodes with suitable cross-sections are used to establish the two-dimensional potential $\phi(x, y) = \phi_0 \left(x^2 - y^2\right)/2r_0^2$. Here r_0 is the radius of an inscribed circle that just touches the electrodes, where the potential $\phi = \pm\phi_0/2$. The field will exert forces in both the x- and y-directions on an ion moving in the z-direction. For a singly charged ion, the equations of motion are:

$$m\frac{d^2x}{dt^2} = -e\frac{\partial\phi}{\partial x} = -e\frac{\phi_0 x}{r_0^2} \qquad m\frac{d^2y}{dt^2} = +e\frac{\phi_0 y}{r_0^2} \tag{13}$$

When the time variation of the potential is $\phi_0(t) = U - V\cos\left[\omega\left(t - t_0\right)\right]$, where $\omega = 2\pi f$ is the angular frequency, ωt_0 is the starting phase and U and V are constant potentials, we obtain:

$$\frac{d^2u}{d\zeta^2} + \left\{a_u - 2q_u \cos\left[2\left(\zeta - \zeta_0\right)\right]\right\}u = 0 \tag{14}$$

Here, the normalised parameters used are $\zeta = \omega t/2$, $\zeta_0 = \omega t_0/2$, $a = 4eU/\left(m\omega^2 r_0^2\right)$ and $q = 2eV/\left(m\omega^2 r_0^2\right)$, u is x or y, and $a = a_x = -a_y$ and $q = q_x = -q_y$.
Solution of the equations shows that the nature of the trajectory depends almost entirely on a and q, varying little with the initial conditions ζ_0, $u(0)$ and $u'(0)$ of the ion. There are a several regions on the $q - a$ plane that give rise to stable solutions. The so-called "lower stability region", most commonly used for mass filtering, is an approximately triangular region, bounded by the loci:

$$\begin{aligned} a_0(q) &= \frac{q^2}{2} - \frac{7q^4}{128} + \frac{29q^6}{2304}\cdots \\ b_1(q) &= 1 - q - \frac{q^2}{8} + \frac{q^3}{64} - \frac{q^4}{1536}\cdots \end{aligned} \tag{15}$$

The locus a_0 defines the limit for trajectories that are stable in the y-direction, while b_1 is the limit for trajectories in the x-direction. Between the two, trajectories are stable in both directions. The apex of the stable region lies at $a = 0.237$, $q = 0.706$ so that $a/2q = U/V = 0.168$. In a quadrupole mass spectrometer, U and V are normally ramped together, following a line passing just below the apex of the lower stability region. Stable trajectories are only obtained for a narrow mass range, so that the device acts as a tuneable mass filter. An attractive feature of miniaturisation is that U and V scale with r_0^2, so that decreasing the linear dimension of an instrument by (say) 10 will reduce both potentials 100-fold.
The mass resolution varies as $m/\Delta m \approx n^2/20$, where n is the number of cycles of the RF field experienced by an ion. Ions are normally injected with a constant axial energy V_a. The number of cycles is $n \approx fL/v$, where L is the quadrupole length, so the uncertainty in mass is:

$$\Delta m \approx \frac{40eV_a}{f^2L^2} \tag{16}$$

Thus, the uncertainty in mass increases as the quadrupole is reduced in size. Compensation can be provided, by increasing the frequency, but this in turn requires an increase in voltage.

Quadrupoles are attractive candidates for miniaturisation, since they do not require either a magnetic field or very fast electronics. However, the challenge in miniaturising a quadrupole is generally to achieve a suitably high mechanical precision, since the accuracy of the hyperbolic field determines the ultimate resolution. One important aspect is electrode mounting, which requires precise assembly. Another is the shape of the electrodes. Hyperbolic electrode cross-sections are normally too complex to machine, and are replaced by cylinders, with the ratio of the cylinder radius r_e to r_0 being chosen to give the best approximation to a hyperbolic potential variation.

Ion Trap Filtering

The ion trap is a variant of the quadrupole mass spectrometer, which was first described by Paul and Steinwedel in 1960. It consists of a circular hyperbolic electrode, with spherical electrode caps at the top and bottom, and can be conceived as a quadrupole bent round in a circle. The three electrodes correspond to three of the rods of the bent quadrupole, while the fourth (inner) rod is reduced to a vanishingly small point.

As with the quadrupole spectrometer, a potential $+\phi_0$ consisting of both DC and radio frequency AC components is applied to the end caps, while a potential $-\phi_0$ is applied to the ring electrode. Ions of all masses are then trapped by the resulting three-dimensional, time-varying electrostatic field, and follow stable, closed trajectories, that are shaped approximately like the figure “eight”.

In a quadrupole, ions are injected continually, and the potentials are adjusted so that only ions of a particular mass can transit successfully. In the ion trap, however, the method of obtaining a mass spectrum is rather different. The different masses are held together inside the trap, and are expelled in sequence by applying a further voltage at a particular resonant frequency to obtain the spectrum. Consequently, the sensitivity of a miniaturized ion trap is limited by the amount of charge that can be stored inside a small volume in the face of charge repulsion effects. A general problem with miniaturisation is therefore loss of sensitivity, but this may be overcome to some extent by using a two-dimensional array of traps. Ion traps are also attractive candidates for miniaturisation. Once again, exactly shaped electrodes are generally too complex to machine, and structures with optimised combinations of cylindrical ring and planar end-cap electrodes are normally used.

Key Research Findings

We now give a few examples of miniaturised mass spectrometer systems, restricting the discussion to cases where planar technology has clearly been employed.

Ion Sources

Most of the results from microfabricated mass filters to date have been obtained from hybrid systems fitted with conventional ion sources, and only limited work appears to have been carried out on planar sources. Consequently, the ideal of a fully integrated chip-based mass spectrometer still appears some way off.

Yoon et al. of Ajou University have successfully fabricated a tungsten filament with an extraction grid and other electrodes formed in nickel on a silicon substrate, as shown in Fig. 1a [1]. To allow its very high operating temperature to be reached, the filament was suspended over a pit formed by anisotropic wet chemical etching. Emission currents up to 7 nA were obtained with an applied voltage of 35 V.

Considerably more attention has been paid to cold cathode sources, due to intensive industrial efforts to develop field emission displays. Emitters are constructed in the classical Spindt geometry, in which a sharp tip with a radius of 1 – 10 nm is fabricated by isotropic dry etching of silicon in a SF_6 plasma. Self-aligned anodes and focusing electrodes have been demonstrated, emission currents have been stabilised, and current densities and lifetimes have been improved using coatings of thin film diamond-like carbon. Figure 1b shows the cross-section and emission characteristic of a source fabricated by Huq of Rutherford Appleton Laboratory, which follows the Fowler–Nordheim relation given earlier [2]. Cold cathode sources have been used extensively with ion traps, because the geometry allows electrons to be injected directly into the trap as shown in Fig. 1c.

Müller of the Technische Universität Hamburg-Harburg has demonstrated an interesting plasma ion source [3]. The source is a small chamber operating at higher pressure than the mass analyser, within which a discharge is excited. Figure 1d shows the source, which uses a three-layer stack of etched Pyrex wafers containing a plasma chamber beneath a DC extraction grid. Ionisation is accomplished with electrons extracted from inert gas plasma. The plasma is ignited by a piezoelectric spark discharge and sustained by microwave excitation. Electron currents of 100’s of μA have been obtained using RF powers of 350 mW at pressures of 80 Pa, with accelerating voltages as low as 100 V.

Considerably more work has been carried out on chip-based electrospray ionisation sources. Ramsey et al. of Oak Ridge National Laboratory were the first to show that a spray could be drawn from the edge of a glass

chip containing an etched capillary [4]. Since then, integrated capillaries have been demonstrated in many materials and geometries. Nozzles have been combined with a sample and buffer reservoirs in glass substrates, and additional channels have been provided for sheath flow. More complicated devices combine sample inlet ports, preconcentration sample loops, separation channels and pneumatic nebilizers. One issue with all glass substrates is their hydrophilic nature, which allows the Taylor cone to spread laterally over the edge of the chip as the flow rate increases, reducing the separation of mass peaks. This problem has been overcome using plastics and a wide variety of coatings and substrate materials have been investigated. Other geometries suitable for planar integration, including open channels and nibs, have also been demonstrated.

Mass Filters

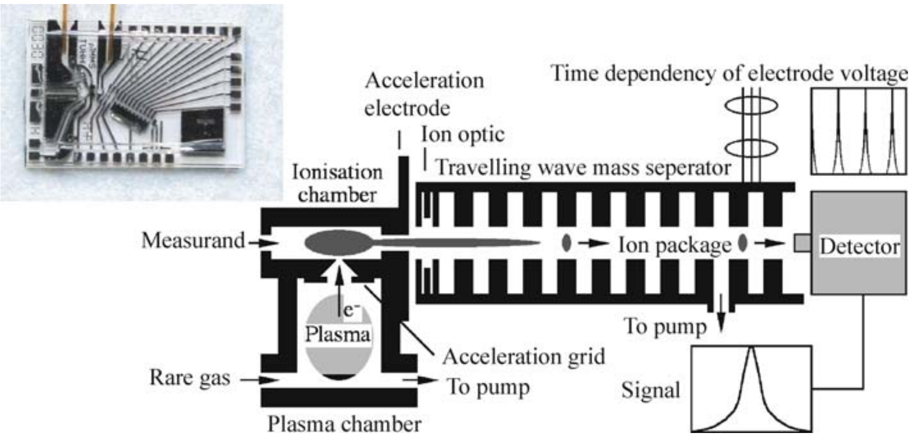
Many of the ‘classical’ variants of mass filter have been demonstrated using planar technology. A recent review by can be found in [5].

The best example of a chip-based time-of-flight filter is the previously mentioned example developed by Yoon [1], which uses electroplated metal electrodes for ion coupling and detection. Using a 1 cm^2 chip, the flight times were up to 5 μS for masses up to 100 atomic mass units (amu). Despite the small size of the chip, mass filtering has been convincingly demonstrated. Figure 2a shows the mass spectrum of acetone, which was however obtained using a Q-switched Nd-YAG laser for ionization rather than the hot-filament source.

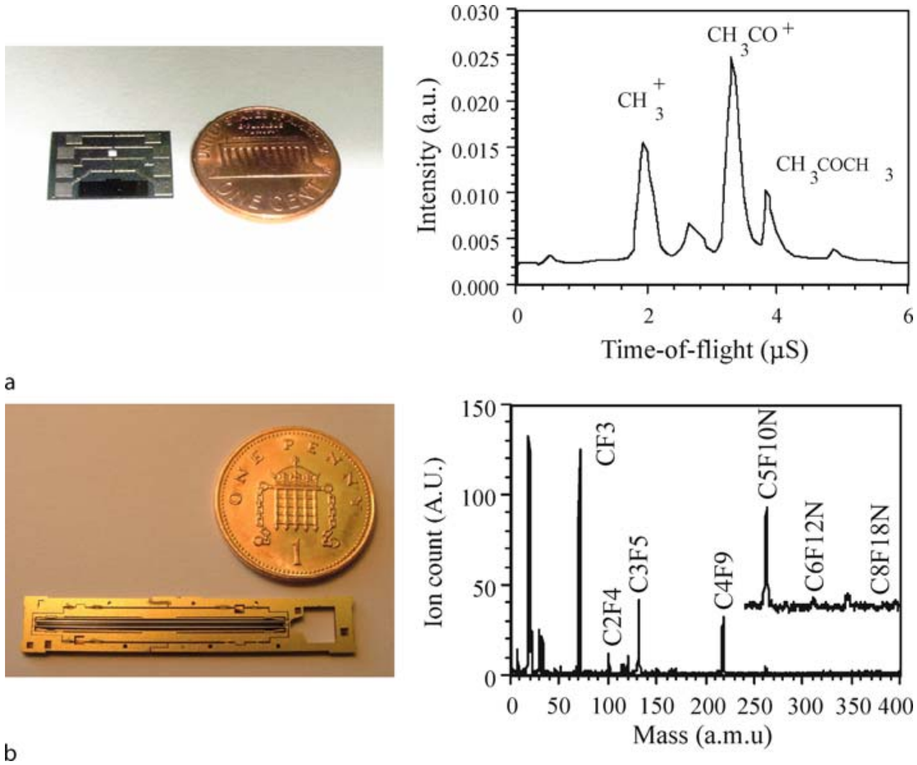
A novel microengineered instrument with a rather different planar electrode layout has been proposed by Müller [3]. Figure 1d shows the device, which uses the microwave ion source described earlier and electrostatic filtering. This time, however, mass selection is based on the filtering action provided by the interaction between the ion beam and a three-phase travelling electrical field, which is created by a periodic electrode structure fed by suitably phased drive signals.

Syms of Imperial College London and Taylor of Liverpool University have demonstrated microfabricated quadrupole filters using a pair of etched silicon substrates separated by glass rods [6]. Each substrate carried two of the four cylindrical electrodes, and the glass rods spaced the assembly apart by the distance needed to achieve the quadrupole geometry. Mass spectra were demonstrated early on, but various aspects of performance (particularly, the mass range, which was restricted to 100 amu) were limited by RF heating caused by capacitative coupling through the substrates.

Geear et al. of Microsaic Systems [7] has demonstrated a more advanced MEMS quadrupole. The device is formed from two bonded silicon-on-insulator substrates, which



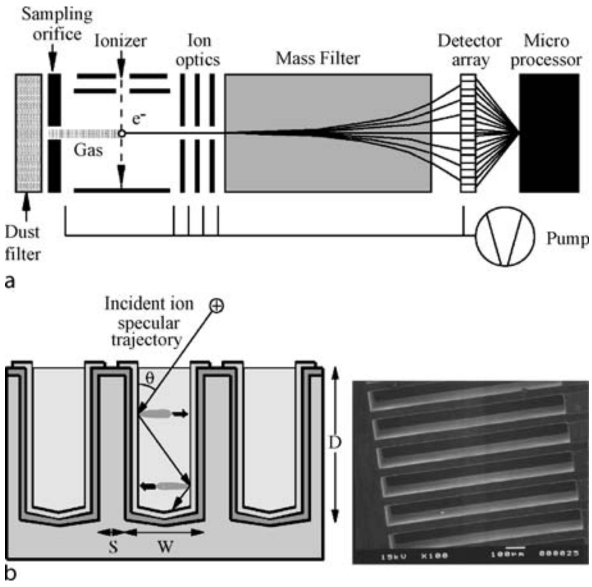
Mass Spectrometry on a Chip, Figure 1 (**d**) Microfabricated plasma ion source with a travelling-wave mass filter (courtesy Prof. Jörg Müller)



Mass Spectrometry on a Chip, Figure 2 (**a**) Microfabricated time-of-flight mass filter and a mass spectrum obtained for acetone (courtesy Dr. Hyeun Joong Yoon); (**b**) Microfabricated quadrupole mass filter and a mass spectrum obtained for PFTBA (courtesy Microsaic Systems Ltd.)

are attached together to form a monolithic block. Deep etched features and springs formed in the outer silicon layers are used to locate cylindrical metal electrode rods, while similar features formed in the inner silicon layers are used to define integrated ion entrance and exit optics. Mass filtering has been demonstrated, with a mass range of ≈ 400 amu and a resolution of 1 amu at a mass of 219 amu, using quadrupoles with rods of 500 μm diameter and 30 mm length, operating at 6 MHz RF frequency. Figure 2b shows the device itself and the mass spectrum of perfluorotributylamine (PFTBA).

Many groups have fabricated ion traps, using the cylindrical approximation to the ideal hyperbolic geometry shown earlier in Fig. 1c. Ramsey and Whitten at Oak Ridge



Mass Spectrometry on a Chip, Figure 3 (**a**) Microfabricated Wien mass filter by (courtesy Dr. Carl Freidhoff); (**b**) Microfabricated Faraday cup array (courtesy Prof. Bruce Darling)

National Laboratory have constructed traps, with 1/1000 of the volume of conventional devices [8]. A mass range from 40 to 400 amu has been demonstrated, with peak widths less than 0.2 amu for single scans. The device has been operated with a frequency quadrupled Nd-YAG laser photo-ionization source, and both hot cathode and cold-cathode electrode impact ionization sources.

Freidhoff et al. of Northrop Grumman has developed a microfabricated Wien filter mass spectrometer [9]. The device is a mass spectrograph based on a continuous ion source, fixed, crossed magnetic and electric fields, and an ion detector array, as shown in Fig. 3a. The whole analyser is formed in a shallow cavity etched into a single silicon substrate a few cm long. Because of the near-planar geometry of the cavity, it is difficult to establish a uniform, fixed electric field, and a discontinuous field approximating the desired field is derived from a set of parallel coplanar electrodes biassed by a resistor chain. Despite these difficulties, preliminary data has been obtained for a mass range of 40 – 200 amu with a peak width of 1 amu at 60 amu.

Ion Detectors

Most miniature mass spectrometers have used a single detector such as a channeltron, which allows spectra to be obtained in serial form by scanning the filter passband. For example, in a magnetic separator, the magnetic field can be ramped, and in a quadrupole, the two components of the electric field can be varied in a fixed ratio. This method has the disadvantage that ions of a given mass are only observed for a fraction of the time available. Improved sensitivity is obtained by parallel detection, which allows continual observation.

The most advanced chip-based ion detectors are the microfabricated Faraday cup arrays fabricated by Darling of Washington University [10], for use with a compact linear dispersion magnetic mass spectrograph. Deep reactive ion etching of silicon was used to form high aspect ratio trenches, which were then oxidised and metallised to form an array of independently addressable MOS capacitors as shown in Fig. 3c. Detector arrays were constructed with up to 256 elements and with pitches down to 150 μm, and the arrays have been combined with an electronic multiplexer to allow serial readout.

Future Directions for Research

The overall goal of miniaturizing mass spectrometers – to allow wider access to the most versatile method of chemical analysis yet developed – is an important one. Particularly, the availability of portable systems could allow the use of accurate identification methods outside the laboratory. The key goals of future work are to improve mass range and mass resolution of miniaturized mass filters, and the reliability and efficiency of compatible ion sources.

Definition

The intensive interplay of engineering and materials science has always been an important driving force in the rapid evolution of microfluidic technologies and their strikingly wide range of applications [1]. To date, numerous materials, including silicon, quartz/fused silica, glass, ceramics, polymers, and metals, have been used in fabricating microfluidic devices bearing diverse functionalities. In general, a microfluidic device can be built by first fabricating (by dry or wet etching, mechanical machining, molding, or casting) open microchannels or features in a flat substrate, and then bonding this substrate to another flat plate with predrilled access holes, thereby forming an enclosed microchannel network with the desired configuration and dimensions. The materials used, which serve as the building blocks of various types of microfluidic devices, are also called the *bulk materials* or *substrates* of these devices.

Chemical and Physical Principles

More than simply serving as the mechanical support and defining the structures of the embedded microfluidic networks, materials also play a critical role in the determination of the specific properties, overall performance, and range of applicability of microdevices [2]. The bulk of the material can serve as a medium for heat transfer, electrical conduction, transmission of light, or transduction of mechanical force; the surfaces that form the channel walls will significantly interact with the fluid medium and, consequently, influence the constitution or physical behavior of the fluid. All these functions of materials are determined by their intrinsic physical and chemical properties, and various techniques for controlling these properties. Table 1 [3] lists some of the materials commonly used for fabrication of microfluidic devices, and typical properties of them that are relevant to the performance of microfluidic devices.

The success of a microfluidic device is significantly influenced by the properties of the substrate materials, and thus it is of crucial importance to choose the right materials for specific devices and, sometimes, it is also necessary to find techniques to modify the bulk or surface properties of these materials. These are very much dependent on the desired application and the required functionality of the microfluidic device. For instance, if one is building a microreactor for a chemical reaction that requires a wide range of controllable operating temperatures and pressures, silicon and stainless steel might be the materials of choice owing to their superior temperature and mechanical performance [4]. On occasions where imaging or optical detection of processes in the device is required, optical transparency within a suitable wavelength range is a prerequisite property of the material. Another example is single-molecule detection, where quartz is generally chosen to fabricate the chip because this material has an extremely low intrinsic fluorescence, thus significantly increasing the signal-to-noise ratio. Consideration should also be given to the processability of the material. For instance, silicon might be a better choice if high-aspect-ratio features are required, as these can be obtained through well-established dry or wet etching procedures; for glass or fused silica, only shallow channels or features with a low aspect ratio are obtainable if wet chemical etching is adopted. For microfluidic devices for cellular analysis, the material in which microchannels are embedded is generally required to be porous to maintain communication of the cells with the external environment (exchange of nutrients, CO_2, O_2, etc). In this case, hydrogels are suitable materials. Their porosity can be adjusted thermally or electrically.

One basic attribute of microchannels or microstructures is their substantially high surface-to-volume ratio, which is a direct consequence of miniaturization. Thus the surface properties of a material usually play a predominant role in realizing specific functionalities or influencing the performance of a microfluidic device. For instance, in a glass

microdevice, hydrolysis of the surface silicon dioxide leads to formation of a negative charge on the channel surface. This property of glass provides a basis for realizing electroosmotic pumping and electrophoretic separation. In addition, there are often occasions where techniques for modifying the surface properties are required. Many biochemical applications, for instance, require surfaces with substantially suppressed adsorption of biomolecules or cells. This can sometimes be achieved by physical or chemical modification of the channel surface with surfactants or polymers, such as polyacrylamide, poly(ethylene glycol), and poly(vinyl chloride) [5]. In this case, the amenability of the material to surface modification (generally determined by the chemical composition of the material) needs also to be considered.

Principally, the selection of an appropriate material for any particular type of microdevice is dependent on the microfluidic assay implemented in the device. In practice, there is often a compromise between the desired properties of the material and the availability of a technology for micromachining or tuning the properties of the material. For this reason, in the field of microfluidics, there has always been interest in testing and designing new materials and, at the same time, developing novel techniques for microfabrication of these materials.

Key Research Findings

Historically, silicon and, later on, glass were the materials mainly used in early microfluidic devices. As a result of the growing desire for new applications of microfluidic devices and the demand for more advanced and flexible functionalities in these devices, however, the range of materials applicable in microfluidic devices has been constantly expanding. At present, the most frequently used substrate materials include silicon, glass or quartz, and various types of polymers.

The early microfluidic devices were mostly fabricated in silicon, because it was a straightforward choice to adopt well-developed microfabrication methods and materials from the semiconductor industry. Well-established wet and dry etching procedures enable the fabrication of microstructures in silicon with controlled geometries and dimensions. The excellent mechanical strength and thermal performance of silicon make it a good material of choice for building microreactors [4]. In addition, the availability of technologies for modification of its surface, for silicon–silicon and silicon–glass bonding, and for fabrication of various chemical or physical sensors has also greatly extended its application in microfluidics. However, the semiconducting properties of silicon have limited its application in electric-field-driven processes such as electroosmotic pumping and electrophoresis. Its opacity to UV and visible light has also hindered applications that require optical detection or imaging.

Glass and fused silica are attractive as substrate materials for microfluidic devices owing to several advantages over silicon and many other materials. Their transparency in the UV and visible range facilitates their application in optical detection and imaging. Their chemical and thermal resistance makes them also applicable in chemical-reaction devices. The desired microchannel features can be easily constructed on glass or quartz substrates by use of photolithographic technology originating from the semiconductor industry [6]. The native surfaces of glass/quartz microchannels bear a negative charge in aqueous media, making them ideal substrates for electrophoresis devices. In addition, since there are many well-established meth-

ods for the physical and chemical modification of the surfaces of glass and fused silica, these materials have frequently become the first choice for building miniaturized bioanalytical devices. The usability of glass or fused silica is mainly limited by the difficulties of fabricating high-aspect-ratio microstructures in these materials. This has limited their application where complex microstructures are required.

Most of the polymeric materials used in microfluidic devices are transparent, and can generally be classified into elastomers (e. g. PDMS) and plastics (e. g. PMMA). The increasing interest in these polymeric materials is driven by the fact that they can be fabricated with desired microstructures with a high throughput and low cost. The microstructures can be fabricated by casting, injection molding, or thermal molding [7]. All of these methods involve repetitive usage of a mold that includes a prefabricated negative of the desired microstructure; a similar process is used widely for the mass production of polymeric products, and thus the costs of production of microfluidic devices from polymers can be substantially lower than from other materials. High-aspect-ratio and complex microstructures are easily obtainable in these materials, although this depends on the quality of the mold. The main concern in using polymeric materials lies in their comparatively poor surface properties and their incompatibility with most organic solvents. Efforts have been put into testing and designing new polymers with improved properties and developing new methods for surface modification [8].

One noteworthy trend in microfluidics is the introduction of novel materials that, conventionally, have rarely been considered as microdevice substrates. One recent example is the use of a biodegradable polymer as a base material to fabricate microdevices with embedded microfluidic networks that resembles microvascular systems [9], work that is helping to expand the range of applications of microfluidic devices into the field of tissue engineering.

Examples of Application

Poly(dimethylsiloxane) (PDMS) is probably the most popular material used in microfluidic devices at present. PDMS is a transparent elastomeric material that is made by heating a precursor mixture containing vinyl-terminated linear polymers of poly(dimethylsiloxane), a certain amount of a cross-linking agent, and a catalyst. The microfabrication of PDMS is rather straightforward and cost-effective: by casting a liquid precursor mixture over a mold and heating at 60 – 80 °C for several hours, an elastomeric solid with a faithfully replicated microstructure can be formed. This process is often referred to as replica molding. The fabricated PDMS slab can be easily bonded to another flat PDMS or glass slab by either conformal contact (reversible bonding) or covalent bonding. Whitesides et al. [10] were the first to propose the use of PDMS for microfabrication and for building microfluidic devices by use of these methods. The PDMS material was demonstrated to be a strikingly versatile material that enabled a wide range of new functions and applications of microfluidic devices. One of the fully explored properties of PDMS is its elasticity. A typical example of an application is the fabrication of multilayered fluidic structures in this material; by applying a force to cause deformation of a fluid channel and then releasing the force, active valves or pumps can be realized [11].

Matrix Assisted Laser Desorption/Ionization

Synonyms

MALDI

Definition

Matrix Assisted Laser Desorption/Ionization (MALDI) is one of two "soft" ionization techniques used to introduce biological samples into a mass spectrometer. In MALDI, the analyte is co-crystallized with a solid matrix to form a dry spot on a surface. Under vacuum, the sample is then irradiated with a laser, which desorbs the sample from the surface and ionizes it. The developers of MALDI (along with the developer of ESI) were awarded the 2002 Nobel Prize in Chemistry.

Definition

Mean filters are also known as box filters. The value to be filtered is averaged with its neighbors.

Mean Free Path

Definition

Mean free path is the average distance travelled by gaseous particle between collisions.

Measurement Depth

Definition

At visualization of flows the measurement depth and field of view define the measurement volume. The extension of the measurement volume in direction of the camera is the measurement depth. If ► volume illumination is used, the measurement depth is dependent on the ► depth of field of the camera optics. Otherwise, when illuminating with a ► light sheet, the measurement depth is defined by the thickness of the ► light sheet, since the ► depth of field is larger than the thickness of a ► light sheet in most applications.

Synonyms

EDL potential; Surface potential

Definition

Zeta potential is defined as the electric double layer (EDL) potential located at the shear plane between the Stern layer and the diffuse layer of the EDL that is formed in the neighborhood of a charged solid–liquid interface. Zeta potential is an experimentally measurable electrical potential that characterizes the strength and polarity of the EDL of the charged solid–liquid interface. Depending on the solid surface and the solution, zeta potentials values are within a range of -100 mV to $+100$ mV for most solid–liquid interfaces in aqueous solutions.

Overview

Electric Double Layer and Zeta Potential

The necessary condition for development of zeta potential is the presence of electrostatic charges at solid–liquid interface. The charging mechanisms of the solid–liquid

interface are complex, possibly including the asymmetric dipoles of water molecules residing at the solid–liquid interface, adsorption of ions, disassociation of ionic groups, charge separation etc. Such surface charges influence the distribution of nearby ions in the solution. Counter-ions (i. e., ions of opposite charge) are attracted towards the solid surface, while co-ions (i. e., ions of like charge) are repelled from the surface. This electrostatic interaction together with the random thermal motion of the ions, leads to the formation of the so-called *electric double layer* (EDL). The model of EDL was first developed by Gouy and Chapman in 1906, and then improved by Stern in 1924 [1]. According to Stern's model, the EDL consists of a compact (or Stern) layer and a diffuse layer. The Stern layer, usually less than one nanometer, exists immediately next to the solid surface, where counter-ions are strongly attracted to the solid surface thus immobile. The diffuse layer of the EDL is the layer from the Stern layer to the bulk liquid, and its thickness ranges from several nanometers to sub-micrometers, depending on liquid solution properties. Compared to the ions in the Stern layer, the ions in the diffuse layer are less influenced by the charged surface and hence are mobile. A review of modern EDL theory including recent descriptions and formulations of the basic structure (and component regions) of the EDL is given by Dukhin et al. [2].

The zeta potential (ζ) is thought to be the same as the Stern potential which is defined at the plane dividing the Stern layer and the diffuse layer of the EDL. Zeta potential is an experimentally measurable electrical potential that characterizes the EDL, and it plays an important role in many applications such as stability of colloidal dispersion, characterization of biomedical polymers, electrokinetic transport of particles, and capillary electrophoresis, etc. In addition, zeta-potentials of the particles and the channel wall are crucial to the design and process control of microfluidic devices. A review on measuring the zeta potential of microfluidic substrates was provided by Kirby and Hasselbrink [3].

Methods for Measuring Zeta Potential

Several techniques have been developed to measure the zeta potential, based on the principle of electrokinetics. In this entry, the conventional methods of measuring the zeta potential using the mechanisms of electrophoresis, streaming potential, and electroosmotic flow will be outlined first. Then, a novel method will be presented for simultaneously determining the zeta potentials of both the microchannel surfaces and the tracer particles by using the microscale particle image velocimetry (micro-PIV) technique. This method combines the theories of electroosmosis and electrophoresis, and uses micro-PIV technique to measure the steady electrokinetic velocity distributions of tracer particles in open- and closed-end microchannels [4].

Electrophoresis Method

Electrophoresis refers to the motion of a charged particle in a solution in response to an applied electric field. The electrophoresis technique has been widely used to characterize the electrokinetic properties of charged particle–liquid interfaces. In the electrophoresis method, fine particles (usually of 1 µm in diameter) are dispersed in a solution. Under an applied electric field, the particle electrophoresis mobility, v_E, defined as the ratio of particle velocity to electric field strength, is measured using an appropriate microscopic technique. The particle ζ-potential is determined from the measured electrophoresis mobility, v_E by using the Smoluchowski equation expressed as

$$v_E = \frac{\varepsilon_0 \varepsilon_r \zeta}{\mu} \tag{1}$$

where ε_r is the dielectric constant of the solution, ε_0 is the permittivity of vacuum, μ is the dynamic viscosity of the solution.

This technique has been also applied to characterize flat solid surfaces by initially grinding the flat surfaces into fine powders. However, it is unclear if the surface electrostatic properties of these grinded particles are equivalent to the precrushed surfaces.

Streaming Potential Method

The streaming potential technique has been extensively used to characterize the electrokinetic properties of flat solid–liquid interfaces. The streaming potential is an induced electrokinetic potential in a pressure-driven flow through a charged capillary. In principle, when a liquid is forced to flow through a capillary under an applied hydrodynamic pressure, the non-zero net charge density in the diffuse layer of the capillary EDL is carried by the flow, giving rise to an electrical current in the pressure-driven flow direction, called the streaming current. Correspondingly, there is an induced electrokinetic potential called the streaming potential which is a potential difference that builds up along the capillary. Such induced streaming potential acts on ions in the electrolyte solution to generate a so-called conduction current in opposite direction of the flow. It is obvious that when ions move in a viscous liquid, they will pull the liquid molecules along

with them, resulting in a reduced flow rate in the pressure-driven flow. As such change in the flow characteristics is associated with the EDL of the capillary, the ζ-potential of the capillary–liquid interface is directly related to the streaming potential. For a steady, laminar liquid flow, the relationship between the streaming potential and the capillary ζ-potential without consideration of the surface conductance effect is given by

$$\frac{E_s}{\Delta P} = \frac{\varepsilon_0 \varepsilon_r \zeta}{\lambda_b \mu} \tag{2}$$

where E_s is the streaming potential, ΔP is the applied pressure difference along the capillary, λ_b is the bulk electrical conductivity. While this technique is inherently suitable for a fluid flow over charged surfaces, accurately measuring the streaming potential seems not a simple task.

Electroosmosis Method

Electroosmosis refers to the liquid motion related to a stationary charged solid–liquid interface due to the interaction between an external electric field applied tangential to the charged surface and the excess net charges in the EDL of the surface. It is known that within the diffuse layer of the EDL, there is an excessive of counter-ions over co-ions, and thus the net charge density is not zero so as to neutralize the surface charge. If an electric field is applied tangentially along a charged surface, the electric field will exert the Columbic force on the ions in the diffuse layer, resulting in a net migration of the liquid in the EDL region. This is called *electroosmosis* (EO). In a charged micro-capillary, due to viscous forces the flow can be developed beyond the EDL region to the rest of the liquid in the capillary, leading to a bulk *electroosmotic flow* (EOF). Certainly the induced EOF is affected by the capillary EDL, which in turns is related to the capillary ζ-potential. Under the slip velocity approximation, the Smoluchowski equation can be used to describe the relationship between the average velocity of the EOF and the capillary ζ-potential, expressed as:

$$u_{eo} = \frac{\varepsilon_0 \varepsilon_r \zeta E}{\mu} \tag{3}$$

where E is the applied electric field strength, and u_{eo} is the average velocity of the EOF.

In the literature, several methods such as the neutral marker method, the current monitoring method [5] etc have been introduced to indirectly determine the average liquid velocity of the EOF in a microcapillary so that the capillary ζ-potential can be determined using Eq. (3). However, in practice, there exist difficulties in identifying a real, electrically neutral marker and in locating the cut-off of the asymptotic current vs. time curve.

In following, a method will be introduced for simultaneously determining the zeta potentials of both the microchannel surfaces and the tracer particles by using the microscale particle image velocimetry (micro-PIV) technique.

Basic Methodology

Theory

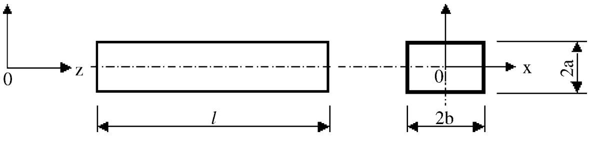
Micro-PIV technique is used to measure the steady velocity of tracer particles in an electrolyte in both open- and closed-end microchannels. Under an applied DC electric field, the observed particle velocity, u_p evaluated from the micro-PIV measurement is the superposition of the electrophoresis velocity of the charged particle, u_{ep}, and the electroosmotic velocity of the electrolyte, u_{eo}:

$$u_p = u_{eo} + u_{ep} \tag{4}$$

In the following, we will provide the analytical expressions for u_{ep} and u_{eo} in an open- and closed-end rectangular microchannel.

Velocity Distribution of the Steady Electroosmotic Flow in Open and Closed-end Microchannels – Slip Velocity Approach

Consider a rectangular microchannel having a height, $2a$, a width, $2b$, and a length, l as shown in Fig. 1. The liquid filled in the microchannel is assumed to be an incompressible, Newtonian, symmetric electrolyte of constant density, ρ, viscosity, μ, and dielectric constant, ε_r. The channel wall is uniformly charged with a zeta potential, ζ_w. When an external electric field, E is applied along the axial direction of the channel, the liquid sets into motion as a result of the interaction between the net charge density in the EDL of the channel and the applied electric field. The driving force of electroosmotic flow is present only within the EDL. The typical thickness of an EDL is in the range of 1 to 100 nm; while the characteristic hydraulic diameter of microfluidic channels is of order 10



Measuring Zeta Potential, Methods, Figure 1 Geometry of the rectangular channel. The channel length is l and the size of the rectangular cross section $2a \times 2b$

to 100 μm. Because of such orders of the magnitude difference, the electroosmotic velocity profile inside the EDL region becomes insignificant, and thus the electroosmotic flow can be considered to be induced by a moving wall with velocity (slip velocity) given by the Smoluchowski equation,

$$u_s = \frac{\varepsilon_0 \varepsilon_r \zeta_w E}{\mu} \tag{5}$$

In the literature, the fluid flow actuated by moving boundary of the wall and driven by hydrodynamic shear stresses is referred to as the Stokes second problem, and is specifically referred to as the slip velocity approach in electroosmotic flows. More general discussions of the applicability of such slip velocity approach in electrokinetic flows were provided elsewhere [6]. Using the slip velocity approach, the steady velocity field of a fully-developed flow driven by an applied electric field, E and a pressure gradient, $\mathrm{d}p/\mathrm{d}z$ is governed by the Stokes equation, expressed as

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = \frac{1}{\mu}\frac{\mathrm{d}p}{\mathrm{d}z} \tag{6}$$

The appropriate boundary conditions applicable to Eq. (6) are

$$u|_{x=b} = u_s \qquad u|_{y=a} = u_s \tag{7a}$$

$$\left.\frac{\partial u}{\partial x}\right|_{x=0} = 0 \qquad \left.\frac{\partial u}{\partial y}\right|_{y=0} = 0 \tag{7b}$$

Equation (6) together with its boundary conditions specified by Eqs. (7a) and (7b) can be non-dimensionalized by using the following dimensionless parameters:

$$\bar{u} = \frac{u}{U} \qquad X = \frac{x}{D_h} \qquad Y = \frac{y}{D_h}$$

$$Z = \frac{z}{D_h \mathrm{Re}_0} \qquad \bar{P} = \frac{p}{\rho U^2}$$

where U is the reference velocity, $D_h = 4ab/(a+b)$ is the hydraulic diameter of the rectangular channel, and $\mathrm{Re}_0 = \rho D_h U/\mu$ is the reference Reynolds number. Further, we introduce a transform

$$\bar{v} = \bar{u} - \bar{u}_s \tag{8}$$

Then, the governing Stokes equation and its boundary conditions can be rewritten in dimensionless form as

$$\frac{\partial^2 \bar{v}}{\partial X^2} + \frac{\partial^2 \bar{v}}{\partial Y^2} = \frac{\mathrm{d}\bar{P}}{\mathrm{d}Z} \tag{9}$$

with the boundary conditions

$$\bar{v}|_{X=b/D_h} = 0 \qquad \bar{v}|_{Y=a/D_h} = 0 \tag{10a}$$

$$\left.\frac{\partial \bar{v}}{\partial X}\right|_{X=0} = 0 \qquad \left.\frac{\partial \bar{v}}{\partial Y}\right|_{Y=0} = 0 \tag{10b}$$

where $\bar{v} = v/U$ and $\bar{u}_s = u_s/U = -(\varepsilon_0 \varepsilon_r \zeta_w E)/(\mu U)$.
Using Green's function method, the solution of Eq. (9) subjected to boundary conditions given by Eqs. (10a) and (10b) can be explicitly expressed as [7]

$$\bar{v}(X, Y) = \lim_{\bar{t}\to\infty} \int_{\tau=0}^{\bar{t}} \mathrm{d}\tau \int_{X'=0}^{b/D_h} \int_{Y'=0}^{a/D_h} G\left(X, Y, \bar{t} \middle| X', Y', \tau\right) \left(-\frac{\mathrm{d}\bar{P}}{\mathrm{d}Z}\right) \mathrm{d}X'\mathrm{d}Y' \tag{11}$$

Here, the Green's function $G\left(X, Y, \bar{t} \middle| X', Y', \tau\right)$ can be obtained by using the separation of variables method. The expression for $G\left(X, Y, \bar{t} \middle| X', Y', \tau\right)$ is given by [7]

$$G\left(X, Y, \bar{t} \middle| X', Y', \tau\right) = \frac{4D_h^2}{ab} \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \cos(\alpha_m X) \cos\left(\alpha_m X'\right) \cos(\beta_n Y) \cos\left(\beta_n Y'\right) \mathrm{e}^{-T_{mn}(\bar{t}-\tau)} \tag{12}$$

where $\alpha_m = \left(\frac{2m-1}{2}\right)\frac{D_h}{b}\pi$, $\beta_n = \left(\frac{2n-1}{2}\right)\frac{D_h}{a}\pi$ and $T_{mn} = \alpha_m^2 + \beta_n^2$.
Substituting Eq. (12) to Eq. (11) and carrying out the integration, we obtain

$$\bar{v}(X, Y) = -\frac{\mathrm{d}\bar{P}}{\mathrm{d}Z}\frac{16}{\pi^2} \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \frac{(-1)^{m+n} \cos(\alpha_m X) \cos(\beta_n Y)}{(2m-1)(2n-1) T_{mn}} \tag{13}$$

Here, two cases are considered:
Case 1: Electroosmotic flow field in an open-end rectangular microchannel
In this situation, $\mathrm{d}\bar{P}/\mathrm{d}Z \equiv 0$, because no external pressure is applied (assuming that the microchannel is infinitely extended). Thus, Eq. (12) becomes

$$\bar{v}\left(X, Y, \bar{t}\right) = 0 \quad \text{or} \quad \bar{u}\left(X, Y, \bar{t}\right) = \bar{u}_s \tag{14}$$

Equation (14) shows that for steady, fully-developed electroosmotic flow in an open-end rectangular microchannel,

the slip velocity approach leads to a "plug-like" velocity profile, given by the Smoluchowski equation:

$$u_{\mathrm{eo-open}} = -\frac{\varepsilon_{\mathrm{r}}\varepsilon_0\zeta_{\mathrm{w}}E}{\mu} \tag{15}$$

Case 2: Electroosmotic flow field in a closed-end rectangular microchannel

Due to the closed-end structure, an inner backpressure gradient $\mathrm{d}\bar{P}/\mathrm{d}Z$ is induced to fulfill the condition of the zero net flow rates, which mathematically is expressed as

$$\int_{-b/D_{\mathrm{h}}}^{b/D_{\mathrm{h}}}\int_{-a/D_{\mathrm{h}}}^{a/D_{\mathrm{h}}} \bar{u}\left(X, Y, \bar{t}\right)\mathrm{d}X\mathrm{d}Y = 0 \tag{16}$$

For an infinitely extended channel, $\mathrm{d}\bar{P}/\mathrm{d}Z$ is constant along the axial flow direction. Substituting Eqs. (8) and (13) into Eq. (16), we can show that the dimensionless induced pressure gradient is given by

$$\frac{\mathrm{d}\bar{P}}{\mathrm{d}Z} = \frac{\pi^4}{64}\frac{\bar{u}_{\mathrm{s}}}{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{1}{(2m-1)^2(2n-1)^2T_{mn}}} \tag{17}$$

Further substituting Eq. (17) back to Eq. (13) and noticing $\bar{v} = \bar{u} - \bar{u}_{\mathrm{s}}$, we can obtain

$$\bar{u}\,(X, Y) = \bar{u}_{\mathrm{s}} - \frac{\pi^2\bar{u}_{\mathrm{s}}}{4}\frac{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{(-1)^{m+n}\cos(\alpha_m X)\cos(\beta_n Y)}{(2m-1)(2n-1)T_{mn}}}{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{1}{(2m-1)^2(2n-1)^2T_{mn}}} \tag{18}$$

Equation (18) gives the electroosmotic velocity distribution in a closed-end rectangular microchannel.

As the microscope objective is focused on the mid-plane of the channel (i. e., $Y = 0$) during the micro-PIV experiment, the dimensional electroosmotic velocity at the mid-plane is expressed as

$$\begin{aligned} u_{\mathrm{eo-closed}}\,(X, 0) &= \bar{u}_{\mathrm{eo-closed}}\,(X, 0)\,U \\ &= -\zeta_{\mathrm{w}}\frac{\varepsilon_0\varepsilon_{\mathrm{r}}E}{\mu}\left[1 - \frac{\pi^2}{4}\frac{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{(-1)^{m+n}\cos(\alpha_m X)}{(2m-1)(2n-1)T_{mn}}}{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{1}{(2m-1)^2(2n-1)^2T_{mn}}}\right] \end{aligned} \tag{19}$$

Electrophoresis Velocity of the Tracer Particles

Under assumptions of the undisturbed EDL structure of a charged particle and the Debye–Hückel approximation, the electrophoresis velocity of tracer particles, according to Henry [1] can be expressed as:

$$u_{\mathrm{ep}} = \frac{2}{3}f\,(\kappa a)\,\frac{\varepsilon_{\mathrm{r}}\varepsilon_0\zeta_{\mathrm{p}}E}{\mu} \tag{20}$$

A simple expression for Henry's function $f\,(\kappa a)$ can be expressed as:

$$f\,(\kappa a) = 1 + \frac{1}{2\left[1 + \frac{2.5}{\kappa a(1+2\mathrm{e}^{-\kappa a})}\right]^3} \tag{21}$$

Here a is the radium of the tracer particle, and κ is the Debye parameter defined as

$$\kappa = \sqrt{\frac{2e^2z_{\mathrm{v}}^2n_0}{\varepsilon_{\mathrm{r}}\varepsilon_0 kT}}$$

(where e is the fundamental charge, z_{v} is the valence of the symmetric electrolyte, n_0 is the ionic number concentration of the bulk electrolyte, k is the Boltzmann constant, and T is the absolute temperature). It should be pointed out here that the Henry's expression for the electrophoresis velocity of tracer particles is applicable to both open-end and closed-end channels.

Relationships Between the Micro-PIV Measured Particle Velocity and the Zeta Potentials of the Channel Surface and the Particles in Open- and Closed-end Channels

As indicated by Eq. (4), the particle velocity measured from the micro-PIV technique is a combination of the electrophoresis velocity of the tracer particles which is related to the particle zeta potential, ζ_{p} and the electroosmotic flow field which is associated with the zeta potential of the channel surface, ζ_{w}. If micro-PIV experiments are carried out in an electrolyte in open-end and closed-end microchannels, according to Eq. (4), we can write the expressions for the micro-PIV measured velocity of the tracer particles in open-end and closed-end rectangular microchannels as below:

$$u_{\mathrm{p-open}} = u_{\mathrm{eo-open}}\,(\zeta_{\mathrm{w}}, E_1) + u_{\mathrm{ep}}\left(\zeta_{\mathrm{p}}, E_1\right) \tag{22}$$

$$u_{\mathrm{p-closed}} = u_{\mathrm{eo-closed}}\,(\zeta_{\mathrm{w}}, E_2) + u_{\mathrm{ep}}\left(\zeta_{\mathrm{p}}, E_2\right) \tag{23}$$

where E_1 and E_2 are the electric field applied across the open-end and closed-end channel, respectively.

We define the particle mobility, μ_p measured by micro-PIV technique in an electric filed, E as

$$\mu_p = \frac{u_p}{E} \tag{24}$$

Making use of the results of Eqs. (15), (19), and (20), we can further rewrite Eqs. (22) and (23) in terms of the measured particle mobility as

$$\mu_{p-open} = \zeta_w F + \zeta_p G \tag{25}$$

$$\mu_{p-closed} = \zeta_w H(x) + \zeta_p G \tag{26}$$

where the expressions for F, H, and G are given by

$$F = -\frac{\varepsilon_r \varepsilon_0}{\mu} \qquad G = \frac{2}{3} f(\kappa a) \frac{\varepsilon}{\mu} \tag{27a}$$

$$H(x) = -\frac{\varepsilon_0 \varepsilon_r}{\mu}\left[1 - \frac{\pi^2}{4} \frac{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \frac{(-1)^{m+n}\cos(\alpha_m x/D_h)}{(2m-1)(2n-1)T_{mn}}}{\sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \frac{1}{(2m-1)^2(2n-1)^2 T_{mn}}}\right] \tag{27b}$$

In principle, Eqs. (25) and (26) show that if the distributions of the particle mobility measured by micro-PIV in the open-and closed-end channels are known, the zeta potentials of both the particles and the channel surface can be determined simultaneously.

Experimental

The measurement cell consists of a borosilicate glass microchannel (VitroCom), a polymer holder, and two reservoirs. Such microchannel has a rectangular 300 μm × 300 μm cross section and is 4 cm long. Prior to experiment, the channel was cleaned in an ultrasonic cleaner with a NaOH base solution and then flushed with deionized water. For the closed-end cell, epoxy glue was used for sealing the two ends of the channel.

Fluorescent polystyrene particles of radius $a = 465$ nm (Duke Scientific Co.) were used for tracking the flow. Such tracer particles have the excitation and emission wavelength of 540 nm and 610 nm, respectively. In all experiments, the number concentration of tracer particles was approximately about 2×10^9 particles per ml.

A DC electric field was applied using platinum wire electrodes inserted into the two reservoirs at the ends of the microchannel. A high-voltage power supply (PS350, Stanford Research) was used to apply 400-V potential difference on the two electrodes, giving rise to a 100 V/cm strength of the applied DC field.

Three types of working fluids were used including sodium chloride and boric acid with various concentrations (10^{-2} M, 10^{-3} M, 10^{-4} M and 10^{-5} M) as well as deionized water.

The micro-PIV setup consists of four main components: an illumination system, an optical system, a coupled charge device (CCD) camera and a control system. The control system consists of a peripheral component interface (PCI) card, and its corresponding software is implemented in a Personal Computer. The computer can control and synchronize all actions related to illumination and image recording. The schematic of the setup is illustrated in Fig. 2.

Particles were imaged using an epifluorescent microscope (Nikon TE2000-S) and a 20× objective lens with a numerical aperture (NA) of 0.45. An interline transfer CCD camera (Sony ICX 084) was used for recording the images. The resolution of the camera is 640 pixels × 480 pixels, with 12 bits grayscale. The active area of the CCD sensor is 6.3 mm × 4.8 mm. The minimum inter-frame transfer time, and thus the fastest time delay for the two PIV images, is $\Delta t_{PIV} = 500$ ns. To ensure that the CCD camera is working at its optimum temperature of −15 °C, a cooling system is integrated in the CCD camera. In the mode of double exposure in double frames, the camera records two frames of the flow fields and then digitizes them in the same image buffer.

Key Research Findings

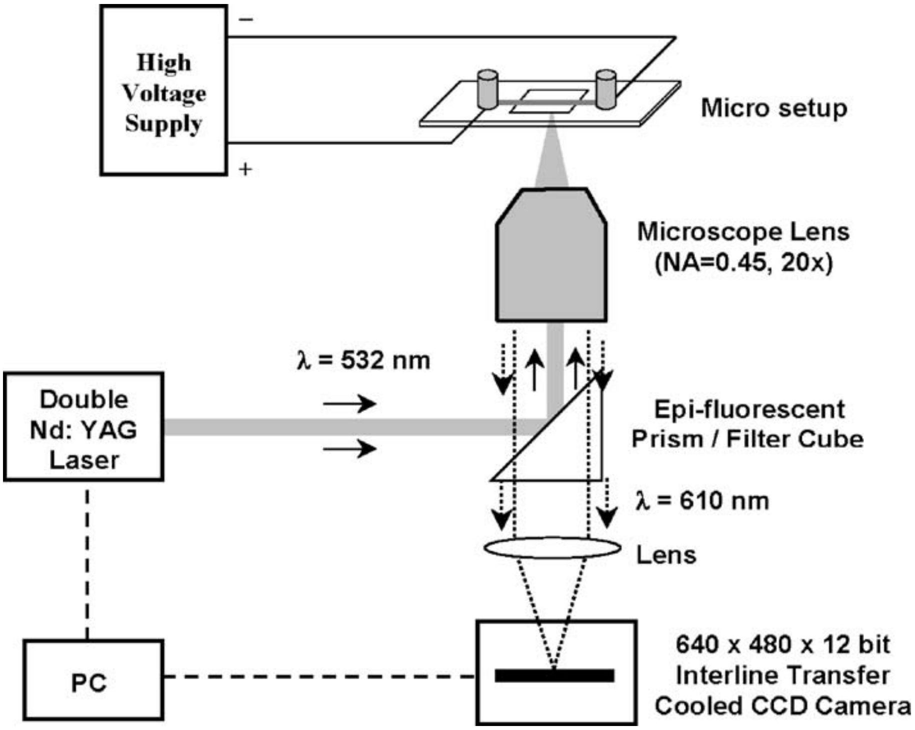
Micro PIV Images and Particle Velocity Data

Focusing the objective lens on the mid-plane (i. e., $y = 0$) of the rectangular channel as shown in Fig. 1, we used the micro-PIV to measure the particle velocity distributions in both the open- and closed-end channels. The images acquired from micro-PIV measurements were then evaluated with PIVview software (PivTec GmbH) to obtain the particle velocity data. Extracting the velocity data and averaging the values along the flowing direction, we can obtain the averaged velocity values.

Least-Square Analysis

With the experimental data, we can use the least-square analysis to determine the values of the fitted zeta potentials of both the particels and the channel surface by minimizing the sum of the square of the errors between the meausured and predicted particle mobility.

Along the lateral (x-axis) direction of the channel, we assume the measured average particle's mobility at the ith position in the open-end channel as $\mu_{p-open,i}$ and the measured average particle's mobility at the$i$th position in



Measuring Zeta Potential, Methods, Figure 2 Schematic of the micro-PIV setup. The PC controls and synchronizes the lasers for illumination, CCD camera for image recording, and high voltage switch for turning on the high voltage supply

the closed-end channel as $\mu_{\text{p-closed},i}$. Applying the least-square method, we introduce the least-square function S as

$$S = \sum_{i=1}^{N} \left[\left(\mu_{\text{p-closed},i} - \mu_{\text{p-closed}}\right)^2 + \left(\mu_{\text{p-open},i} - \mu_{\text{p-open}}\right)^2 \right] \quad (28)$$

where N is the number of the measured points along the lateral direction of the mid-plane of the channel. Thus, the best-fitted values of the two zeta potentials, ζ_{w} and ζ_{p} can be obtained by minimizing the value of S. Substituting Eqs. (25) and (26) into Eq. (28), we know that the derivatives of function S with aspect to ζ_{w} and ζ_{p} should be equal to zero:

$$\frac{\partial S}{\partial \zeta_{\text{w}}} = \sum_{i=1}^{N} \left[2\left(\mu_{\text{p-closed},i} - \mu_{\text{p-closed}}\right)\left(-H\left(x_i\right)\right) + 2\left(\mu_{\text{p-open},i} - \mu_{\text{open}}\right)(-F) \right] = 0 \quad (29)$$

$$\frac{\partial S}{\partial \zeta_{\text{p}}} = \sum_{i=1}^{N} \left[2\left(\mu_{\text{p-closed},i} - \mu_{\text{p-closed}}\right)(-G) + 2\left(\mu_{\text{p-open},i} - \mu_{\text{open}}\right)(-G) \right] = 0 \quad (30)$$

Rearranging Eqs. (29) and (30) and making use of Eqs. (25) and (26), we obtain

$$\zeta_{\text{w}} \sum_{i=1}^{N} \left[F + H\left(x_i\right)\right] + \zeta_{\text{p}}\,(2NG) = \sum_{i=1}^{N} \left(\mu_{\text{p-open},i} + \mu_{\text{p-closed},i}\right) \quad (31)$$

$$\zeta_{\text{w}} \sum_{i=1}^{N} \left[F^2 + \left(H\left(x_i\right)\right)^2\right] + \zeta_{\text{p}} \sum_{i=1}^{N} \left[G\left(F + H\left(x_i\right)\right)\right] = \sum_{i=1}^{N} \left[F\mu_{\text{p-open},i} + H\left(x_i\right)\mu_{\text{p-closed},i}\right] \quad (32)$$

It is convenient to express Eqs. (31) and (32) in the matrix form

$$\begin{bmatrix} \sum_{i=1}^{N} \left[F + H\left(x_i\right)\right] & 2NG \\ \sum_{i=1}^{N} \left[F^2 + \left(H\left(x_i\right)\right)^2\right] & \sum_{i=1}^{N} \left[G\left(F + H\left(x_i\right)\right)\right] \end{bmatrix} \begin{bmatrix} \zeta_{\text{w}} \\ \zeta_{\text{p}} \end{bmatrix}$$

$$= \left[\begin{array}{c} \sum_{i=1}^{N} \left(\mu_{\mathrm{p-open},i} + \mu_{\mathrm{p-closed},i} \right) \\ \sum_{i=1}^{N} \left[F \mu_{\mathrm{p-open},i} + H(x_i)\, \mu_{\mathrm{p-closed},i} \right] \end{array} \right] \tag{33}$$

Introducing

$$A = \left[\begin{array}{cc} \sum_{i=1}^{N} [F + H(x_i)] & 2NG \\ \sum_{i=1}^{N} \left[F^2 + (H(x_i))^2 \right] & \sum_{i=1}^{N} [G(F + H(x_i))] \end{array} \right] \tag{34}$$

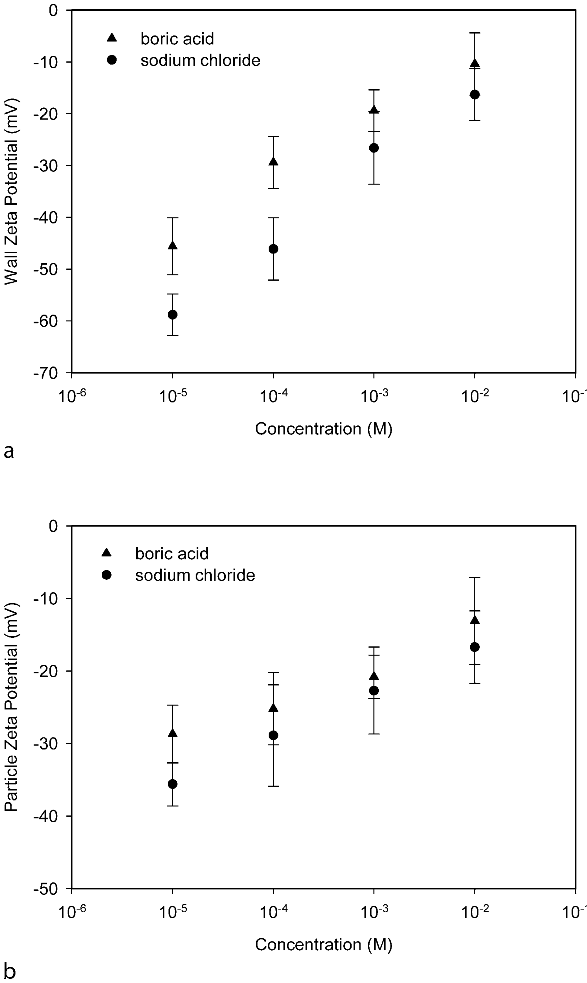
and

$$B = \left[\begin{array}{c} \sum_{i=1}^{N} \left(\mu_{\mathrm{p-open},i} + \mu_{\mathrm{p-closed},i} \right) \\ \sum_{i=1}^{N} \left[F \mu_{\mathrm{p-open},i} + H(x_i)\, \mu_{\mathrm{p-closed},i} \right] \end{array} \right] \tag{35}$$

we get

$$\begin{bmatrix} \zeta_{\mathrm{w}} \\ \zeta_{\mathrm{p}} \end{bmatrix} = A^{-1} B \tag{36}$$

With the measured data for $\mu_{\mathrm{p-open},i}$ and $\mu_{\mathrm{p-closed},i}$, A and B are known matrices. Using Eq. (36), we can simultaneously determine the two zeta potentials of the channel surface and the tracer particles in deionized water as $\zeta_{\mathrm{w}} = -62 \pm 6$ mV and $\zeta_{\mathrm{p}} = -37 \pm 4$ mV, respectively. Furthermore, we used the same method to determine the zeta potentials in the sodium chloride and boric acid solutions with various concentrations. We plot the zeta potential data versus the electrolyte concentration and present the results in Fig. 3. It is noted that all the zeta potentials are negative. It can also be observed that the higher the electrolyte concentration, the smaller the absolute value of zeta potentials will be. This tendency is common for the zeta potentials of glass or polymer surfaces in aqueous solutions such as NaCl. Using the streaming potential technique, Gu and Li [8] measured the zeta potential of glass surface in contact with different aqueous solutions of various concentrations. For NaCl solutions, they reported the zeta potential values, ranging from -20 mV to -60 mV, which are in good agreement with our data obtained in the present work.



Measuring Zeta Potential, Methods, Figure 3 Measured zeta potentials versus solution concentration (mole/liter) of the sodium chloride and boric acid electrolytes for (**a**) the microchannel surface, and (**b**) the tracer particles

Measurement Errors Due to Brownian Motion

In micro-PIV measurement, the major uncertainty is due to the Brownian motion of tracer particles. In particular, the Brownian motion plays an important role when submicron tracer particles are used in PIV experiments with flow velocities of less than 1 mm/s. According to Einstein, the Brownian motion induced random velocity can be estimated from

$$u_{\mathrm{B}} = \sqrt{\frac{2D}{\Delta t_{\mathrm{PIV}}}} \tag{37}$$

The mass diffusivity of dilute tracer particles suspended in water is given by the Einstein-Stokes equation expressed as,

$$D = \frac{kT}{6\pi \mu a} \tag{38}$$

Given the tracer particles of $a = 465$ µm, room temperature $T = 298$ K and the PIV exposure time $\Delta t_{\mathrm{PIV}} = 500$ ns,

the Brownian velocity is estimated as 30 μm/s. As a result, the measurement error due to the Brownian motion, $\varepsilon_B \equiv u_B/u_f$ is about 3% when the characteristic fluid velocity u_f is chosen as 1 mm/s.

Future Directions for Research

Zeta potential plays an important role in micro- and nano-scale flow and transport processes. More experimental data regarding zeta potential are needed for various liquid-microchannel systems. As in nanofluidic channels, it is not clear whether the zeta potential will be maintained constant or the surface charge density will be kept constant, it is highly desirable to develop new theoretical models, experimental methods and the experimental data for determining zeta potential of nanochannels.

Mechanical nanodetectors

Definition

Mechanical nanosensors are devices that measure physical and chemical properties in a nano-scale region or detect the presence of (bio)molecules based on principles of mechanics.

Overview

Mechanical nanosensors possess comparative advantages over optical nanosensors and electromagnetic nanosensors for the measurement of nanoscale mechanical properties [1].

Elastic Modulus Measurement

The Young's modulus of a cell can be measured using an atomic force microscope (AFM) by indenting the cell with the AFM tip. Based on Hertz model, the Young's modulus, E, can be calculated as [2]

$$E = \frac{\pi}{2}\left(\frac{1-\nu^2}{\delta^2 \tan\alpha}\right)F\,, \tag{1}$$

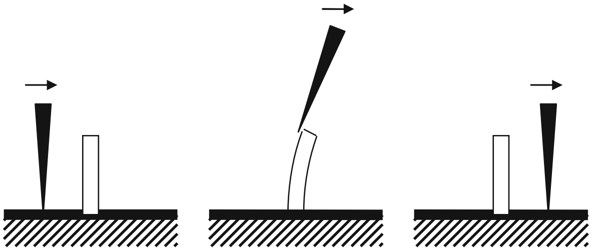
where ν is the Poisson's ratio (taken as 0.5 assuming the cell to be incompressible), δ is the indentation depth, α is the opening angle of the AFM tip, and F is the applied indentation force.

The Young's modulus of a vertical nanowire or nanorod can be measured using an AFM through applied lateral force, as shown in Fig. 1.

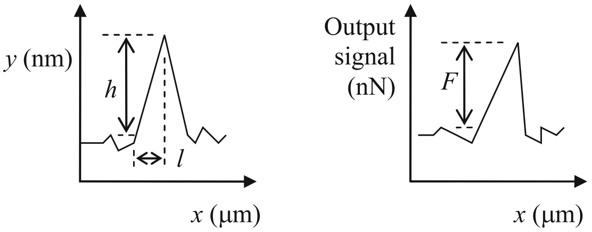
The Young's modulus of a fixed fixed-free column undergoing such lateral deflection can be estimated by

$$E = 0.61584F\frac{\left[h^2 + (l - h\tan\theta)^2\right]^{\frac{3}{2}}}{r^4(l - h\tan\theta)}\,, \tag{2}$$

where F is the maximum lateral bending force, h is the vertical retraction of the AFM tip, l is the corresponding lateral displacement of the AFM tip from initial contact to the nanorod to the point where the nanorod and AFM tip disconnection, θ is the half apex angle of the AFM tip,



Mechanical Nanosensors, Figure 1 Measuring the Young's modulus of a nanowire using AFM tip [3]



Mechanical Nanosensors, Figure 2 Typical profiles of AFM tip retraction and measured lateral force versus lateral displacement

and r is the nanorod radius [3]. The readings of F, h and l can be obtained from the typical profile of AFM output, as shown in Fig. 2.

Force Measurement

Identification of specific molecules can also be made through the measurement of unbinding (or adhesion) force between a pair of molecules with specific binding, such as ligand–receptor, ligand–protein, antigen–antibody, etc. This is because the force needed to separate a ligand from its binding site is significantly higher than the force required to remove a non-specifically bound ligand [4, 5]. The adhesion force can be inferred from the force-distance curves plotted from the AFM.

Cantilever Beam-Bending

The presence of specific molecules can be detected using a microscale cantilever beam functionalized on a single side. As a result of beam bending due to adsorption on one side of the cantilever, the beam curvature amplifies to nanoscale displacement at the free edge of the cantilever [6]. Assuming the cantilever length, L, to remain constant throughout the event of molecular adsorption, then the deflection, d, at the free edge is

$$d = \rho\left[1 - \cos\left(\frac{L}{\rho}\right)\right], \quad (3)$$

where the cantilever radius of curvature, ρ, is assumed to be inversely proportional to the amount of molecular adsorption and the type of molecules adsorped.

Nano-Scale Mass Measurement

The resonant frequency of a cantilever is inversely proportional to the square root of its mass. Hence attachment of mass to a cantilever results in a change to the cantilever's resonant frequency. The resonant frequency shift of a carbon nanotube (CNT) is [7]

$$\Delta f = f - f_0\,, \quad (4)$$

where f_0 is the original resonant frequency of the CNT, while f is the CNT's resonant frequency upon attachment of mass.

Strain, Pressure and Temperature Measurement

Although the use of cantilever, such as CNT, for measuring the resonant frequency shift is obvious in regard to the measurement of mass, Eq. (4) can also be applied for measurement of other mechanical conditions such as strain and the changes in pressure and temperature. As a result of prescribed strain, applied pressure and temperature change, the coordinates for carbon atoms in the CNT are altered. This coordinate change leads to a change in the CNT resonant frequency [8]. The decrease in

- CNT length,
- attached mass and
- relative distance from mass to CNT fixed-end

result in increase of resonant frequency.

Shorter and thinner CNT are associated with higher change in resonant frequency resulting from axial CNT strain, and temperature and pressure increment. Apart from CNT, the resonant frequency shift technique can also be applied on cantilever beam due to change in mass as a result of molecular adsorption [9].

Membrane Actuation for Micropumps

Laxman Saggere
University of Illinois at Chicago, Chicago, IL, USA
saggere@uic.edu

Synonyms

Diaphragm actuation; Thin-film actuation; Thick-film piezoelectric actuation

Definition

Membrane actuation for micropumps refers to the reciprocating periodic motion of a thin flexible layer–diaphragm or membrane made of silicon or other materials–bounding one side of a displacement micropump to create volume and pressure oscillations in a fluid (i. e., liquid or gas) stored in the chamber of the micropump that is rectified by other means to accomplish a net fluid flow through the micropump. The mechanical energy necessary for the membrane actuation in micropumps is generally derived from electrical, thermal, optical or other forms of energy.

Overview

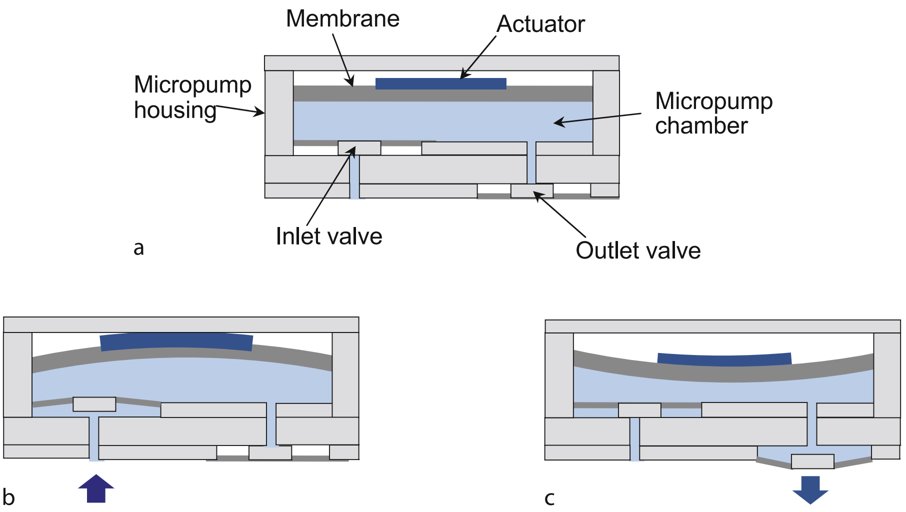
Micropumps based on a variety of operating principles have been developed since early 1970s for pumping and/or precisely controlling fluid volumes on the order of a milliliter and below, which has enabled numerous emerging applications including dosing therapeutic drugs into the body, Lab-on-a-Chip diagnostic tools, microelectronics cooling, chemical and biological analysis, and micropropulsion. Micropumps have been classified in many different ways in the literature over the years. However, based on the manner in which energy is transmitted to fluid, micropumps are often classified broadly into two types:

1. *mechanical pumps* or *displacement pumps*, which exert pressure on the working fluid through one or more moving boundaries and
2. *non-mechanical pumps* or *dynamic pumps*, which continuously add energy to the working fluid in a manner that increases either its momentum or its pressure directly [1, 2].

Displacement micropumps generally operate by transmitting a periodic motion, which mostly is of reciprocating type, to the working fluid by means of a moving boundary surface using a principle similar to their macro-scale counterparts. The moving boundary surface in macro-scale reciprocating displacement pumps is generally realized by a piston sealed inside a cylinder; however, at micro-scale, owing to complexities of three-dimensional microfabrication and assembly, the piston-like reciprocating action is achieved by means of a thin deformable plate–the membrane or the diaphragm–that is micromachined integrally with the micropump structure such that it attaches to the sides of the micropump chamber bounding one side of the micropump. Generally, by itself, the membrane is passive and driven by an actuator–either integrated with the membrane or external to the membrane–that converts electrical or other forms of energy into mechanical energy of the membrane's reciprocating motion. The various principles of membrane actuation are discussed below in more detail. A schematic of a generic reciprocating displacement micropump including flow rectification components (either passive or active valves or simply two nozzles) on other side(s) of the micropump is shown in Fig. 1.

Membrane Geometry

Reciprocating displacement micropumps have been designed with a wide range of geometry and performance characteristics for various applications. Most reported



Membrane Actuation for Micropumps, Figure 1 Schematics of a generic reciprocating displacement micropump and its working principle. (**a**) Membrane in the initial flat configuration, (**b**) membrane bowing upwards during the suction stroke, (**c**) membrane bowing downwards during the discharge stroke

reciprocating displacement micropumps are roughly planar structures between 1 mm and 4 mm thick [2]. The membranes in these micropumps are also mostly planar with thickness values ranging from 5 μm to several hundreds of micrometers. Non-planar membrane geometries with bosses at their centers have also been applied to a limited extent in reciprocating displacement micropumps. Most membranes are circular in shape; however, square shaped membranes have also been used in few micropumps reported in the literature. The overall size of the membrane, which must be large enough to produce the required volume displacements, depends on the micropump capacity and the actuation driver force capacity. Even if the driver is capable of supplying effectively large force, the membrane displacement is limited by the diaphragm's failure criteria, which scale unfavorably with decreasing membrane diameter. Scaling down the membrane diameter presents a significant challenge for designers of reciprocating displacement micropumps.

Membrane Materials

The choice of the passive membrane material is critical to the performance of micropump and is often dictated by the type of actuator and the fabrication method selected. For micropumps driven by low frequency and/or low-force actuators, a low-modulus material generally allows the volume displaced by the membrane to be maximized, favorably impacting performance. Commonly used low modulus materials for membranes are elastomers, polyimide, pyrelene, and polydimethylsiloxane (PDMS), and silicone rubber. However, since the membranes act against with the working fluid in the micropump, soft polynmer membranes suffer from stability issues. For actuators capable of operating at a high frequency and adequate force, the fast mechanical response of a stiff membrane generally yields the best performance. For this reason, silicon, glass and plastic are the most commonly used materials for membranes driven by piezoelectric actuation, which is capable of operating at very high frequencies.

Membrane Fabrication

The most common method for fabricating passive silicon membranes for micropumps is micromachining combined with glass bonding layers. The micromachining techniques generally involve photolithography followed by either wet etching or deep reactive ion etching (DRIE) from one side of the wafer. Integration of actuators and electrodes with the passive membrane involves additional fabrication steps that are often complicated. For example, a composite of thin film piezoelectric material layer sandwiched between two electrode layers is formed on the membrane by a variety of techniques including: physical vapor deposition techniques (ion beam sputtering, RF planar magnetron sputtering, dc magnetron sputtering), chemical vapor deposition (CVD) techniques (metal-organic-chemical vapor deposition or MOCVD), chemical solution deposition (CSD) techniques (including sol-gel routes, metal-organic-decomposition), and pulsed laser deposition (PLD) [5]. A number of reciprocating displacement micropumps have been fabricated through means other than traditional silicon/glass micromachining such as precision machining of brass, stereolithography of an

ultraviolet-photocurable polymer. Improvements in techniques for fabricating precision components from plastic have led to increasing use of plastics in reciprocating displacement micropumps.

Purpose of the Membrane Actuation in Micropumps

The main purpose of the membrane actuation in a displacement micropump is to create volume, and therefore, pressure oscillations in the chamber of the micropump to enable displacement of the fluid stored in the micropump chamber. During its operation, an actuator drives the membrane displacing the membrane from its initial flat configuration in a transverse (up and down) motion in a periodic manner. The membrane actuation frequencies vary widely from DC to several kilohertz in the micropumps reported depending on the application. The working principle of a reciprocating displacement micropump can be described by a cyclic process, which is divided into a supply mode (the pump chamber volume increases) and a pump mode (the pump chamber volume decreases). The alternating stroke volume ΔV of the membrane causes increase and decrease in the dead (initial) volume V_0 of the micropump chamber cyclically leading to pressure oscillations of amplitude $|\Delta p|$ in the pump chamber. During the supply mode, low pressure is generated in the pump chamber, which causes fluid to be drawn into the pump chamber through the inlet valve, *as soon as* Δp *becomes larger than the inlet valves threshold pressure* Δp_{crit}. During the pump mode, overpressure occurs in the pump chamber, which transfers liquid from the pump chamber into the outlet *as soon as* Δp *becomes larger than the outlet valves threshold pressure* Δp_{crit} [3]. In this stage, the inlet valve is designed to prevent a reverse flow, and likewise the outlet valve does during the supply phase. Thus the membrane volume oscillations are rectified into a net flow through the micropump over a two-stroke pump cycle by means of valves at the inlet and outlet oriented to favor flow into and out of the micropump chamber during the chamber expansion stroke and contraction stroke respectively.

Basic Methodology

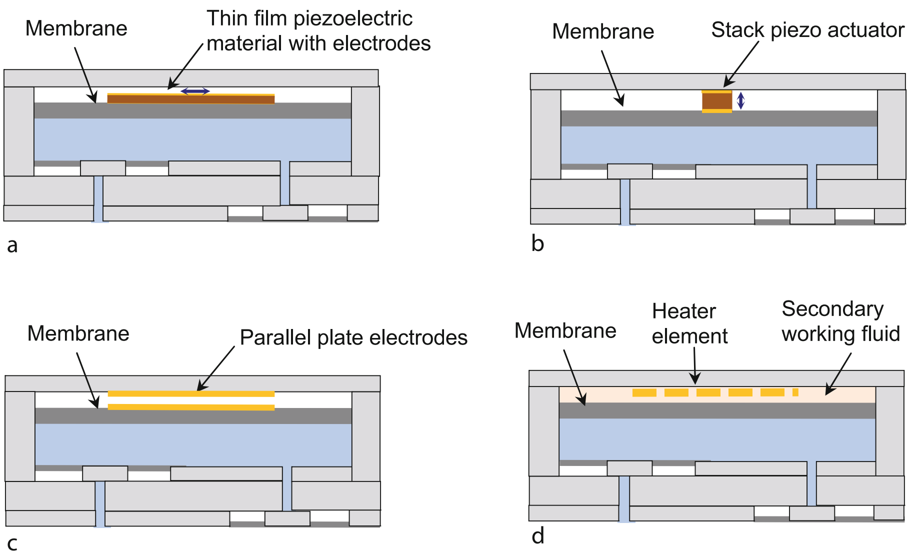
This section details the actuation techniques used to drive the membrane, the modeling techniques for designing a membrane actuator, and the fabrication techniques employed to realize membrane actuators.

Membrane Actuation Techniques

The periodic motion of the passive membrane structure in a micropump is achieved by means of an actuator that is either external to the membrane or integrated with the membrane. A wide range of actuation principles involving both external and integrated actuators have been applied to drive membranes in micropumps. The membrane actuator stroke, stiffness, frequency of operation, response time, and hence, the performance of the micropump, are directly impacted by the choice and design of the actuator principle. External actuation principles used for membranes in micropumps include: electromagnetic actuators with solenoid plunger and external magnetic field, disk type or cantilever type piezoelectric actuators, stack type piezoelectric actuators, pneumatic actuators, and shape memory actuators. While external actuators have the advantage of imparting relatively large forces and displacement to the membranes, their bulkiness restricts the packaged size of the micro-pumps. Integrated actuators are micromachined with the pumps. Most common integrated actuators are thin film type piezoelectric actuators, electrostatic actuators, thermopneumatic actuators, electromagnetic actuators, and thermomechanical (bimetallic) actuators [3, 4]. Other less commonly used actuation principles used for membrane actuation in micropumps include shape memory alloys, magnetostrictive materials, electrowetting, bimetallic drivers, and magnetoelastic drivers. The three most common integrated actuator principles are discussed in more detail below.

Piezoelectric Actuation

Piezoelectric actuation provides the advantages of a comparatively high stroke volume, a high actuation force combined with a fast mechanical response, and is, therefore, a very attractive and most commonly used actuation principle for micropumps. The disadvantages of the piezoelectric actuation are relatively high actuation voltage and quite involved fabrication process. Most membranes actuated by the piezoelectric principle are made of brass, silicon, glass and plastic, and the most commonly used piezoelectric materials are zinc oxide and PZT (lead zirconate titanate) family of ceramics due to their excellent dielectric properties and compatibility with micromachining in a thin film form [5]. Piezoelectric materials in their bulk or stack forms have also been manually integrated with the passive membrane and used to drive the membrane. In thick or thin film form, the piezoelectric material can drive a membrane in either predominantly lateral or predominantly axial configurations as illustrated in Fig. 2a respectively, whereas in a bulk or stack form, the piezoelectric material drives the membrane predominantly in its axial direction Fig. 2b. The maximum piezoelectric free strain that can be produced in the membrane, which directly relates to the stroke volume of the microp-



Membrane Actuation for Micropumps, Figure 2 Schematic illustration of the principal types of membrane actuations in micropump. (**a**) Thin film piezoelectric actuation, (**b**) Stack piezoelectric actuator, (**c**) Parallel plate electrodes for electrostatic actuation, (**d**) Thermopneumatic actuation using thermal expansion of a secondary working fluid

ump, is determined by the driving voltage and the piezoelectric characteristics of the piezo material such as the polarization limit and the strain coefficients in lateral and transverse directions and the fabrication process. Piezoelectrics can be driven at several hundreds of kHz frequencies by electric fields on the order of $10\,\text{kVcm}^{-1}$ or higher.

The physical basis for the design of piezoelectric membranes is based on simple combined electrical and mechanical relations (Gauss' law and Hooke's law). The relationship between the electrical and mechanical properties of piezoelectrics is governed by the following constitutive equations:

$$s_i = s_{ij}^E T_j + d_{ki} E_k$$

$$D_i = d_{lm} T_m + \varepsilon_{ln}^{\tau} E_n$$

where $i, j, m = 1, \ldots, 6$ and $k, l, n = 1, 2, 3$. Here, S, D, E, and T are the strain, dielectric displacement, electric field, and stress, respectively, and S_{ij}^E, d_{kl}, and $\varepsilon_{ln}^{\tau} E_n$ are the elastic compliances (at constant field), the piezoelectric constants, and dielectric permittivities (at constant stress) [5].

Electrostatic Actuation

The electrostatic actuation for membranes in micropumps provides several advantages: fast response time, compatibility with micromachining techniques, ability to operate at high frequencies and good reliability; however, electrostatic actuation produces relatively small stroke and small force, and as such, this principle is suitable for micropumps with very low power consumption. Due to geometric constraints, electrostatic actuator is realized mostly in parallel-plate configuration as shown in Fig. 2c by creating one of the plate electrodes on the membrane and the other plate electrode is fixed above the electrode on the membrane with the electric field applied across the air gap between the plates. In the parallel plate configuration, the bottom electrode mounted on the moving membrane typically bows during micropump operation and the actuation force becomes non-uniform across the width of the membrane and the force values are difficult to calculate, however, the electrostatic force at the very beginning of the pump stroke (when both electrodes are flat) can be easily calculated. The capacitance between a pump membrane of diameter d and a counterelectrode of equal size separated by a distance s is

$$C = \frac{\varepsilon \pi d^2}{4s}$$

The electrostatic force between the two plates is given by

$$F = \frac{1}{2}\frac{\partial C}{\partial s}V^2 = \frac{\varepsilon \pi d^2}{8s^2}V^2$$

where ε is the permittivity of the medium separating the plates and V is the potential difference between them.

Thermopneumatic Actuation

The thermopneumatic actuation has the ability to produce relatively large stroke and pressures, but needs a large amount of thermal energy, and consequently, such actuators consume considerable amount of electric power. The temporal response of thermopneumatic actuators is limited by the rate of heat transfer into and out of the secondary working fluid, and so thermopneumatically driven membranes typically operate at relatively low frequencies. Other drawbacks of thermopneumatic actuation include high temperatures and complicated thermal management. The thermopneumatic principle, illustrated in Fig. 2d, involves heating (usually with an integrated thin-film resistive heater) of a secondary working fluid causing it to expand, and thereby, actuate the membrane. In order to maximize the volume displaced by the membrane, low-modulus materials such as polyimide, pyrelene, elastomer and polydimethylsiloxane (PDMS) are often used for membranes driven by thermopneumatic principle.

Key Research Findings

Membrane actuation used in reciprocating micropumps has enabled numerous applications involving precise fluid handling very small volumes of the working fluid over the past two decades. The piezoelectrically driven micropumps, which can be traced to a class of ink jet printheads developed in the 1970s, have received considerable attention and such micropumps are now available commercially. Micropumps using membrane actuation have been developed for dispensing therapeutic agents into the body [6]. Among such micropumps, implantable insulin delivery systems for maintaining diabetics' blood sugar levels without frequent needle injections are currently available. Micropumps might also be used to dispense engineered macromolecules into tumors or the bloodstream. Micropumps are also found in a few current-generation micro total analysis systems (μTAS) employed in chemical and biological analysis.

Future Directions for Research

The membrane actuation is crucial for micropumps as researchers are working on developing new applications for micropumps and further miniaturization of micropumps for precise handling of even smaller amounts fluids on the order of nano- and picoliters. On the new applications side, micropumps are being developed for use in cryogenic spot cooling of microelectronic devices and micropropulsion for space exploration [2]. Control of smallest amounts of fluids is of increasing interest in modern bioanalytical and pharmaceutical research and industry. Micropumps including those utilizing membrane actuation will see a more widespread application especially in life sciences area as researchers are seeking to address issues related to their reliability, complexity of microfabrication, power consumption, cost and biocompatibility. Research is also ongoing to improve the performance of currently available membrane actuation technologies and active materials for membrane actuation.

Synonyms

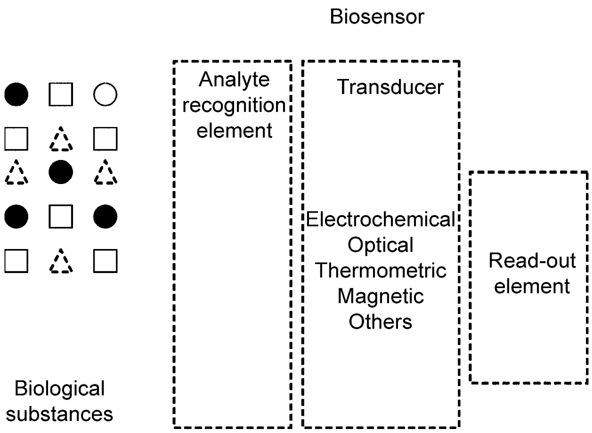
MEMS biosensor; Microbiosensor

Definition

A *MEMS-based biosensor* is a biosensor which is realized by microfabrication technology and takes advantage of the small size. It incorporates a biological component with a physiochemical transducer such as a microsystem. It is a special class of chemical sensor that takes advantage of the high selectivity and sensitivity of biologically active materials. It involves immuno, enzyme and microorganism sensors.

Overview

Since the first biosensor was described by Clark and Lyons in 1962, a vast number of biosensors have been proposed for detecting tissue, microorganisms, organelles, cell receptors, enzymes, antibodies, nucleic acids and so on. A biosensor consists of three parts as shown in Fig. 1: an analyte recognition element, a transducer whose mechanism may be electrochemical, optical, thermometric or magnetic and a read-out element. At the analyte recognition element, the analyte is specifically recognized by a biologically sensitive substance while other biological substances are not detected. The recognition leads to a specific change of the transducer which is subsequently converted into a measurable form, generally an electrical signal, in the read-out element. A biosensor can be classified by various standpoints such as its application field or its transducing mechanism. It is also called a medical



MEMS-Based Biosensor, Figure 1 Schematic of a conventional biosensor

or environmental sensor when it is applied in the corresponding field. The transducing mechanism may be electrical, chemical, mechanical, optical, magnetic or acoustic. In this entry, a biosensor will be classified by its transducing mechanism such as electrochemical, optical, etc.

In the case of conventional biosensors, each of the three components is realized separately, have different scientific background but their own function in the biosensor. For example, biology, physics, chemistry or medical science are the main scientific fields for the analyte recognition element, mechanical, electrical and electronic engineering for the transducer, and mechanical, electrical, electronic engineering and physics for the detection element. Even though the conventional biosensors are successful to an extent, they are expensive and their usage is limited to a specifically organized environment.

Due to well-established micromachining technology, the transducer and read-out elements are starting to be realized in a single device. Such a miniature device is called a MEMS biosensor generally. However, full function of the read-out element is not integrated yet. The current MEMS biosensor is a miniature device in which the transducer is miniaturized and a part of the function of the read-out element is also integrated. The MEMS biosensor has many advantages such as small size, low cost, sharply reduced power consumption and enhanced usability. A good example is a microcantilever biosensor [1]. This includes a read-out element as well as a physical transducer. When an analyte is reacted with a recognition element which is immobilized on the surface of the microcantilever, it induces chemical stresses and subsequently bending of the microcantilever. This results in a change of electrical resistance which is due to a piezoresistor integrated with the microcantilever.

Basic Methodology

Electrochemical Method

Introduction

MEMS biosensors based on electrochemical methods can measure quantitative concentrations of biochemicals in biological systems such as immunological systems and glucose metabolism. They convert biochemical reactions to electrical signals. Changes in potential, conductance and current between two electrodes are the main parameters that are measured. Electrochemical methods are a dominant biosensing methodology because of the simple structure and easy measurement compared with other MEMS biosensors such as optical biosensors, acoustic biosensors and so on. MEMS biosensors based on electrochemical methods can be classified into three types according to measured parameters [2].

Potentiometric MEMS biosensors (potentiometry) are based on potential measurement of an electrode in a solution. This potential is measured in an equilibrium state. In other words, current flow should not exist during the measurement. According to the Nernst equation, the potential is proportional to the logarithm of the concentration of the electroactive species.

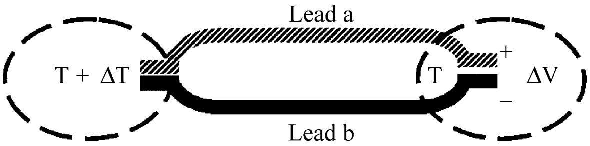
Voltammetric MEMS biosensors (voltammetry) are based on measuring the current-voltage relationship in an electrochemical cell consisting of electrodes in a solution. After a potential is applied to the sensor, current, which is proportional to the concentration of the electroactive species of interest, is measured. Amperometry is a special case when potential is maintained so as to be constant with time.

Conductometric MEMS biosensors (conductometry) are based on measuring conductance between two electrodes in a solution. Conductance is measured by applying a small quantity of AC potential to block a polarization. The existence of ionic elements is measured as an increase in conductance.

Theory of Electrochemical MEMS Biosensors

Potentiometric MEMS Biosensors Potentiometric MEMS biosensors are a direct analytical application of the Nernst equation through measurement of the potential of non-polarized electrodes when current is zero. A reference electrode is necessary to investigate potential changes due to biochemical reactions. Without a stable reference electrode, reliability of the biosensor cannot be achieved [3].

Among MEMS biosensors based on potentiometric methods, a microcalorimeter is a good example. A microcalorimeter is a kind of a self-generation sensor in which the heat of a biochemical reaction is detected. Generally, an output voltage is a function of the concentration of the substance to be measured. It is based on thermocouples. Thermocouples are two-lead elements that measure the temperature difference between the ends of the wires. They are based on the thermoelectric Seebeck effect that a temperature difference ΔT in a biosensor creates an electrical voltage $\Delta V/\Delta V = \alpha_S \Delta T$, where α_S is the Seebeck coefficient expressed in V/K [4]. Figure 2 shows a schematic of the Seebeck effect and a simplified thermopile.



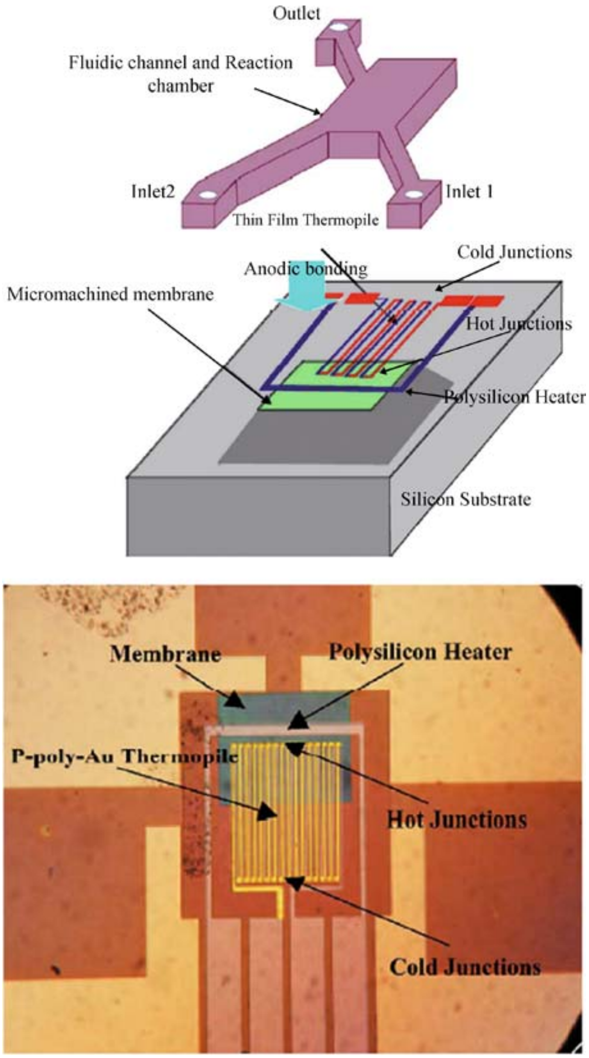
MEMS-Based Biosensor, Figure 2 The Seebeck effect: an electrical voltage ΔV is generated due to a temperature difference ΔT [4]

Microcalorimeters can be used for both gaseous and liquid media. In both cases, the substance to be measured is converted into another substance by means of a catalytic or enzymatic reaction that produces heat. The catalyst or enzyme is deposited on the sensing area of the thermal sensor. Figure 3 shows an example of a microcalorimeter [5].

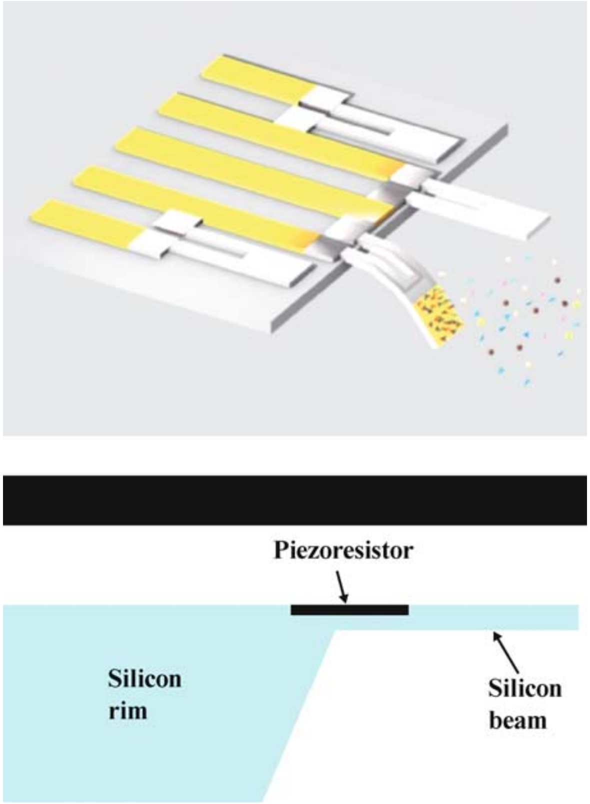
Voltammetric MEMS Biosensors Voltammetric MEMS biosensors measure the current flow at an electrode which is a function of the potential applied to the electrode. Voltammetric measurement gives the current–potential curve or voltammogram. These curves can be used for qualitative, quantitative, thermodynamic and kinetic studies. In contrast to potentiometry, voltammetry gives a linear current response as a function of the concentration, which is a notable advantage [6].

Among voltammetric MEMS biosensors, a piezoresistive microcantilever is a good example. The general configuration of a piezoresistive microcantilever sensor is shown in Fig. 4. The stress caused by biochemical reactions is concentrated on the surface of the microcantilever. Piezoresistors are usually placed on the microcantilever to the rim, where the stress is maximal. When the microcantilever is bent due to biochemical reaction, the resistivity of the microcantilever is changed. And by measuring the change, the concentration of the biochemical is detected [7].

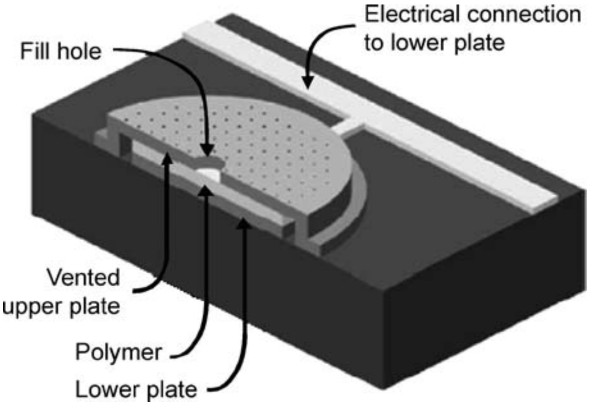
Conductometric MEMS Biosensors Electrolytic conductance is a non-faradaic process that can give useful chemical information. Electrolytic conductance originates from the transport of anions to the anode and cations to the cathode. In order to complete the current path,



MEMS-Based Biosensor, Figure 3 Calorimetric biosensor with integrated microfluidic channels [5]



MEMS-Based Biosensor, Figure 4 Schematic and cross-sectional view of a piezoresistive microcantilever [7]



MEMS-Based Biosensor, Figure 5 A cross-sectional view of a conductometric sensor [9]

electrons are transferred at the electrode surface to and from the ions. The conductance of an electrolyte is measured in a conductance cell consisting of two identical non-polarizable electrodes. To prevent polarization, an AC potential is applied to these electrodes and the AC current is measured [8].

A chemicapacitive sensor is a capacitor that has a selectively absorbing material such as a polymer as a dielectric: As chemicals are absorbed into the dielectric, effective permittivity of the capacitive sensor is changed. This leads a change of the capacitance. A cross-sectional view of the basic structure of micromachined parallel plates is shown in Fig. 5 [9]. The conductance of the polymer depends on the types and quantities of biochemicals.

Optical Method

Introduction

The principle of optical biosensors is measuring the change in optical absorption or emission of a molecule or molecules at a particular region of the spectrum [10]. Inter-

action of the component being measured with the immobilized reagent phase causes a change in the optical properties of the reagent phase.

In traditional optical biosensors, the measurement setup consists of a light source, a detecting system, waveguiding equipment and chemical chambers where the interaction occurs. The use of optical fibers makes it possible to bring light from a source to a sample and back to the detecting system. And the use of immobilization makes it possible to do chemistry on the sample in situ [11].

In MEMS-based optical biosensor systems, similar configurations are used. Light propagates in free space or is guided by optical fibers or planar optical waveguides. In one setup, only the mechanical structure (mirror, cantilever or reaction chamber) is fabricated on wafers. After dicing, optical fibers are aligned and fixed on the structure to build the complete device. In another setup, all the elements are fabricated with collective techniques on the same substrate. Therefore, MEMS-based optical biosensors have the advantages of enhanced reliability and low cost. They also benefit from the advantages offered by mechanical structures [12–14].

Optical sensors offer some advantages over electrochemical methods [10, 11]. First, no reference electrode is required; however, reference intensity is necessary to minimize environmental effects on the system. Second, fiber-optic sensors are immune to electrical noise, but ambient light can be a problem. Finally optical sensors have the potential for higher information content than electrical sensors because there is a complete spectrum of information available. However, the linearity is usually limited to a very narrow range.

General Optical Detection Methods

Direct Method When the analyte binds to the receptor, a change in optical absorption or fluorescence occurs. The interaction of an indicator reagent with analyte may be represented as

$$A + R \leftrightarrow A \cdot R$$
$$K_R = \frac{[A \cdot R]}{[A][R]} \tag{1}$$

where R is a reagent and A is an analyte. Given that the total amount of reagent is fixed, then $[R]_{tot} = [R]_{eq} + [A \cdot R]_{eq}$. The equilibrium concentration of the bound analyte-reagent is given by

$$[A \cdot R]_{eq} = \left(\frac{[A]_{eq}}{(1/K_R) + [A]_{eq}} \right) [R]_{tot} \tag{2}$$

and the equilibrium free-reagent concentration is given by

$$[R]_{eq} = \left(\frac{1}{(1/K_R) + [A]_{eq}} \right) [R]_{tot} \tag{3}$$

- If the measured optical parameter is proportional to $[A \cdot R]_{eq}$, then response is proportional to $[A]_{eq}$ at low concentrations ($[A]_{eq} \ll 1/K_R$). The response shows saturation behavior reaching a limiting value as $[A]$ increases to values $\gg 1/K_R$ Eq. (2).
- If the measured optical parameter is proportional to $[R]_{eq}$, then the signal decreases with added analyte. In this case, a linear working curve is obtained based on Eq. (3).
- If one can measure both $[A \cdot R]_{eq}$ and $[R]_{eq}$, since the ratio of the two is directly proportional to analyte concentration, the dependence on $[R]_{tot}$ can be eliminated:

$$\frac{[A \cdot R]_{eq}}{[R]_{eq}} = K_R [A]_{eq}$$

Where feasible, this is the preferred situation. The measurement of $[R]_{eq}$ serves as the reference for the measurement of $[A \cdot R]_{eq}$, since the measured ratio is independent of instrumental fluctuations and any changes in reagent-phase optical properties.

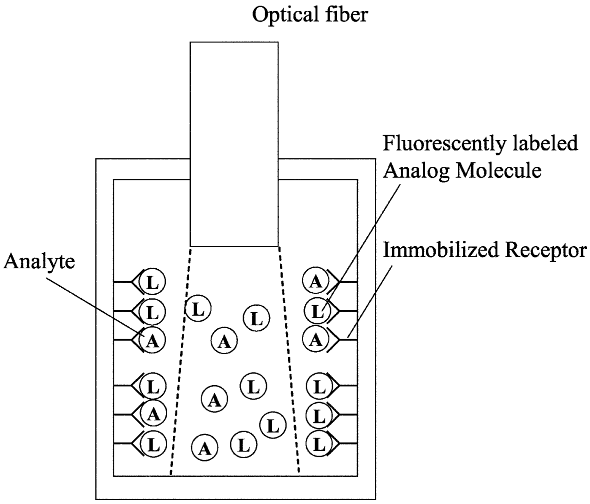
Indirect (Competitive Binding) Method There are two competing reactions occurring, the analyte-receptor reaction and an analog-receptor reaction. The analog molecules are fluorescently labeled molecules that are similar in structure to the analyte molecules. Thus, the analog molecules will bind to the receptors, though not as strongly as the analyte molecules. The optical change, which is measured, is in the analog-receptor reaction.

Figure 6 shows the competitive-binding scheme. Since there are fixed concentrations of receptor and analog immobilized in the chamber, as the concentration of the analyte increases, the amount of analog bound to the receptors decreases, and thus the optical signal will change.

- Analyte-receptor reaction: Eq. (1).
- Analog-receptor reaction, which is described by

$$L + R \leftrightarrow L \cdot R$$
$$K_L = \frac{[L \cdot R]}{[L][R]} \tag{4}$$

where the analog molecules and the receptor molecules are represented by L and R, respectively.



MEMS-Based Biosensor, Figure 6 The competitive-binding scheme for optical biosensors. The analyte molecules are indicated by A and the fluorescently labeled analog molecules are indicated by L [10]

The total number of receptors is fixed, and the total amount of analog is also fixed:

$$[R]_{\text{tot}} = [A \cdot R]_{\text{eq}} + [L \cdot R]_{\text{eq}} + [R]_{\text{eq}} \tag{5}$$

$$[L]_{\text{tot}} = [L \cdot R]_{\text{eq}} + [L]_{\text{eq}} \tag{6}$$

Thus, the concentration of analyte is

$$[A] = \frac{[A \cdot R][L]}{[L \cdot R]} \frac{K_{\text{L}}}{K_{\text{R}}} \tag{7}$$

If the equilibrium constants are large, $[R] \ll [L \cdot R], [A \cdot R]$, then

$$[A] = \frac{([R]_{\text{tot}} - [L \cdot R])\,[L]}{[L \cdot R]} \frac{K_{\text{L}}}{K_{\text{R}}} \tag{8}$$

Thus, the analyte concentration can be determined from the optical detection of either the analog, L, or the bound analog-reagent complex, $L \cdot R$.

Other Methods

Catalyst The immobilized reagent can catalyze transformation of an analyte to a product with different optical properties. For example, a sensor based on the use of immobilized alkaline phosphatase to catalyze the hydrolysis of *p*-nitrophenylphosphate to *p*-nitrophenoxide has been reported [15].

Bioluminescence- and Chemiluminescence-based Biosensors These reactions are the most sensitive chemical probes. The simplest accepted mechanism for the production of light from biological reactions is that of the crustacean *Cypridina hilgendorfi*:

$$\text{Luciferin} + \text{luciferase} \xrightarrow[H_2O]{O_2} \text{Oxyluciferin*}$$

$$\text{Oxyluciferin*} \longrightarrow \text{Oxyluciferin} + \textit{light}$$

where the luciferin is the molecule that emits light and the luciferase is the enzyme that oxidizes the luciferin to its excited state, which is denoted by the asterisk. Typical bioluminescence reactions are much more complicated [16].

Fluorophore- and Chromophore-based Biosensors Chromophore and fluorophore molecules show a change in absorbance or fluorescence at a particular wavelength due to a change in oxidation state of the molecule. Thus a chemical sensor can be constructed for the usual chemical parameters, such as pH, oxygen and ammonia, which then can be coupled to enzyme reactions.

M

Optical Sensor Configurations

- Bifurcated device in which separate fibers are used to transmit light to and from an immobilized reagent phase.
- Sensor in which the same (single) fiber carries light to and from the immobilized reagent.
- Sensor in which the reagent phase is coated on the outside of the fiber. This arrangement takes advantage of the fact that light transmitted through the optical fiber penetrates a small distance of cladding. Changes in the refractive index and/or the absorptive properties of the reagent phase will modify the intensity of light transmitted through the fiber.

Examples of Optical MEMS Biosensors

Integrated Mach–Zehner Interferometer

Principles These sensors make use of guided waves or modes in planar optical waveguides. The waveguide materials usually include high-refractivity silicon dioxide and silicon nitride films on oxidized silicon wafer substrates. Interaction of an analyte molecule with a recognition structure immobilized on the waveguide surface changes the effective refractive index near the evanescent field. These changes induce changes of guided wave modes

since the effective refractive index is the most important physical quantity of the guided modes [12–14, 17].

Configuration A waveguide is split into an open measurement path and a protected reference path and recombined after some distance. The phase difference introduced by analyte interaction (refractive index change) in the sensing path is detected by interference effects.

Typical Applications These include the detection of different organic solvents in liquid phase and biotin/streptavidin-meditated immuno-sensing involving antibody-antigen binding experiments.

Fabry–Pérot-based Microspectrometer

Principles A Fabry–Pérot interferometer (FPI) is an optical element consisting of two partially reflecting, low-loss, parallel mirrors separated by a gap. The optical transmission characteristics through the mirrors consist of a series of sharp resonant transmission peaks occurring when the gap is equal to multiples of half a wavelength of the incident light. These transmission peaks are caused by multiple reflections of the light in the cavity. Small changes in the gap (width, absorptivity) can produce large changes in the transmission response. The transmission is a function of both the gap spacing and the radiation wavelength [12, 13].

Configuration There are many kinds of FPI for biosensors. A typical FPI interferometer consists of an LED, a channel for bio reaction, a micro-FPI and a detector.

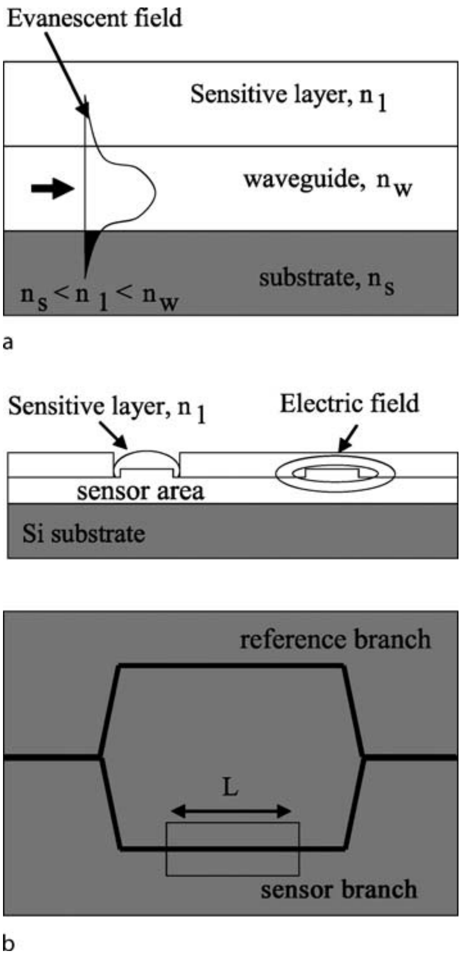
Typical Applications These include gas sensors to monitor carbon monoxide, carbon dioxide and hydrocarbons, and biosensors to measure the absorption spectrum of blood.

Other MEMS Biosensors

Besides MEMS-based electrochemical and optical biosensors, there are other types of MEMS biosensors: acoustic wave, nanomaterial-based and magnetic microbiosensors.

MEMS-Based Acoustic Wave Biosensors

Introduction A MEMS-based acoustic wave biosensor is a chemical sensor which detects changes in resonant frequency of a mechanical resonator when biomolecules are adsorbed on the surface of a biologically active membrane. Since frequency change can be measured very precisely, very small mass changes can be measured. This leads high sensitivity of the biosensors. Typical acoustic wave biosensors are bulk acoustic wave (BAW) and surface acoustic wave (SAW) sensors.

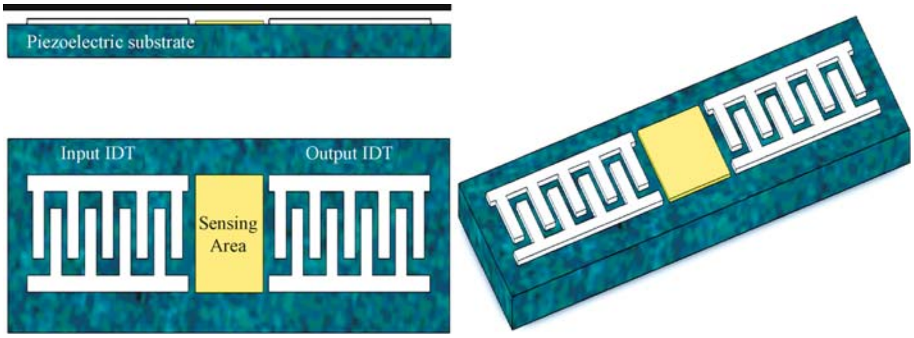


MEMS-Based Biosensor, Figure 7 (**a**) Schematic of an evanescent wave traveling in an optical waveguide. The traveling light in the waveguide is influenced by analyte-induced changes of the refraction index in the adjacent sensitive layer. (**b**) Schematic of a conventional Mach–Zehnder interferometer: The cross-section shows the separate sensor and reference branches [12]

Theory BAW sensors utilize quartz crystal as a substrate. Generally, the crystal is a thin disk where square or rectangular metal electrodes are deposited on the opposite faces. Frequency is changed according to mass change, which can be calculated by Eq. (9) under the assumption that the change in mass is negligible compared to the mass of the crystal ($\Delta m \ll m$):

$$\Delta f = -f_0 \frac{\Delta m}{m} \tag{9}$$

where m is the mass of the crystal and Δm is the mass change due to a biological substance.



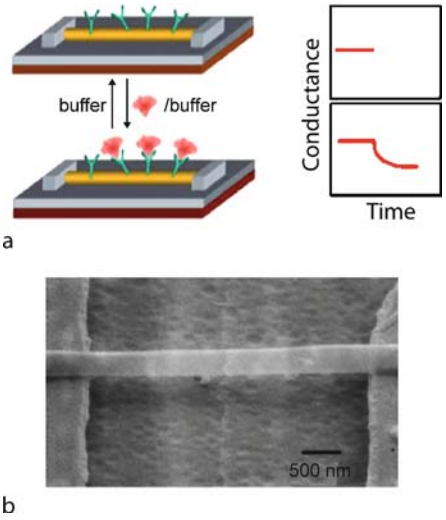
MEMS-Based Biosensor, Figure 8 Schematic of MEMS-based acoustic wave biosensor

In contrast, SAW transducers use Rayleigh waves that are excited from one pair of interdigital electrodes (IDT). The transit time of the wave packet from one set of electrodes to the other will be extended by adsorption of mass on the delay-line surface:

$$\Delta f = (k_1 + k_2) f_0^2 \frac{\Delta m}{A} \tag{10}$$

where k_1 and k_2 are material constants of the SAW substrate. Figure 8 shows the typical structure of a MEMS-based SAW biosensor.

When a biological substance reacts with a sensing layer which is coated on the piezoelectric substrate, the resonant frequency of the MEMS biosensor is changed. The frequency shift is related to the mass change of the biologically sensitive membrane.



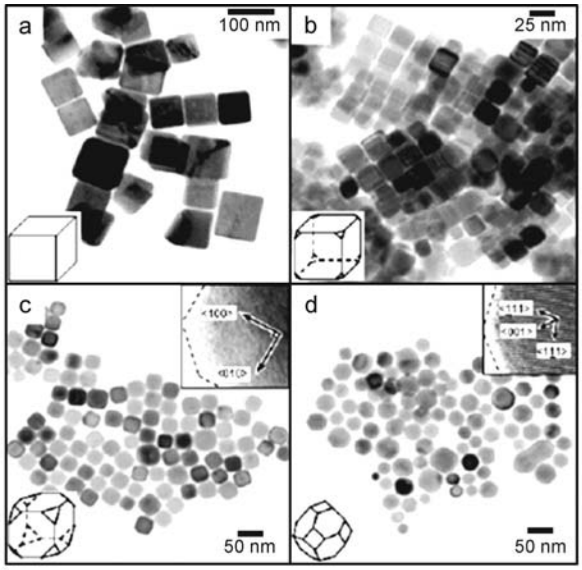
MEMS-Based Biosensor, Figure 9 (**a**) Schematic of MEMS-based nanowire biosensor [20]; (**b**) SEM image [21]

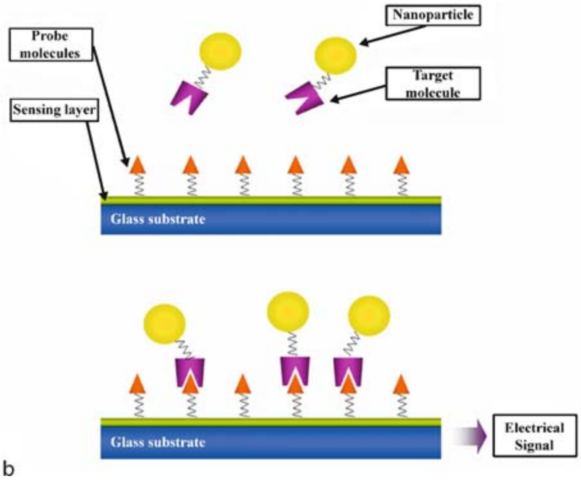
Nanomaterial-Based MEMS Biosensors

Introduction A nanomaterial-based MEMS biosensor utilizes nanostructured materials as sensing media as well as a transducer. This is a unique characteristic compared to the other types of MEMS biosensors mentioned up to now. The nanomaterials have good electrical properties and high sensitivity for biological substances. Furthermore, they are transducers as well as sensing media. This enables direct detection of biological substances without any labels. Nanomaterial-based MEMS biosensors are used for the detection of DNA, RNA, proteins, ions, small molecules, cells and even the pH values [19].

MEMS Biosensors Based on Nanowires A MEMS biosensor based on the unique properties of nanowire enables highly sensitive and selective detection because nanowire as an electrode has a high surface-to-volume ratio for adsorption. When a chemically functionalized nanowire is immersed in an analyte solution, analytes react to biological active materials. As results of the reaction, electrical properties of the nanowire such as resonant frequency, conductivity and resistance are changed [20, 21]. Schematic and SEM images of a MEMS-based nanowire biosensor are shown in Fig. 9.

MEMS Biosensors Based on Nanoparticles Nanoparticles are often utilized as an analyte recognition element in MEMS biosensors. Nanoparticles have a quite large sensing area mainly due to their extremely small size. This enhances the reaction possibility of biomolecules. Furthermore, sensitivity of the biosensor can be increased when metal nanoparticles are positioned between two metal electrodes. When the analyte conjugated with metal nanoparticle is captured between two electrodes, the electric field intensity is amplified. Gold, silver, metal oxide and magnetic nanoparticles are widely used for detection





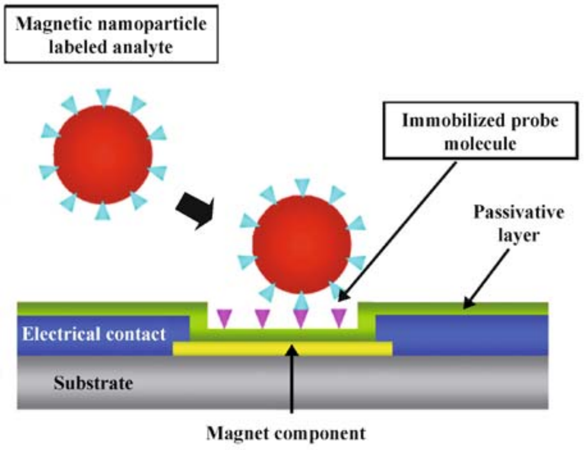
MEMS-Based Biosensor, Figure 10 (**a**) SEM image of nanoparticle [22]; (**b**) schematic of MEMS-based nanoparticle biosensor

of biomolecules in electrochemical biosensors. Figure 10a shows a SEM image of a semiconductor nanoparticle, PbS [22]. A general configuration of biosensing based on nanoparticles is shown in Fig. 10b. Probe molecules in a recognition layer are reacted with target biomolecules specifically. This reaction leads to changes in electrical signals.

MEMS-Based Magnetic Biosensors

Introduction Most MEMS-based magnetic biosensors manipulate a magnetic bead where biomolecules are conjugated. It is still a challenging problem to manipulate biomolecules directly. However, the manipulation of a magnetic bead is relatively easy because a magnet such as an inductor facilitates control of the biomolecules when they are conjugated with a magnetic bead. Thus, this section focuses on magnetic MEMS biosensors based on a magnetic bead.

Theory Typical MEMS-based magnetic biosensors are magnetoresistive (MR) sensors, anisotropic magnetoresistive (AMR) sensors and giant magnetoresistive (GMR) sensors. The MR effect is a change in the electrical resistivity when magnetic field changes. The AMR effect is the change of electrical resistivity when the magnetization changes from parallel to transverse with respect to the current flow. The GMR effect is based on resistivity change due to magnetic alignment of two magnetic layers which is a stacked structure of a ferromagnetic, nonmagnetic and ferromagnetic layer. When the magnetic direction of the two ferromagnetic layers is parallel, the electrical resistance of the structure is low. When the direction is perpendicular, the resistance is high [23]. In most MEMS-based magnetic biosensors, the analyte to be detected is magnetically labeled and passes over an array of specific probe molecules that is immobilized on magnetic field sensors. When the magnetic beads are captured on a magnetic component, unbound biomolecules are washed away. The magnetic property change of the magnetic component is then measured. Figure 11 shows schematically the sensing principle of a MEMS-based magnetic biosensor. MEMS-based magnetic biosensors have been used to detect various biomolecules including streptavidin, microorganisms and cells.



MEMS-Based Biosensor, Figure 11 Schematic of MEMS-based nanoparticle biosensor [23].

Future Directions for Research

MEMS-based biosensors offer uninterrupted analysis of biological substances potentially because detection and evaluation are carried out by a transducer and a read-out element simultaneously. Up to now, miniaturization of transducers has progressed successfully. However, integration of read-out elements is quite limited. So it is necessary for conventional measurement equipment to provide recognizable results. Thus, it is highly desirable to integrate a read-out element that is capable of offering recognizable detection results having its full function, so eliminating the need for conventional measurement equipment.

Definition

Meshless methods belong to a class of techniques for solving boundary/initial value ►partial differential equations in which both geometry representation and numerical ►discretization are principally performed based on nodes or particles. In meshless methods, there is no inherent reliance on a particular mesh topology meaning that no ►element connectivity is required. In practice, however, in many meshless methods recourse must be taken to some kind of background meshes at least in one stage of the implementation.

Overview

Analysis of many practical processes in modern engineering requires modeling of problems with time dependent geometry or boundary conditions. Pulsating flow of blood in heart, metal forming processes and stretching of a polymer filament are only a few examples. Conventional mesh based methods such as the Finite Volume and Finite Element Methods face serious difficulties when dealing with large element deformations and/or element entanglement. This is particularly true in the case of problems involving discontinuities and moving boundaries. Examples of such problems are complex free surface flows, fluid-structure interactions, projectile impact and material break up during manufacturing processes. Standard mesh based techniques handle such problems using adaptive remeshing techniques. This means that the computational mesh (grid) is remeshed either globally or locally to correctly represent the deformed geometry. This technique however suffers from two drawbacks. Firstly, generating a new mesh may not only be troublesome but also consume considerable time. This is particularly true when complex three-dimensional geometries are to be meshed using automatic mesh generators. Secondly, the mapping of the state variables from the old mesh to the new mesh can introduce significant numerical errors into the computations. To alleviate this problem, special numerical techniques have been devised in which the material and the mesh move independently.

In recent years, interest in meshless methods has grown rapidly because such methods can circumvent the above mentioned difficulties in a more convenient fashion. The main advantages of meshless methods can be summarized as follows:

- Problems with large deformations can be handled since the connectivity among nodes is generated during the computation and can change in time.
- There are no constraints imposed from the system geometry and the system may evolve far from the initial conditions.
- The accuracy of the solution can be controlled easily, since nodes can be added in the regions where refinement is required.
- Complex geometries can be accurately represented by particles.
- The particles map onto the mass density of the fluid, leading automatically to higher resolution in the high-density regions.
- Fairly simple implementation procedure.

Abundance of meshless methods, as well as many variations in the terminology adopted in the literature makes a thorough review unfeasible for the purpose of this manuscript. Instead, this review attempts to give an overview of this class of methods by briefly describing some of their most important features.

Based on the physical principle, meshless (particle) methods can be classified as deterministic and probabilistic. Many of the meshless methods are based on probabilistic principles. The Molecular dynamics, Monte Carlo methods, the Lagrangian Probability Density Functions (PDF) methods, and the Lattice Boltzmann (LBM) method are among these methods. Methods such as the Smoothed Particle Hydrodynamics (SPH) and the Vortex method ini-

tially developed as probabilistic methods but nowadays they are most frequently used as deterministic.

The meshless methods can be also classified as strong and ▶ weak formulations of the associated partial differential equations. The strong formulation of a partial differential equation is usually obtained by a collocation technique. The Smoothed Particle Hydrodynamics method, the Vortex method and the Generalized Finite Difference method (GFD) are based on the strong form. On the other hand, weak forms are often based on Galerkin formulations. The Diffuse Element Method (DEM), the Element Free Galerkin Method (EFGM), the Reproducing Kernel Particle Method (RKPM) (▶ Kernel function), the hp cloud method, the Partition of Unity Method (PUM), and the Meshless Local Petrov–Galerkin Method (MLPG) are all among this category. Some particle methods like the Particle-in-Cell method can be used in both strong and weak formulations.

When studying phenomena such as dynamic interaction of molecules or the non-equilibrium movements of atoms in nano-scales, in which the object under consideration is a set of particles (i. e. molecules and atoms), particle methods are a natural choice. The current trend in computational methods is to use particle methods both as discretization tools as well as physical models for continuum physics simulation.

In reality many of meshless methods are not truly mesh free and belong to one of the following categories:

- Methods that require background grids for the computation of resulting integrals numerically. The creation of a background mesh is generally a trivial task and can be automated. Element Free Galerkin methods belong to this group.
- Methods that require background grids only locally for the integration process. Generally, creation of local mesh is a far easier task. Meshless Local Petrov–Galerkin method belongs to this category.
- Methods that do not require a mesh at all, but their stability and accuracy depend considerably on the selection of nodes. Collocation methods and the Generalized Finite Difference methods using irregular meshes belong to this group.
- Particle methods that require a predefinition of particles for their computations. Such methods require some kind of mesh to predefine the particles. Smoothed Particle Hydrodynamics method belongs to this category.

As the name *meshless methods* is used for a wide range of numerical techniques, it is difficult to specify a definite starting date for these methods. The earliest works, however, may be attributed to those reporting extension of the Finite Difference Methods to general irregular or unstructured grids in the early 60's. While the classical finite difference method uses regular grids, the GFD method can use even irregular sets of points. The GFD method is suitable for irregular geometries and the number of points in different regions of the solution domain can vary. This is achieved by adding or removing points anywhere required to increase the accuracy or decrease the computational expenses. This method has been used in studying many engineering problems involving heat transfer, flow in deformable channels and deformation of membranes. The GFD method is explained briefly in the sequel.

In 1977, Lucy [1] and Gingold and Monaghan [2] independently introduced the so-called Smoothed Particle Hydrodynamics method which is one of the oldest meshless methods. The method was originally developed for astrophysical studies such as formation of asteroids and the evolution of galaxies and has now become a standard tool in this field. In recent years, SPH has been extensively used for various fluid flow problems including both compressible and incompressible flow regimes. The method has been recently used for simulation of the generalized non-Newtonian and viscoelastic fluid flow problems. The SPH method has been also employed in the field of solid mechanics involving complex phenomena such as crack propagation and material fragmentation.

M

In 1996, a complete volume (Vol. 139) of the journal of Computer Methods in Applied Mechanics and Engineering was devoted to meshless methods and some of the pioneering works at the time were published. In the past ten years the meshless methods have constantly gained more popularity and been applied to a wider range of engineering applications.

Today, there are books written about meshless methods [3] and several excellent review articles are also available each emphasizing on a particular class of meshless methods [4–6]. There are also several specialist groups worldwide working on various types of meshless methods.

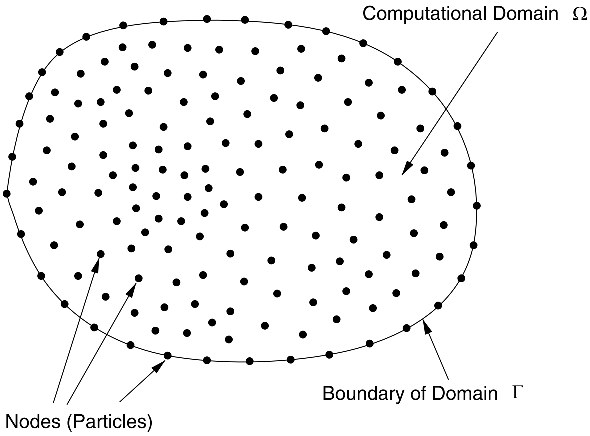
Basic Methodology

Meshless methods like all other computational methods for solving partial differential equations consist of the following general steps:

1. Specify a ▶ computational domain from the ▶ physical domain of the problem under consideration and define the proper boundary and initial conditions for it.
2. Generate an initial node (particle) distribution on the computational domain. In mesh-based methods, a mesh is generated at this stage.
3. Choose a proper approximation function so that every function can be constructed in the computational domain.

4. Construct the discretized form of the governing equations. This stage normally results in a system of linear equations.
5. Solve the system of equations to obtain the unknowns (e. g., velocity or temperature) at each computational node (particle).
6. Post-process the solution to obtain any additional required engineering data, e. g., drag or heat flux rate.

The main difference between the meshless methods and the mesh-based methods lies at the stage three. Below, this stage is described in more detail for a number of meshless methods. It should be kept in mind that the meshless techniques are by no means restricted to the following methods.



Meshless Methods, Figure 1 Computational domain and nodes

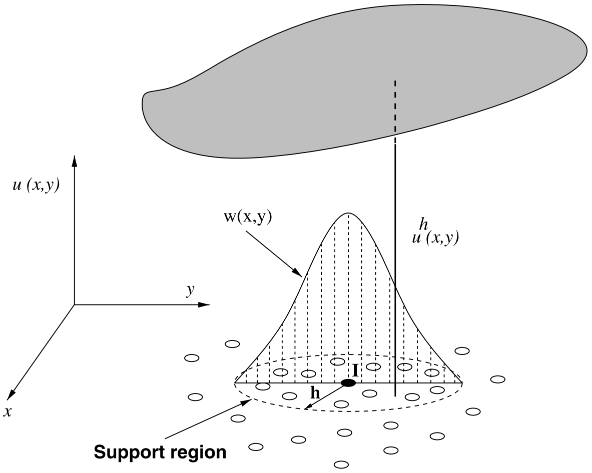
Meshless Approximation Functions

Consider a function $u(\boldsymbol{x})$ in a domain Ω. Within the domain, a set of nodes (particles) $\boldsymbol{x}_I$, $I = 1, ..., n$, is constructed and the value of u at I is denoted by u_I. Then, the approximated value of u, i. e. u^h, at any other point $\boldsymbol{x}$ is given by

$$u^h(\boldsymbol{x}) = \sum_I w(\boldsymbol{x} - \boldsymbol{x}_I)\; u_I\, \Delta V_I\,, \tag{1}$$

where w is the weight function of the approximation and ΔV_I is some measure of the domain surrounding node I. A weight function is defined to have ▶compact support. This means that the subdomain over which the weight function is nonzero is small relative to the rest of domain. Then, the summation is only over points I, where $w(\boldsymbol{x} - \boldsymbol{x}_I) > 0$. To each node I, a subdomain $\Delta\Omega_I$ is associated which is sometimes called the domain of influence of the node. These subdomains are usually in the form of either rectangles or circles in a two-dimensional domain. For three-dimensional problems, discs or balls are often used. Subdomains of different shapes may be used in a single model. Figure 1 shows a typical computational region, nodes and their associated support regions. Note that in practice there is a considerable overlay of support regions. Usually five to ten subdomains overlap each node.

Figure 2 presents distribution of the weighting function around a typical node I in a two-dimensional domain along with the approximated function $u(x, y)$. Below, the approximation functions for a number of meshless methods are briefly described. The presentation will be according to their historical appearance.



Meshless Methods, Figure 2 Weight function, support region and the approximated function

Generalized Finite Difference Methods

The extension of the classical Finite Difference Method to irregular grids and geometries led to the development of the Generalized Finite Difference Methods. The bases of GFD were published in early seventies. The method relies on the Taylor's series expansion and its accuracy depends on the number of terms kept in the series. The main disadvantage of this method is the possibility of becoming singular or ill-condition when improper set of nodes are used in the approximation formula. Removal of this singularity or ill-conditioning is the subject of current research in the field [7].

Like all other meshless methods, the first step in GFD is to scatter nodal points in the computational domain and along the boundary. To each node (point) a collection of neighboring nodes are associated which is called star. The number and the position of nodes in each star are decisive factors affecting the Finite Difference approximation. Par-

ticular node patterns can lead to ill-conditioned situations and ultimately degenerated solutions. Using the Taylor's series expansion the value of any sufficiently differentiable smooth function u at the central node of star, u_0, can be expressed in terms of the value of the same function at the rest of nodes, u_i, with $i = 1, \dots, N$ where N is the total number of neighboring nodes in the star and is one less than the total number of nodes in it. In two dimensions, a second-order accurate Taylor series expansion can be written as

$$u_i = u_0 + h_i \frac{\partial u_0}{\partial x} + k_i \frac{\partial u_0}{\partial y} + \frac{1}{2}\left(h_i^2 \frac{\partial^2 u_0}{\partial x^2} + k_i^2 \frac{\partial^2 u_0}{\partial y^2} + 2 h_i k_i \frac{\partial^2 u_0}{\partial x \partial y} \right), \tag{2}$$

where $h_i = x_i - x_0$, $k_i = y_i - y_0$, the coordinates of the central node are (x_0, y_0) and the coordinates of the i nodes are shown by (x_i, y_i). This expression is valid for all $i = 1, \dots, N$ and may be added to obtain:

$$\sum_{i=1}^{N} (u_i - u_0) = \sum_{i=1}^{N} h_i \frac{\partial u_0}{\partial x} + \sum_{i=1}^{N} k_i \frac{\partial u_0}{\partial y} + \frac{1}{2}\left(\sum_{i=1}^{N} h_i^2 \frac{\partial^2 u_0}{\partial x^2} + \sum_{i=1}^{N} k_i^2 \frac{\partial^2 u_0}{\partial y^2} + \sum_{i=1}^{N} 2 h_i k_i \frac{\partial^2 u_0}{\partial x \partial y} \right). \tag{3}$$

It is then possible to define the function $B(u)$ in the following form:

$$B = \sum_{i=1}^{N} \left[\left(u_0 - u_i + h_i \frac{\partial u_0}{\partial x} + k_i \frac{\partial u_0}{\partial y} + \frac{h_i^2}{2} \frac{\partial^2 u_0}{\partial x^2} + \frac{k_i^2}{2} \frac{\partial^2 u_0}{\partial y^2} + h_i k_i \frac{\partial^2 u_0}{\partial x \partial y} \right) w(h_i, k_i) \right]^2 \tag{4}$$

where $w(h_i, k_i)$ is the weight function. The ► least square method is then used and the function B is minimized with respect to $\partial u_0/\partial x$, $\partial u_0/\partial y$, $\partial^2 u_0/\partial x^2$, $\partial^2 u_0/\partial y^2$ and $\partial^2 u_0/\partial x \partial y$. This results in a set of five linear equations with the aforementioned partial derivatives as five unknowns. The solution to this system of equations gives explicit equations of the unknowns in terms of the nodal value of function u in the star. Note that in the present situation, the star must have at least five nodes. When solving a partial differential equation using GFD, one needs to substitute the relevant expressions for the partial derivatives in the differential equation so that an algebraic equation is obtained for every node in the computational domain. These equations are in the following form:

$$u_0 = \sum_{i=1}^{N} m_i u_i . \tag{5}$$

This is called the star equation. When the same process is carried out for each node of the domain, an equation is obtained for each unknown and the system can be solved to determine the nodal values of the unknown function u and all its partial derivatives.

Several factors affect the adequacy of the star equation. These are:

- Number of nodes of the star. The minimum number of nodes in star depends on the problem. For a second-order partial differential equation to be solved in two dimensions, the minimum number of nodes is five. The use of excessive number of nodes makes the computations more time consuming without any significant improvement in the accuracy.
- The shape of star or in other words the relative coordinates of the nodes of the star with regards to the central node is also important. The quality of the GFD is sensitive to grid smoothness. Thus, very sharp changes of mesh density should be avoided. Several criteria have been developed to appropriately select nodes for the star. A simple yet efficient method in two dimensions is the so called four quadrant criterion which uses the nearest nodes in each quadrant constructed around the central node.
- The importance of the weight function is obvious from the definition of $B(u)$. In fact, the value of the function in every node of the domain is the weighting sum of its values in the rest of the nodes of the star. Various weighting functions are used in practice. The exponential function $w(x, y) = \exp(-10(x^2 + y^2))$ and the cubic spline function are only two examples. Weight functions usually have a compact support.

Smoothed Particle Hydrodynamics

In the context of SPH methods, Monaghan [8] introduced an approximation in the form of

$$u^h(\boldsymbol{x}) = \int_{\Omega} w(\boldsymbol{x} - \boldsymbol{x}', h) u(\boldsymbol{x}') \mathrm{d}\Omega , \tag{6}$$

where $w(\boldsymbol{x} - \boldsymbol{x}', h)$ is a kernel, smoothing or weight function, and h refers to the size of the support region. Various requirements or properties for the smoothing function are applied in different literatures. Summarized below are the most general ones:

- The smoothing function must be normalized, $\int_{\Omega} w(\boldsymbol{x}-\boldsymbol{x}', h)\, \mathrm{d}\Omega = 1$.
- It should have a compact support. That is $w(\boldsymbol{x}-\boldsymbol{x}') = 0$ for $|\boldsymbol{x}-\boldsymbol{x}'| > \kappa h$ where κ is a constant parameter.
- $\lim_{h\to 0} W(\boldsymbol{x}-\boldsymbol{x}', h) = \delta(\boldsymbol{x}-\boldsymbol{x}')$ in the compact support region $|\boldsymbol{x}-\boldsymbol{x}'| \leqslant \kappa h$. Here, δ is the ► Dirac delta function.
- The function w should be monotonically decreasing.
- The smoothing function should be a sufficiently smooth even (symmetric) function.

Various weight functions have been proposed in the literature. Two of these are the exponential ($\alpha = 0.4$)

$$w(s) = \begin{cases} \exp\left[-(s/\alpha)^2\right] & \text{for } s \leqslant 1 \\ 0 & \text{for } s > 1\,, \end{cases} \tag{7}$$

and the cubic spline

$$w(s) = \begin{cases} \frac{2}{3} - 4s^2 + 4s^3 & \text{for } s \leqslant \frac{1}{2} \\ \frac{4}{3} - 4s + 4s^2 - 4\frac{s^3}{3} & \text{for } \frac{1}{2} < s \leqslant 1 \\ 0 & \text{for } s > 1\,, \end{cases} \tag{8}$$

weight functions. In these definitions, $s = S/S_{\max}$ where S is the length of vector $\boldsymbol{x}-\boldsymbol{x}'$ and $S_{\max}$ is the radius of the support region. These are isotropic or polar weight functions where the supports are circular. It is also possible to generate weight functions with rectangular supports using tensor products. For example in two dimensions, one can write $w(\boldsymbol{x}-\boldsymbol{x}') = w(x-x')\, w(y-y')$.

In the context of SPH, one needs a discrete form of Eq. (6) to devise practical approximations. In multi-dimensions, a formula similar to Eq. (1) is used. In this equation, $\varphi_I(\boldsymbol{x}) = w(\boldsymbol{x}-\boldsymbol{x}_I)\Delta V_I$ is the shape function of the SPH method. Note that in most cases $u_I \neq u^h(\boldsymbol{x}_I)$ and the shape functions do not pass through the data making imposition of Dirichlet boundary conditions difficult.

Moving Least Square

This type of approximation originates in data fitting. In the Moving Least Square method (MLS), the following approximation form is used [4]

$$u^h(\boldsymbol{x}) = \sum_{i=1}^{m} p_i(\boldsymbol{x})\ a_i(\boldsymbol{x}) \equiv \mathbf{p}^{\mathrm{T}}(\boldsymbol{x})\ \boldsymbol{a}(\boldsymbol{x})\,, \tag{9}$$

where m is the number of terms in the basis, $p_i(\boldsymbol{x})$ are monomial basis functions, and $a_i(\boldsymbol{x})$ are their coefficients. Examples of common basis functions in one and two dimension are

$$\begin{aligned} &\text{1D:} \begin{cases} \mathbf{p}^{\mathrm{T}}(\boldsymbol{x}) = (1,\ x) & \text{linear} \\ \mathbf{p}^{\mathrm{T}}(\boldsymbol{x}) = (1,\ x,\ x^2) & \text{quadratic} \end{cases} \\ &\text{2D:} \begin{cases} \mathbf{p}^{\mathrm{T}}(\boldsymbol{x}) = (1,\ x,\ y) & \text{linear} \\ \mathbf{p}^{\mathrm{T}}(\boldsymbol{x}) = (1,\ x,\ y,\ x^2,\ xy,\ y^2) & \text{quadratic} \end{cases} \end{aligned} \tag{10}$$

In MLS methods, although it is more common to use monomial functions, it is also possible to use other functions as basis. For example, in problems with singular solutions, singular functions can be used.

The coefficients $a_i(\boldsymbol{x})$ are obtained by performing a weighted least square fit for the local approximation $u^h(\boldsymbol{x})$. This is achieved by minimizing the following quadratic form

$$\begin{aligned} J &= \sum_I w(\boldsymbol{x}-\boldsymbol{x}_I)\left[u^h(\boldsymbol{x}, \boldsymbol{x}_I) - u(\boldsymbol{x}_I)\right]^2 \\ &= \sum_I w(\boldsymbol{x}-\boldsymbol{x}_I)\left[\sum_i p_i(\boldsymbol{x}_I)\ a_i(\boldsymbol{x}) - u_I\right]^2 \end{aligned} \tag{11}$$

where $w(\boldsymbol{x}-\boldsymbol{x}_I)$ is a weighting function with compact support. Usually the same weight functions as in the SPH method are used. It should be emphasized that in Eq. (11), index I refers to points while index i is used for the polynomial terms.

Therefore, coefficients $a_i(\boldsymbol{x})$ can be obtained by solving the following system of m equations

$$\frac{\partial J}{\partial \boldsymbol{a}} = \boldsymbol{A}(\boldsymbol{x})\boldsymbol{a}(\boldsymbol{x}) - \boldsymbol{B}(\boldsymbol{x})\boldsymbol{u} = 0 \tag{12}$$

where $\boldsymbol{u} = (u_1,\ u_2,\ ...,\ u_n)^{\mathrm{T}}$, $\boldsymbol{A} = \boldsymbol{P}^{\mathrm{T}}\boldsymbol{W}(\boldsymbol{x})\boldsymbol{P}$ is a $m\times m$ matrix, and $\boldsymbol{B} = \boldsymbol{P}^{\mathrm{T}}\,\boldsymbol{W}(\boldsymbol{x})$ is a $m\times n$ matrix. Note that $\boldsymbol{a}(\boldsymbol{x}) = \boldsymbol{A}^{-1}(\boldsymbol{x})\,\boldsymbol{B}(\boldsymbol{x})\,\boldsymbol{u}$. In these definitions, $\boldsymbol{P}$ is a $m\times n$ matrix whose (i,j)-th element is $p_j(x_i)$ and $\boldsymbol{W}(\boldsymbol{x})$ is a $n\times n$ diagonal matrix whose (i,i)-th element is $w(x-x_i)$.

By these definitions, the approximation for $u(\boldsymbol{x})$ can be written as

$$u^h(\boldsymbol{x}) = \sum_{I=1}^{n} \varphi_I^k(\boldsymbol{x})\, u_I\,, \tag{13}$$

where the shape functions are given by $\varphi^k = [\varphi_1^k(\boldsymbol{x})\ \ \varphi_2^k(\boldsymbol{x})\ \ ...\ \ \varphi_n^k(\boldsymbol{x})] = \boldsymbol{p}^{\mathrm{T}}(\boldsymbol{x})\boldsymbol{A}^{-1}(\boldsymbol{x})\boldsymbol{B}(\boldsymbol{x})$. Here, superscript k denotes the order of the polynomial basis. The lowest order form of the Moving Least Square, i. e. for $k = 0$, are called the Shepard function

$$\varphi_I^0(\boldsymbol{x}) = \frac{w(\boldsymbol{x}-\boldsymbol{x}_I)}{\sum_I w(\boldsymbol{x}-\boldsymbol{x}_I)}\,. \tag{14}$$

Equation (11) presents a discrete form of the MLS method. A continuous counterpart of this method can be obtained by defining $J(\boldsymbol{x})$ as

$$J(\boldsymbol{x}) = \int_{\Omega} w(\boldsymbol{x}-\boldsymbol{x}') \left[u^h(\boldsymbol{x},\boldsymbol{x}') - u(\boldsymbol{x}')\right]^2 \mathrm{d}\Omega \tag{15}$$

where $w(\boldsymbol{x}-\boldsymbol{x}')$ is a weight function as before and $u^h(\boldsymbol{x},\boldsymbol{x}') = \sum_i p_i(\boldsymbol{x}')a_i(\boldsymbol{x})$.

Applying the least square technique to (11) results in

$$u^h(\boldsymbol{x}) = \int_{\Omega} p_i(\boldsymbol{x})\, A_{ij}^{-1}(\boldsymbol{x})\, p_j(\boldsymbol{x}')\, w(\boldsymbol{x}-\boldsymbol{x}')\, u(\boldsymbol{x}')\, \mathrm{d}\Omega \tag{16}$$

where

$$A_{ij}(\boldsymbol{x}) = \int_{\Omega} w(\boldsymbol{x}-\boldsymbol{x}')\, p_i(\boldsymbol{x}')\, p_j(\boldsymbol{x}')\, \mathrm{d}\Omega \tag{17}$$

A comparison between Eq. (16) and Eq. (6) reveals that there is an interesting similarity between the SPH and MLS approximations and $p_i(\boldsymbol{x})\, A_{ij}^{-1}(\boldsymbol{x})\, p_j(\boldsymbol{x}')$ can be considered as a modification function. In fact, this similarity has been used to devise modified SPH methods.

Partition of Unity

This approximation technique is another base to construct meshless methods. In this method, the computational domain is covered by overlapping subdomains Ω_I associated with each point I. Within each subdomain I, a function $\varphi_I(\boldsymbol{x})$ is defined which is nonzero only in Ω_I and has the following property in Ω

$$\sum_I \varphi_I(\boldsymbol{x}) = 1\,. \tag{18}$$

Note that the shape functions φ^k for any k in the MLS are partitions of unity. The view point used in partition of unity inspired researchers to develop several meshless methods such as the hp-clouds method and the partition of unity finite element method.

Numerical Implementation

Meshless methods are normally based on two types of discretization:

- Collocation methods, which are used in SPH, Generalized Finite Difference and Moving Least Square methods.
- Galerkin methods, which are used in Element Free Galerkin method, Reproducing Kernel Particle method, etc.

Below, the implementation of both methods is briefly described for solving the Poisson equation in a domain Ω with boundary Γ. The problem is formulated as

$$\begin{cases} \nabla^2 u = f & \text{in } \Omega \\ u = u_D & \text{on } \Gamma_D \\ \frac{\partial u}{\partial n} = g & \text{on } \Gamma_N \end{cases} \tag{19}$$

where Γ_D and Γ_N ($\Gamma = \Gamma_D \cup \Gamma_N$) are segments of the boundary on which Dirichlet and Neumann boundary conditions are imposed, respectively. Also, $\boldsymbol{n} = (n_1, n_2, n_3)$ refers to the direction normal to the boundary, u_D is a prescribed value and g is the prescribed normal gradient of u on Γ_N.

To implement the collocation method, the computational domain including its boundaries is covered with a set of n nodes so that Eq. (12) holds. Then, the approximation is applied to the Poisson equation only for internal nodes (i. e. $\Omega - \Gamma$). The resulting discrete equations are

$$\begin{aligned} \sum_I \nabla^2 \varphi_I(\boldsymbol{x}_J)\, u_I &= f(\boldsymbol{x}_J)\,, \\ \sum_I \varphi_I(\boldsymbol{x}_J)\, u_I &= u_D(\boldsymbol{x}_J)\,, \\ \sum_I \nabla \varphi_I(\boldsymbol{x}_J)\,.\,\boldsymbol{n}\, u_I &= g(\boldsymbol{x}_J)\,, \end{aligned} \tag{20}$$

which must be solved for a set of unknowns u_J for $J = 1, \ldots, n$.

In the context of SPH methods, the procedure is frequently implemented by multiplying the governing equation (Poisson equation) by the weight function w. Then, the resulting equation is integrated over the domain followed by twice applying integration by parts on the left hand side. After dropping the boundary terms, the discretized form for internal nodes becomes

$$\sum_I \nabla^2 w_I(\boldsymbol{x}_J)\, \Delta V_I\, u_I = \sum_I w_J(\boldsymbol{x}_I)\, \Delta V_I\, f(\boldsymbol{x}_J) \tag{21}$$

The implementation of either of the above approaches is simple and straightforward. First, at any node J, one should determine the nodes which contain node J within their domain of influence. Then, the construction of Eq. (21) simply involves calculating the second derivative of the shape functions of all relevant nodes at $\boldsymbol{x} = \boldsymbol{x}_J$.

To implement the Galerkin method, one needs a weak form or a variational principle the same way as in the Finite Element Method. For the Poisson equation, this reads

$$\int_{\Omega} \nabla\delta u\, \nabla u\, \mathrm{d}\Omega = -\int_{\Omega} \delta u f\, \mathrm{d}\Omega + \int_{\Gamma_N} \delta u\, g\, \mathrm{d}\Gamma \tag{22}$$

M

where $\delta u(\boldsymbol{x})$ is a test function and $u(\boldsymbol{x})$ is a trial function. After selecting an appropriate shape function, the discrete form becomes

$$\sum_J \left(\int_\Omega \nabla\varphi_I \, \nabla\varphi_J \, \mathrm{d}\Omega \right) u_J = -\int_\Omega \varphi_J f \, \mathrm{d}\Omega + \int_{\Gamma_N} \varphi_J \, g \, \mathrm{d}\Gamma \,. \tag{23}$$

This again gives a system of linear equations for a set of unknowns u_J for $J = 1, \ldots, n$.

An important step in implementation of meshless methods is the way integrals are computed. An approach which is frequently used employs the following form

$$\int_\Omega f(\boldsymbol{x}) \, \mathrm{d}\Omega = \sum_{I=1}^{n} f(\boldsymbol{x}_I) \, \Delta V_I \,. \tag{24}$$

There are however other approaches which exploit a background grid to compute integrals. Such approaches are therefore not truly meshless.

Key Research Findings

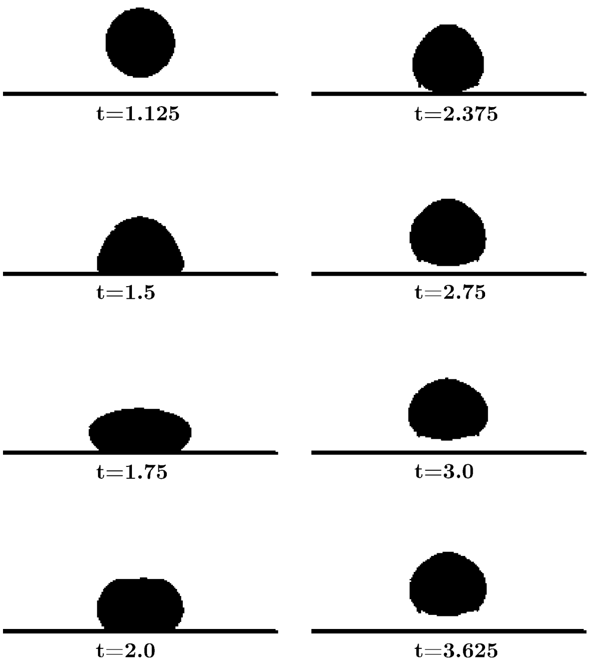
The meshless methods have found their applications in various fluid mechanics and solid mechanics as well as multi-disciplinary problems. They have also been successfully used for multi-physics problems such as the use of magnetohydrodynamcis (MHD) to control turbulence and the study of non-Fourier heat conduction.

Meshless methods like the Dissipative Particle Dynamics (DPD) methods are especially suitable for mesoscopic analyses involved in combined nanofluidics and mircofluidics problems because the discrete representation of the underlying physics can be inherently linked to interacting particles. These methods provide a unifying formulation for both continuum and discrete systems enabling systematic and robust multiscale simulations [5]. Meshless methods are also appealing for emerging technologies such as Microelectromechanical Systems (MEMS) and microdevices because they can eliminate the need for various meshes to analyze different physical phenomena. The use of meshless methods for numerical simulation of electro-osmotic transport and microfluid in the capillary electrophoresis has already been reported in the literature. The meshless methods have been successfully used in free-surface flow and moving boundaries problems. The methods have also proven to be very powerful in dealing with interfacial flow problems enabling simulation of multi-phase and multi-fluid flows. The effect of surface tension has also been investigated.

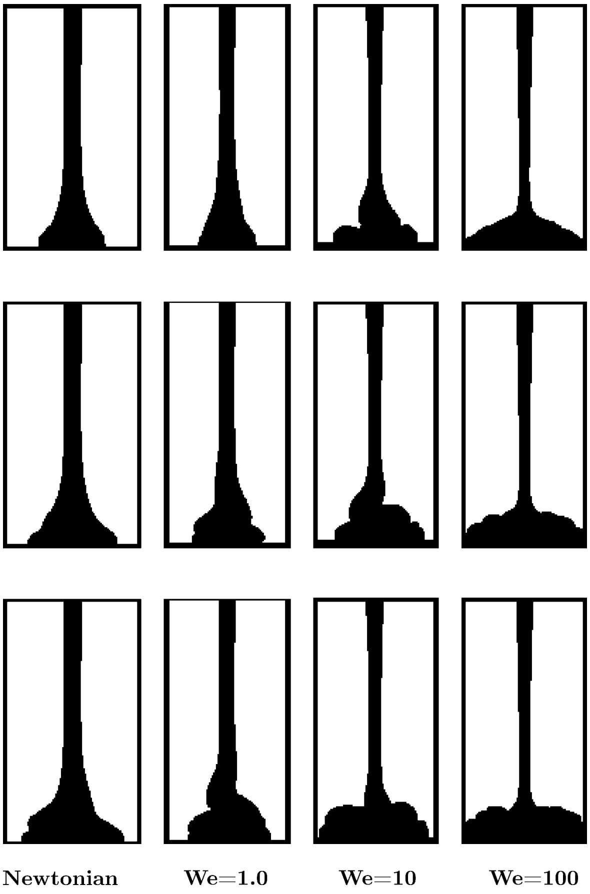
In recent years, the SPH methods in particular have gone through major improvements and their application was expanded into a wider range of engineering problems. These include both more advanced physical models and more advanced engineering processes. For example, SPH was successfully used to simulate non-Newtonian fluid flows and viscoelastic materials. It has been also used for the analysis of fluid-structure interaction problems, fluid flow in porous media and fractures, heat transfer and reacting flow problems.

The meshless methods are particularly useful in dealing with large deformations involved in solid mechanics applications where mesh-based methods face significant difficulties. These methods have been successfully used for simulation of crack propagation under various loading conditions.

Figures 3 and 4 show typical solutions obtained by the SPH method. In Fig. 3, the results of SPH simulation for the impact of a liquid droplet with a horizontal rigid wall are shown. The droplet originally has a circular shape of diameter 1.0 cm and is dropped from a distance 4.0 cm above the plate with a vertical speed −1.0 m/s. The fluid is considered to be a viscoelastic Maxwell fluid. The SPH results show capabilities of the method in representing complex features such as elasticity of the fluid, deformations of the droplet and the bouncing up phenomenon.



Meshless Methods, Figure 3 Impacting droplet – results of SPH simulations for a Maxwell viscoelastic fluid at various times



Meshless Methods, Figure 4 Jet buckling – results of SPH simulations for various fluids at three different times

In Fig. 4, the results of SPH simulation for the so-called jet buckling problem are shown. The problem was solved for both Newtonian and viscoelastic fluids. For the viscoelastic analyses, the problem was solved using the Oldroyd-B fluid model over a wide range of Weissenberg (We) numbers. The jet buckling problem involves transient flow of a jet injected downwards from a height $H = 10\,\text{cm}$ into a rectangular cavity. The gravitational force acts downwards with $g = 9.81\,\text{m/s}^2$. The jet is injected into the cavity from a nozzle of width $D = 0.5\,\text{cm}$ and a uniform injection velocity $V = 50\,\text{cm/s}$. It is seen that the SPH method has been able to solve this problem over a wide range of flow regimes and fluid properties.

Future Directions for Research

Only during the past six years from the beginning of the 21st century, more than sixteen hundreds papers in the field of meshless methods have appeared in the literature. Despite their recent fast growth, the meshless methods still require some improvements before they can be an appropriate substitute for the standard methods such as FEM and FDM. Above all, meshless methods need a better computational speed as well as improved robustness. The computational efficiency can be increased by using parallel computing techniques as the meshless methods are naturally parallelizable. An improvement in robustness is problem dependent and needs a more thorough investigation.

Meshless methods have high potentials to be employed in simulation of fluid-structure interactions. Complex geometries and interaction history can be defined using meshless methods requiring far less efforts.

The SPH method seems a viable method to study multiphase flow problems. In this context, effects such as surface tension, surface wetting and miscibility need better and more general algorithms.

It is also important to develop more efficient techniques to handle interface problems including fluid–fluid, fluid–solid and solid–solid contact interfaces.

More efficient contact algorithms also need to be devised if more complex impact or penetration problems are to be solved.

Coupling of the meshless methods with other standard methods such as the Finite Element Method and the Finite Volume Method can enhance the capabilities of both sides significantly. Such couplings can especially offer advantages in modeling problems with extreme deformations within a Lagrangian framework. This area of research can be expanded much further.

MEMS actuators

Definition

Microactuators are small-scale active devices capable of generating mechanical motion of solids or fluids. Motion is generated via converting one form of energy (for instance electrical) into kinetic energy. Typical sizes of microactuators vary from a few millimetres to a few micrometers, but total sizes can reach centimetres when packaged. When generating mechanical motion of solids, typical displacements are in the nanometer to millimeter range, and typical forces generated are in the nanoNewton to miliNewton range. For microfluidic actuators, typical flow rates generated are in the picoLiter/minute to microLiter/minute ranges.

Overview

Microactuators operate by converting one form of energy (e. g. electrical, thermal, electromagnetic) into kinetic energy of movable components. They are sometimes referred to as Micro-Electro-Mechanical-Systems (MEMS) actuators, but the later term is more commonly used in the United States to denote microactuators made from Silicon. Microactuators are not simply scaled-down versions of typical macroactuators (the later are usually called mini-actuators). Instead, microactuators are fabricated using specially developed fabrication and packaging technology including established techniques from the semiconductor industry such as lithography, etching, or deposition [7]. They can also be fabricated using precision versions of conventional machining such as laser machining, electro-discharge machining (EDM), or micromilling [2]. There are numerous materials that have been used to fabricate microactuators, including Crystalline Silicon, Poly-Silicon, Silicon-on-Insulator (SOI), Piezo Ceramics (PZT), Shape Memory Alloys (SMA), and Electro-Active Polymers (EAP). Microactuators exploit various physical conversion effects in order to generate motion such as: electrostatic, electrothermal, piezoelectric, electromagnetic, thermal expansion, or metallurgical phase change [10].

Microactuators can be implemented in one or more degrees of freedom, leading to another way to classify them as: linear (or prismatic), rotary (or revolute), in-plane (1D to 3D), and out-of-plane (1D to 6D). A micromotor contains several movable parts, including the microactuator and a transmission system. The transmission system consists of bending (or flexture) joints and links, rigid links, stick-and-slip contact elements, or micromechanical hinges. Like macroscale actuators, microactuators are chosen for different applications based on tradeoffs between:

- range of motion,
- precision (resolution, repeatability, accuracy),
- force characteristics,
- power consumption,
- bandwidth and transient effects,
- nonlinear effects.

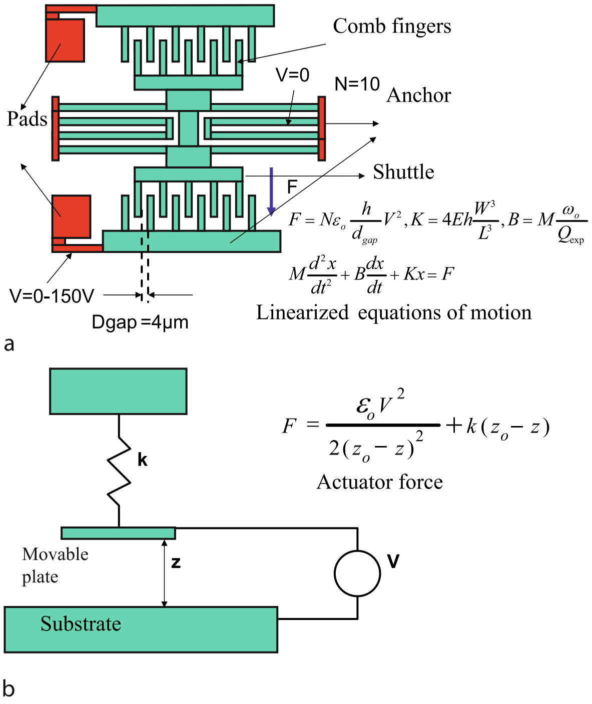
Microfluidic actuators generate motion of fluids, which can be accomplished directly, by means of peristaltic motion from actuated solid membranes, or indirectly, by means of hydrodynamic or osmotic effects. Microfluidic actuators are typically used in micropumps and microvalves. The primary characteristic that distinguishes a micropump from other types of fluid delivery systems is that the primary driving force for delivery by a pump is a pressure difference, rather than a concentration/molecular gradient. This difference can be generated by pressurizing a fluid reservoir using a gas, by osmotic action, or by direct mechanical actuation. Flow rates in the range of picoLiter/minute to microLites/minute have been demonstrated [5].

Basic Methodology

Major Types of Microactuators

Electrostatic Actuation

Motion is generated by electrostatic attraction force between electrically charged surfaces. Examples of electrostatic MEMS actuators are in-plane comb drives (Fig. 1a), and out-of-plane parallel plate actuators (Fig. 1b) [4]. Both types of actuators require large driving voltages (hundreds of Volts), and can achieve displacements of tens of microns or less. In-plane electrostatic actuators exhibit small force capability (microNewton range), while out-of-plane actuators exhibit regions of instability limiting their range of motion (pull-down effects). Typical bandwidths are in the KHz to MHz ranges. Electrostatic actuators are fabricated using various clean-room compatible micromachining processes, including surface micromachining (such as MUMPS) or bulk micromachining (such as Deep Reactive Ion Etching – DRIE).



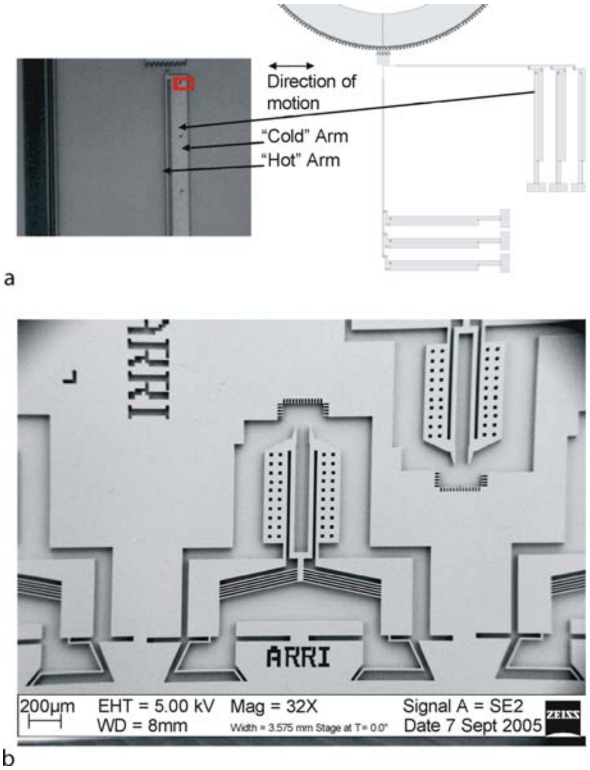
Microactuators, Figure 1 Diagrams of (**a**) in-plane electrostatic comb-drive actuator and actuation force, and (**b**) out-of-plane parallel plate electrostatic actuator

Electrothermal or Thermal Actuation

Motion is generated by differential thermal expansion in materials such as Silicon or Metals, while heat is typically injected into the actuator by means of Joule heat dissipation. Some actuator components expand more than others due to different cross-sections, and therefore electrical resistance. Typical microactuator configurations include in-plane bimorph elements (Fig. 2a), out-of-plane bimorph plates, in-plane Chevron, or bent-beam elements (Fig. 2b) [3]. These types of actuators exhibit larger force capabilities (in mN range), can achieve displacements of 100 μm or less, but generally consume a lot of power (hundreds of mW), and have low bandwidth (Hz to KHz). Common methods of fabrication for electrothermal microactuators include surface micromachining (such as MUMPS) and bulk micromachining (Metal MUMPS, LIGA) or DRIE.

Piezoelectric Actuation

Motion is generated by the piezo-electric effect in certain crystalline materials (for instance Quartz), ceramics such as PZT – Pb(ZrTi)O_3, and polymers (Polyvinylidene fluoride – PVDF). In addition, thin films with piezo-electric properties such as Aluminum Nitride (AlN)



Microactuators, Figure 2 Pictures and diagrams of (**a**) in-plane, surface micromachined electrothermal bimorph MEMS actuator and microactuator bank, and (**b**) in-plane microgripper consisting of an Chevron beam electrothermal actuator, and two bimorph MEMS actuators (Image courtesy of Texas Microfactory Lab, ARRI-UTA)

have been demonstrated in MEMS [8]. The application of a large electrical field produces mechanical actuation along crystal planes. This effect is reversible (mechanical displacement produces an electric field), which is why such materials can be also used as energy harvesters. Typical microactuator configurations include bimorph elements or stacks. These microactuators require large driving voltages (hundreds of Volts), are capable of very large forces (N range), operate at high frequency (KHz to MHz ranges), but generally have limited displacements (nanometer to micrometer ranges). Methods of fabrication includes laser micromachining of bulk materials, or thin film deposition and patterning using lithography.

Magnetic and Electromagnetic Actuation

Motion is generated through magnetic forces generated by placing a magnetic material inside the magnetic field, typically generated by an electromagnet. One type of magnetic microactuator utilizes hard, permanent magnets, composed of rare-earth elements such as Neodymium – $Nd_2Fe_{14}B$, which can be constrained to move by levitation [6]. Other types of microactuators utilize magnetic materials deposited as thin films, that exhibit Magnetostrictive and Giant-Magnetostrictive (GMR) effects. Examples of materials that exhibit a large change in shape when subjected to a magnetic field, is Terfenol-D – Tb(0.3) Dy(0.7) Fe(1.9). Microactuators using magnetic materials are currently not very common, because they are difficult to fabricate, characterize, assemble and control, however, they have the potential to exhibit large bandwidths, low power consumption, large displacements, and large forces.

Shape-Memory Actuation

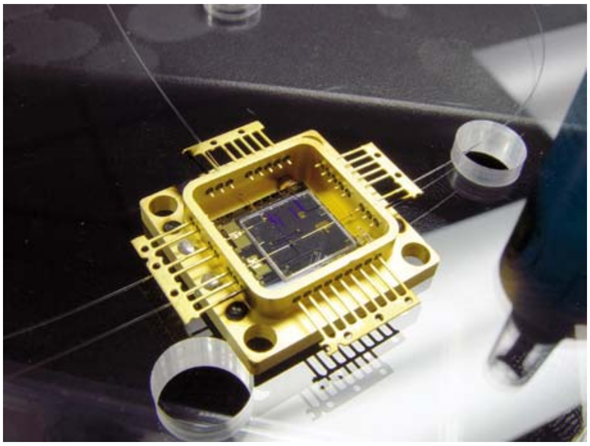
SMA microactuators are based on alloys that exhibit specific phase transformations when undergoing thermal cycling. The change in phase allows the actuator to remember its original shape when heated. After a SMA sample has been deformed from its original crystallographic configuration, it regains its original geometry by itself during heating by changing between crystal structures known as martensite (at lower temperatures) and austenite (at higher temperatures). An example of SMA material is Nitinol – NiTi. Microactuators made from SMA require a heating source, which can be due to Joule heating of a substrate on which the actuator is attached. Microactuators using SMA materials are currently not very common because they are difficult to manufacture, but laser or EDM micromachined NiTi microgrippers with high force and displacement capabilities have been fabricated [1]. Drawbacks of SMA actuators include low bandwidths (Hz range), and large power consumption (hundreds of mW) due to the need for heating-cooling cycles.

Packaging of Microactuators

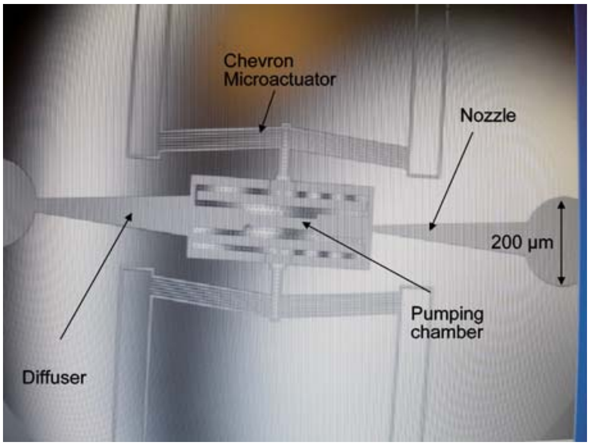
In addition to design and fabrication, current research work in microactuation includes aspects related to motion control (open-loop and closed-loop), microassembly (manipulation of small components using robotic devices), packaging (joining, sealing, and interconnecting of actuator components and driving circuitry), and reliability (predicting modes of failure and ensuring operation after repeated cycles) [9]. See Fig. 3 for an example of packaged microactuators.

Microactuators for Microfluidics

Microactuators are also used in microfluidics, for many applications including Lab-on-a-Chip and Implantable Drug Delivery Systems. Such fluidic actuators can be categorized as follows:



Microactuators, Figure 3 Packaged electrothermal microactuators, including a protective carrier, electrical and optical interconnects (Image courtesy of Texas Microfactory Lab, ARRI-UTA)



Microactuators, Figure 4 In-plane micropump for drug delivery composed of diffuser, nozzle, pumping chamber, and electrothermal microactuator (Image courtesy of Texas Microfactory Lab, ARRI-UTA)

- Mechanical, including diaphragm actuators (Fig. 4), rotary and reciprocating actuators.
- Pneumatic, including micropistons, microjets and micronozzles.
- Electro-osmotic, e.g. the motion of ions through microchannels, where an applied electrical potential across the channels cause the ion migration.
- Hydrodynamic, for instance, magneto-hydrodynamic pumps for which magnetic fields can induce currents in a moving conductive fluid.

Synonymns

Miniature aerial vehicles; Small unmammed aerial vehicles; Micro air vehicles

Definition

Micro Aerial Vehicles are a class of aircraft, which are defined by the Defense Advanced Research Projects Agency (DARPA) to have a maximum dimension no greater than 15 cm (approximately 6 in.). A more flexible definition includes aircraft whose flight is characterized by low Reynolds number.

Overview

Recent aircraft design has focused on the development of Unmanned Aerial Vehicles (UAVs). This class of aircraft has been successfully adapted to preform many of

the same roles as manned aircraft but at lower cost. The absence of a pilot eliminates many of the safety and life support requirements, and also changes the control objectives. For example, rapid acceleration or a bumpy trajectory can hinder a pilot's ability to control the aircraft but do not affect the control system of a UAV. Another advantage of UAVs is that they can be used in environments that are undesirable for humans. This may include a combat zone or a toxic chemical plume. Moreover, many mission profiles do not require a large payload, and UAVs can be built much smaller to perform these missions because they do not have to support the extra weight of a pilot. Advancements in miniaturization have simultaneously made it possible to build smaller and smaller aircraft.

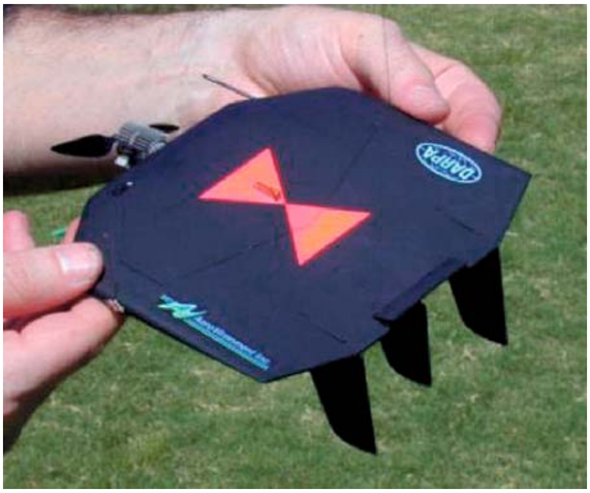
Research into small UAVs was given a top priority by DARPA in 1996 with the Micro Air Vehicle (MAV) Program initiative [1]. The goal of the program was to develop the technology for a small reconnaissance and communication microdrone for militarty applications. DARPA defined a MAV as an aircraft with a maximum dimension no greater than six inches. It also set objectives for endurance of approximately two hours and mass around 100 g. This definition of a MAV placed it in a flight regime with small birds, bordering on large insects. The difficulties faced for this type of flight are much different than those encountered at conventional scales, and consequently researchers had to come up with novel designs, in many cases learning directly from flying animals themselves.

In response to this project, many independent research groups have researched, designed, and tested their own solutions to the problem. The result was a wide variety of concepts for flight at small scales. A brief overview of some of the most successful and well-known MAVs is presented here to give a picture of the state of MAV design.

AeroVironment MAV Family

AeroVironment is a technology company that was founded in 1971 by Paul MacCready. The company focuses on energy technologies and Unmanned Aircraft Systems (UAS). They are perhaps best-known for the solar-powered Helios Prototype that was built for NASA. They have also built and produced a wide range of UAVs.

Dragon Eye is a tactical reconnaissance and surveillance UAV that is currently used by the U.S. Marine Corps. While it does not fit within the MAV classification, Dragon Eye is smaller than most commercially available UAVs, with a wingspan of 1.1 m and a mass of 2.3 kg. AeroVironment's most famous MAV is the Black Widow, show in Fig. 1a. Due to the desire to have the maximum possible wing area, but still fit within the MAV definition, the originial design had a circular planform. The initial flight lasted 9 s, and by November of 1997 the duration had increased to 16 min. Multidisciplinary Design Optimization (MDO), combined with a genetic algorithm, led to an optimized design with a wingspan of 15.2 cm and a total mass of approximately 80 g, with an endurance of around 30 min and video downlink to the operator. The Black Widow demonstrated the capability for flight in the MAV regime, and also showed that direct propulsion with an electric was more efficient than using a gearbox [2]. A third MAV developed by AeroVironment is called Wasp (Fig. 1b). Similar to the Black Widow, Wasp has a low-aspect ratio wing, meaning that the ratio of the wingspan chord is on the order of unity; however, Wasp's 41 cm. wingspan places it outside the technical definition of a MAV. Wasp's unique characteristic is the use of batteries as structural members.



Micro Aerial Vehicles, Figure 1 AeroVironment's Black Widow MAV [2]

NRL MITE

The Naval Research Lab began development of a MAV in 1996. The MITE, for Micro Tactical Expendable, came to designate a family of MAVs based on a similar design concept. The MITE features a low-aspect ratio wing with twin propellers mounted at leading edge wingtips, and vertical triangle-shaped control surfaces at the wingtips (Fig. 2). The propellers rotate in the opposite direction of the wingtip vortices, thus reducing the induced drag effects. Once again, the low-aspect ratio planform is chosen to obtain the required wing area while fitting within the maximum dimensions specified for a MAV. A series of design configurations were built and tested, ranging in span from 8 in. (20.3 cm) to 18 in. (45.7 cm).

Micro Aerial Vehicles, Figure 2 MITE2, developed by Naval Research Lab [3]

Micro Aerial Vehicles, Figure 3 MAV prototype built and flown by University of Florida research group [5]

NRL researchers used Computational Fluid Dynamics (CFD) as an aid in the design process and to evaluate the aerodynamic coefficients needed for automatic control. The propellers were modeled as an actuator disk with the proper distribution of momemtum sources. The NRL team is currently investigating various control schemes, ranging from a simple technique with only pressure-based altitude and magnetic heading as sensors, to a more complex full autopilot including three axis rate gyros. They are also looking at the use of optical sensors for control, and contol of swarms of MAVs [3].

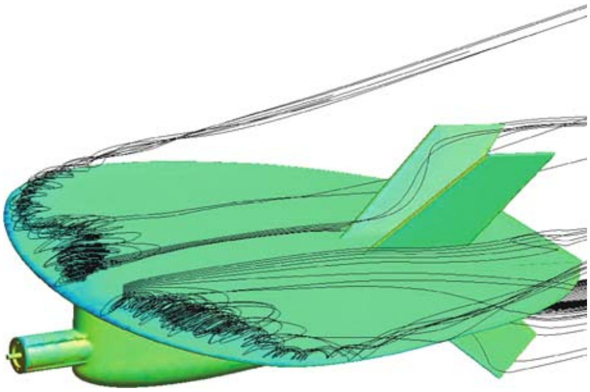
University of Florida

In recent years the University of Florida has developed a very strong MAV program. Their fleet of MAVs and small UAVs, which differ from one another in both size and shape, has been highly successful in competition (Fig. 3). Their first vehicle has a near-circular planform with a 6 in. span. They also have a smaller version which has a 4 in. span. These two aircraft feature membrane wing construction. There are two other aircraft which have more conventional design, including medium-aspect ratio wings, fuselage, and tail. They are designed with semi-flexible wings that can be morphed for control. All vehicles are driven by single nose-mounted propellers. The primary focus of their research has been on the use of flexible membrane wings. Most of their MAVs are designed with low-aspect ratio wings to fit the MAV criteria. The idea for the flexible wing comes from nature and materials science. Many flying animals in the low-Reynolds number regime use some from of passive morphing to perform flow control, i. e. membrane wings on bats and dragonflies. At the same time, composite materials are very effective for constructing lightweight aircraft frames. The UF team combined the two by building carbon fiber skeletons, over which a membrane of latex rubber was stretched. The result was a light wing capable of deforming based on the local flow conditions. One effect of the flexible wing design is to provide adaptive washout to smooth the effect of wind gusts [4]. They have reported that the flexible wing makes the aircraft easier to control than a similar vehicle with a rigid wing. The UF team has also demonstrated that flexible wings can attain greater lift than their rigid counterparts.

The UF group has also researched extensively computational techniques for MAVs with flexible wings [5]. Their simulations showed that a membrane wing generates more lift at high angles of attack, which leads to better stall properties. They have done numerical and experimental investigations of the deformation of the membrane wings during flight conditions and the pressure redistribution which results. The UF researchers investigated the stability and control properties of MAVs as well. They were able to control the MAV with elevons – elevators when actuated symmetrically, ailerons when actuated asymmetricallys – and throttle. They also used wing morphing for control [6].

University of Colorado

Researchers at the University of Colorado are developing a vehicle for the investigation of toxic chemical plumes. This mission requires relatively long endurance, which corresponds to a high lift-to-drag ratio. Early designs were similar to those of the University of Florida and other groups in that they used a low aspect ratio (Fig. 4), but this resulted in poor endurance. In order to extend the flight duration, the 15 cm restriction was abandoned in favor of



Micro Aerial Vehicles, Figure 4 Streamlines around the first-generation Colorado MAV, computed from CFD [8]

a high aspect ratio, which results in a better lift-to-drag ratio. However, because of the small chord length and the low cruise speed, the aircraft still operates in the low Reynolds number flight regime. Research has been performed on cooperative control of large flocks of MAVs, as well as the aerodynamic performance of various MAV designs [7, 8].

Basic Methodology

As mentioned briefly above, the flow regime which MAVs occupy is much different than that of conventional manned aircraft. Due to the combination of small length scale and slow flight speed, the Reynolds number for a typical MAV is on the order of 10^5, while for a jet airliner it is on the order of 10^7.

There is a stark change in aerodynamic efficiency, measured with lift-to-drag ratio L/D, as Reynolds number decreases below about 3×10^5 (Fig. 5). The decreased efficiency has a significant impact on the mechanics of flight in this regime. For example, eagles and hawks can be seen to soar without flapping, sometimes for long durations; however, bees and hummingbirds must beat their wings at a high frequency to remain airborne. Long endurance flight is difficult to achieve for MAVs because of this. Design of MAVs must focus on achieving the desirable flight characteristics while considering the low Reynolds number effects, unsteady flow, and the typical aerodynamic concerns such as balance and stability.

The primary cause of decreased efficiency at low Reynolds numbers is a laminar separation of the flow from the airfoil surface. This leads to a phenomenon known as a laminar separation bubble. The shape of the airfoil and pressure distribution have a significant impact on the location and size of the separation bubble, and so design and testing of airfoils can dramatically improve MAV performance.

As demonstrated in the examples given above, most MAVs have a low aspect ratio. The reason for this type of wing design is not based on aerodynamics, but simply the desire to fit within the specifications set forth by DARPA for a MAV. Consequently, to get the maximum amount of lift for an aircraft which fits in a 15 in. diameter sphere, a low aspect ratio is preferrable. There are a variety of planforms (i. e., wing shapes) which can accomplish this goal. The most obvious is a circular planform. However, many designs incorporate a modified delta wing or a Zimmerman planform, which is widest at the leading edge and tapers smoothly towards the rear.

If meeting the strict definition of a MAV is not a design requirement, a large aspect ratio is more advantageous. This is due to the induced drag, $C_{D,i} \propto 1/AR$, where AR is the aspect ratio. It is relevent to note that there is a trade-off between induced drag and the drag caused by low Reynolds number effects. Reynolds number is defined as $\mathrm{Re} \equiv \rho v c/\mu$, where ρ is the fluid density, v is the free stream velocity, c is the chord length, and μ is the dynamic viscsity. For the flight regime of MAVs, the profile drag on an airfoil increases as this parameter decreases. Thus, one way to increase the Reynolds number is to make the chord longer, i. e. increase c. If the wing area and cruise velocity are maintained constant while c increases, then AR must decrease. There is a value of AR which will balance the induced drag effects with the low Reynolds number effects.

To illustrate this point, one must look at the derivative of drag with respect to chord length. We wish to treat velocity, area, and lift coefficient as constants, so the span must be a function of aspect ratio. Using the definition for aspect ratio and defining the average chord length $\bar{c} \equiv A/b$, we obtain:

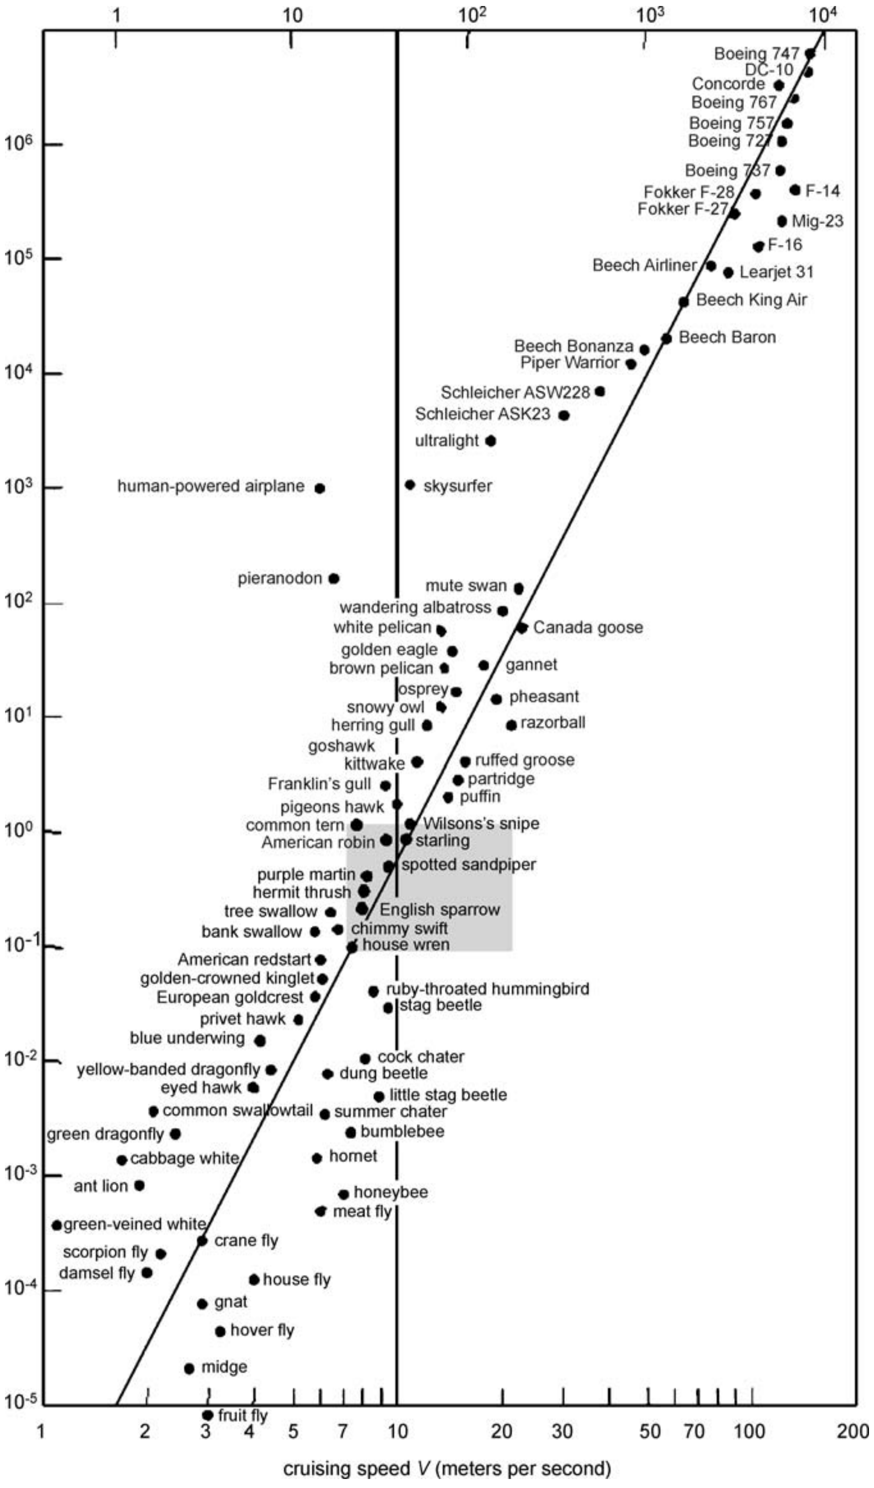
$$AR = \frac{b^2}{A} = \frac{b}{\bar{c}} = \frac{A}{\bar{c}^2} \tag{1}$$

Now we express the drag coefficient in terms of $\bar{c}$:

$$\begin{aligned} C_D = C_{D,0} + C_{D,i} &= k_1\,\mathrm{e}^{-k_2\mathrm{Re}} + \frac{{C_L}^2}{\pi\,\mathrm{e}AR} \\ &= k_1\,\mathrm{e}^{-k_3\bar{c}} + k_4\bar{c}^2 \end{aligned} \tag{2}$$

Here we have made the approximation that $C_{D,0}$ at a given C_L scales as a decreasing exponential of Reynolds number. The k's represent collections of constant scalar values. The next step is to take the derivative with respect to $\bar{c}$. The optimal shape is characterized by $\partial C_D/\partial\bar{c} = 0$.

$$\frac{\partial C_D}{\partial x\bar{c}} = -k_1 k_3\,\mathrm{e}^{-k_3\bar{c}} + 2k_4\bar{c} \tag{3}$$



Micro Aerial Vehicles, Figure 5 Weight vs. cruising velocity for various aircraft and animals [14]

For a MAV with a six inch diameter circular wing flying at 25 mph, we find that the rate of change of $C_{D,0}$ with respect to Re is not great enough to overcome the change in induced drag. However, as the length scale and

Reynolds number decrease further, there is a point where the change of $C_{D,0}$ with respect to Re is great enough to make a smaller aspect ratio profitable.

Other considerations for designers are balance and stability. For longitudinal stability (pitch and vertical motion), the center of gravity should be placed in front of the aerodynamic center, through which the lift vector passes. If the MAV incorporates a flying wing design, the wingtips should be swept back and twisted, or an airfoil specific to flying wings should be employed, in order to balance the moments produced by the lift force. Because the aerodynamic forces scale with the square of characteristic length while the mass scales with the cube, inertial forces are much smaller for MAVs than conventional aircraft. Because of this, the control is often simpler. Many MAVs utilize either rudder or ailerons for lateral control surfaces, rather than both.

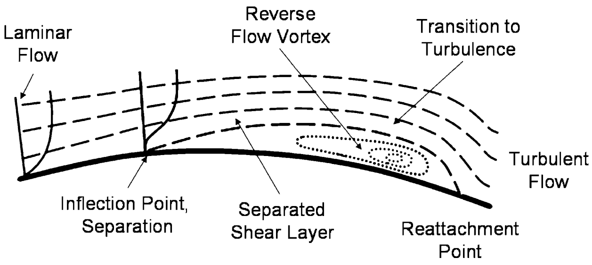
Key Research Findings

There are many areas of research which are related to MAVs; of notable interest are the effects of low Reynolds number flow, unsteady flow, and flapping wings. A compilation of research on MAV aerodynamics can be found in [9].

Low-Reynolds Number Flow

As mentioned above, laminar separation bubbles affect the aerodynamic performance of MAVs. At higher Reynolds numbers, the transition occurs closer to the leading edge, and the mixing caused by turbulence transfers momentum from the free stream to the boundary layer, delaying separation of the flow. As Reynolds number decreases, the location of the transition point moves toward the trailing edge until the pressure gradient becomes unfavorable, and the flow separates. The resulting shear layer is initially laminar, but Kelvin-Helmholtz instability triggers a transition to turbulent flow. If the angle of attack is not too high, or the adverse pressure gradient is not too strong, the separated shear layer will gain enough momentum through entrainment to reattach to the surface of the airfoil. The region between the separated flow and the airfoil is called the laminar separation bubble, or LSB [10]. Figure 6 diagrams the streamlines of a laminar separation bubble.

The upstream portion of the LSB is sometimes referred to as the "dead air region". Here the flow is nearly stagnant. Slightly downstream from this region is the point in the separated shear layer where instabilities begin to grow. As the instabilities reach a critical size, they detach as vortices and begin to move downstream. Depending on Reynolds number and local flow conditions which are dependent on the particular airfoil, these vortices may "roll up", or pair



Micro Aerial Vehicles, Figure 6 Diagram of time-averaged view of a laminar separation bubble

to form larger vortices. Eventually they move downstream to the trailing edge, where they are shed from the airfoil and are advected by the wake to form a vortex street. The LSB can be seen in the time-averaged velocity field as a region of recirculation.

Reynolds number has a significant impact on the structure of the LSB. Below approximately Re = 50,000, the separated shear layer may not transtition to turbulence in time to reattach to the airfoil. The attendant increase in pressure drag significantly diminishes the airfoil's efficiency. Between Re = 50,000 and Re = 200,000, the size of the LSB decreases and hence performance increases.

Angle of attack also plays a large roll in the size and effect of the LSB, especially at low Reynolds numbers. For the midrange of angle of attack, i. e. from 4° to 8°, the LSB covers a large portion of the chord. As C_L approaches 1.0, the bubble moves toward the leading edge and transition occurs earlier, shortening the bubble. The result is a decrease in drag due to LSB. This can be seen on the drag polar for most airfoils at low Reynolds number as an increase in drag over the midrange of C_L, which is referred to as the laminar separation bucket.

Many studies have been performed on the flow over airfoils at low Reynolds number. One airfoil which has received significant attention due to its interesting behavior is the Eppler 387. McGhee et al. studied the airfoil experimentally and reported on lift and drag for various Reynolds number, ranging from 60,000 to 400,000, and angles of attack [11]. They also found the separation and reattachment points on the airfoil, and tabulated pressure data versus chordwise position. Other experiments were performed by Selig et al. on a wide range of airfoils at low Reynolds numbers [12]. At very low Reynolds numbers, the discrepancy between defferent sets of experimental data grows large. One possible cause for the experimental scatter is the three-dimensionality of the flow during the vortex shedding; moreover, because of the small resultant forces on the airfoil a wake survey is usually employed for drag calculation, and the spanwise location of these mea-

surements can be a factor. There have also been a number of numerical studies of low Reynolds number flow. Elimelech et al. studied NACA-0009 and Eppler 61 airfoils both numerically and in a water tunnel, and reported on the structure of the vortex shedding [13]. They also found that reasonable accuracy could be obtained without the use of a turbulence model for the numerical simulations.

Unsteady Effects

Unsteady effects become more pronounced as vehicle size decreases. First, the unsteady forces due to vortex shedding and the LSB become stronger in magnitude and percentage of mean force. The unsteady pressure distribution is probably responsible for the observed vibration at $\sim 100\,\text{Hz}$ on membrane wings. However, it is currently unclear what effect these forces have on the global quantities of lift and drag. The second and more significant effect of unsteadiness comes from variations in the free stream flow due to wind gusts and turbulence. As aircraft decrease in size, the inertial effects decrease with the cube of length scale while wing area decreases with the square of length scale. This means that MAVs and other small aircraft have low wing loads, and are therefore more likely to undergo severe acceleration in the presence of unsteady flow. Also, for a large aircraft, a wind gust might only cause a 10% change in airspeed, while the same gust could cause a change of 100% for a MAV.

The techniques devised at the University of Florida directly address the issue of wind gusts. When the local airspeed over the wing changes suddenly, the increased pressure causes the membrane to deform and lose camber. As a result the C_L decreases, but the increase in velocity yields a nearly constant value of lift. This type of passive morphing is referred to as load spilling.

Biomimetics and Flapping Wings

A great deal about flight at low Reynolds numbers can be learned from the study of birds and insects. The difference between the flight of eagles and hummingbirds is a direct result of the changing aerodynamics and decreasing lift-to-drag ratio as Reynolds number decreases [14]. Application of the lessons learned from nature is called biomimetics.

A third type of unsteady effect can be observed in insects and very small birds: flapping. These animals move their wings in a cyclic fashion to produce and usteady flow, which they use to create lift. Wing deformation is also very important for this type of flight. In fact, dragonflies and other insects do not have cambered wings at all, but rather membrane wings attached to flexible skeletons. The combination of aeroelasticity and unsteady flow are crucial to flight at these ultra-low Reynolds numbers.

Future Directions for Research

Many fields related to MAVs still require a great deal of research. While the low Reynolds number flight regime has received some attention, values of Re below 30,000 are still largely unexplored. Biomimetics has the potential to greatly improve the knowledge base of MAV flight. As researchers develop a better understanding of the aerodynamic properties of MAV flight, new control techniques will evolve as well. For example, microsynthetic jets could be used to control the vortex shedding over the wing, or vary the lift and drag along the wings for roll and yaw control. Advances in materials also have potential to change MAV design. As actuators become smaller and batteries lighter, MAV flight will progress to even smaller scales.

Microarray

Synonyms

DNA array; Protein array and cell array

Definition

Microarrays constitute highly parallel biosensors used in biomedical applications for studying a multitude of complex biological interactions simultaneously to determine the presence and/or amount (quantitation) of nucleic acids and proteins in biological samples, respectively, to investigate gene expression levels or for proteomics studies (e. g. in blood, cell extract, tissue extract). These miniaturised two-dimensional arrays contain a large number (hundreds up to hundreds of thousands) of different unique biological capture agents [nucleic acids (e. g. oligonucleotides, genes, gene fragments), proteins (e. g. antibodies)] on a solid substrate that are arranged in small chemical reaction areas (spots) in a predetermined spatial order (ranging from the hundreds of micrometre down to the sub-micrometre range). Typical substrates are glass, membranes, or silicon wafers.

The complex biological interactions are identified by the specific location of the capture molecules on the microarray. The arranged multitude of biological agents acts as capture probes to bind molecules out of a complex biomedical sample to be analysed in a high-throughput, and parallel manner. After hybridization of labelled complementary molecules, i. e. binding of sterically compatible molecules, a scanning microscope detects the bound, labelled sample and measures the visualised probe to ascertain the presence and/or amount of the specific type of complementary molecule in the complex sample.

Microchannel

Definition

Although the concept of microchannel has been in the field literature for some time now, a clear definition of it has not yet been enunciated. However, it is the general understanding that any channel that has a characteristic dimension is between 500 microns and 1 micron is considered to be a microchannel. Most of the microchannels discussed in the literature are manufactured through microfabrication techniques, but not exclusively.

jdzahn@rci.rutgers.edu

Definition

Microdialysis is a continuous sampling technique based on controlling the mass transfer rate of small molecules across a semipermeable membrane while excluding the larger ones. For biochemical monitoring, microdialysis systems are usually placed (inserted or implanted) inside the tissue of interest with an isotonic perfusion fluid flowing through the system and diffusional exchange occurring between the perfusate and the surrounding interstitial fluid (ISF). Since the dialysis process does not change or affect the surrounding fluid, it is viewed as a tool for continuous monitoring. Microdialysis systems have recently been adapted to microfluidic technologies for sample preparation prior to sample analysis or for miniaturized biochemical probes.

Overview

Researchers have been interested in the biochemical functions of the body in vivo, especially in the extracellular compartment where signaling chemicals can affect cellular function. Neuroscientists were the pioneers in developing microdialysis techniques due to their interest in analyzing neuron signaling processes within intact brains. The technique was originally used in neuroscience for the measurement of neurotransmitters. It allows sampling of brain regions in conscious, freely moving animals and directly delivering drugs into specific areas. There have been experimental attempts to analyze the tissue of interest without changing or affecting the surrounding fluid environment. The concept of introducing a semipermeable membrane into the tissue of interest to dialyze or continuously sample molecules was first introduced in the late 1960s and early 1970s. In 1966, Bito and colleagues implanted membrane-lined *dialysis sacs* containing 6% dextran in a saline solution into the cerebral hemispheres of dogs. The sacs were surgically removed after ten weeks postimplantation and analyzed for amino acid content. This experiment introduced the idea of using a membrane dialysis compartment to monitor the extracellular environment. In 1972, Delgado and colleagues developed the first-generation version of present-day microdialysis probes, which they called a *dialytrode*. The dialytrode consisted of two stainless steel tubes soldered together forming a push–pull cannula terminating with a small permeable bag. They were the first research group to perfuse the dialysis membrane in vivo in monkeys and the first to practice the technique which has since become known as *microdialysis*.

Development of microdialysis from a long-term dialysis sac implantation, to the push–pull cannula, and finally to the current continuous perfusion flow sampling/monitoring emerged in the neuroscience field in

1974 when Ungerstedt and Pycock first developed a linear, hollow-fiber probe design to continuously monitor neurotransmitter concentration within rat brains [1, 2]. They implanted the probe by drilling holes in each temporal bone of rats and guided the fiber into an area of the brain known to be devoid of a blood–brain barrier. Since then, more designs of microdialysis probes have been presented and utilized not only in neuroscience but also in other fields where continuous sampling/monitoring is needed. Today, the technique is widely applied to body organs and fluids, including blood, heart, liver, kidney, bile, lung, bone, eye, muscle and breast. Microdialysis has been used in the medical community to continuously monitor various metabolites (glucose, lactate, sodium, etc.) in patients.

Glucose microdialysis is of particular interest in diabetes treatment. In diabetics, the consistently high glucose levels results in long-term complications including retinopathy, nephropathy and neuropathy which often leads to amputation of extremities. Studies have shown that tight glycemic control reduces the complications dramatically. In diabetes treatment, these probes are usually inserted subcutaneously into either the abdomen or forearm, sampling glucose from the interstitial space. A large amount of research has been performed on creating a microdialysis sampling system where the dialysate exiting from the probe is then transferred to a glucose sensor by a tubing connection for continuous monitoring in vitro or in vivo. The ability to continuously monitor blood glucose levels in a diabetic patient is especially important for a patient undergoing continuous insulin infusion therapy from an insulin pump, so that the patient does not become severely hypoglycemic. During in vivo microdialysis studies, the microdialysis probes used to dialyze glucose from interstitial tissue were connected to glucose sensors, where the glucose concentration of the dialysate from the probe was determined. The true glucose concentration is back-calculated by using a calibration curve as described in the next section.

Aside from monitoring biomolecules in humans and animals, the microdialysis technique is also utilized in the area of environmental research. Probes are inserted into freshwater systems or soil for real-time and continuous sampling with minimum disturbance of the outer environment [3].

Basic Methodology

Basic Principles

The most common type of microdialysis probe is constructed as a concentric tube as shown in Fig. 1. The probes usually consist of a semipermeable membrane, such as polysulfone, polyethersulfone, polyamide, polycarbonate–polyether copolymer or cuprophan [4], glued between the tip of the inner cannula and the outer shaft, which are made of steel or plastic. The perfusion fluid (perfusate) enters the inlet flowing through the inner tube to its distal end and exits the inner tube to enter the space between the inner tube and the outer dialysis membrane where molecular exchange takes place. After the exchange, the fluid containing the molecules of interest (dialysate) is transferred towards the proximal end of the probe and is collected at the outlet for later analysis. Several different types of microdialysis probe construction are commercially available, including linear, loop, concentric and side-by-side [5] (Fig. 2).

In order to conduct microdialysis experiments several other components are required. Syringe pumps are often used to control the perfusate flow rate. The pump has to be able to deliver flow rates precisely in the microliter per minute range. Tubing is needed to connect between the probe and the pump which drives the perfusion flow and, in some cases, between the probe and a sample collector as well. The total dead volume of tubing should also be maintained as small as possible to have better time resolution. The perfusion fluid is a medium resembling the composition of extracellular fluid with minimal or zero concentration of the molecules of interest. Dialysate exiting from the outlet of the microdialysis probe is usually collected in a vial for later analysis. It is also possible to connect the outlet directly to an analysis instrument without using a collector, which is usually preferred, if possible, for its convenience and usually faster analysis results.

The concentration gradient between the perfusate and the component of interest in the ISF (e. g., glucose) is the driving force to transport molecules to the lumen of the probe. The concentration of the molecules of interest in the perfusion fluid at the output of the microdialysis probe is a representative of the ISF and can be correlated to the concentration within the ISF. The term recovery is defined as

$$\text{Recovery} = \frac{C_{\text{d,out}} - C_{\text{d,in}}}{C_{\text{r}} - C_{\text{d,in}}} \tag{1}$$

where $C_{\text{d,in}}$, $C_{\text{d,out}}$ and C_{r} are the concentration of the analyte of interest in the inflow perfusate, outflow dialysate and the exterior surroundings. When $C_{\text{d,in}}$ equals zero, the recovery can be simplified as

$$\text{Recovery} = \frac{C_{\text{out}}}{C_{\infty}} \tag{2}$$

where C_{out} equals $C_{\text{d,out}}$ the outlet concentration and C_{∞} equals C_{r} the bulk concentration in the surrounding fluid.

Quantitative Microdialysis Models

Concentric Microdialysis Probe

When a microdialysis probe with perfusion fluid flowing at a flow rate of Q_d is placed in a bath of analyte of concentration C_r, the microdialysis recovery, also known as *dialysate extraction fraction*, is described by a balance of the diffusion of the analyte across the microdialysis membrane into the perfusion fluid with the convective flux due to the perfusion flow:

$$\mathrm{Recovery} = \frac{C_{\mathrm{d,out}} - C_{\mathrm{d,in}}}{C_r - C_{\mathrm{d,in}}} = 1 - \exp\left[-\frac{1}{Q_\mathrm{d}(R_\mathrm{d} + R_\mathrm{m} + R_\mathrm{ext})}\right] \quad (3)$$

where $C_{\mathrm{d,in}}$, $C_{\mathrm{d,out}}$ and C_r are as previously defined in Eq. (1), R_ext is the external mass transfer resistance, R_m is the membrane resistance and R_d is the perfusion fluid resistance. Q_d is the perfusate/dialysate flow rate. This equation was proposed and demonstrated by Bungay and colleagues assuming that the membrane hydraulic conductivity and transmembrane pressure differences are sufficiently small so that no appreciable transmembrane fluid flow was produced [6, 7].

The overall product of permeability of the microdialysis probe (K) and surface area (A) is defined as

$$KA = \frac{1}{R_\mathrm{d} + R_\mathrm{m} + R_\mathrm{ext}} \quad (4)$$

It is governed by the resistance of analyte transport through three regions: the external surrounding medium (R_ext), the membrane (R_m) and the dialysate (R_d). Since they are in series and the mass transfer is the same across the three regions, the three resistances are additive.

A schematic of a cross-section of a microdialysis probe is shown in Fig. 1b, in which r_i is the inner radius of the inner cannula, r_α is the outer radius of the inner cannula, r_β is the inner radius of the membrane and r_0 is the outer radius of the membrane. The dialysate resistance, R_d, may be described as

$$R_\mathrm{d} = \frac{13(r_\beta - r_\alpha)}{70\pi L r_\beta D_\mathrm{d}} \quad (5)$$

where L is the effective dialysis membrane length and D_d is the diffusion coefficient through the dialysate. The membrane resistance, R_m, is described as

$$R_\mathrm{m} = \frac{\ln\left(r_0/r_\beta\right)}{\pi L D_\mathrm{m} \phi_\mathrm{m}} \quad (6)$$

M

where D_m is the diffusion coefficient through the membrane and ϕ_m is the void fraction of the membrane.

It is not possible to generalize the external mass transfer resistance, R_{ext}, based on the knowledge of the analyte molecular weight, shape and charge or the probe dimensions. Knowledge of other factors such as the analyte efflux to the microvasculature, metabolism and cell membrane transport processes are required. However, under most operating conditions R_{ext} is much smaller than R_m. This is especially true when the tissue analyte concentration is constant and does not vary over the sampling time.

Microfluidic Microdialysis Systems

Most microfluidic microdialysis systems consist of a two-compartment system with a sample flow channel and perfusion flow channel separated by the microdialysis membrane. A two-compartment cocurrent mass transport model of microdialysis is shown in Fig. 3. For this microdialysis system, molecules inside the sample channel are dialyzed across the membrane into the perfusion flow channel. Again, this system may be modeled by balancing the sample and perfusion convective fluxes with the diffusion of analyte across the membrane. Assuming the overall permeability is constant, K, over the diffusion path, the mass transfer along the membrane diffusional area, A, can be described as

$$\ln \frac{C_{r,out} - C_{d,out}}{C_{r,in} - C_{d,in}} = -KA\left(\frac{1}{Q_r} + \frac{1}{Q_d}\right) \tag{7}$$

where $C_{d,in}$, $C_{d,out}$ and C_r are as previously defined in Eq. (1). Q_r is the flow rate of the sample flow channel and Q_d is the perfusion flow rate. K is the overall molecular permeability and A is the diffusional surface area.

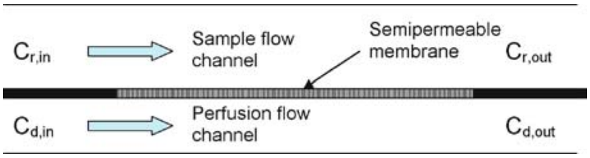
Under most operating conditions, $C_{d,in}$ is zero, and the sample channel acts as an infinite reservoir where $C_{r,in}$ and $C_{r,out}$ are assumed to be equal to C_∞, because Q_r is much larger thanQ_d so there is minimal mass loss from the sample flow channel. In addition, when Q_r is larger than Q_d ($1/Q_r \ll 1/Q_d$), the $1/Q_r$ term can be ignored on the left of the equation. Therefore, Eq. (7) can be simplified to

$$\ln\left(1 - \frac{C_{out}}{C_\infty}\right) = -KA\left(\frac{1}{Q}\right) \tag{8}$$

where Q stands for Q_d and $C_{d,out}$ is simply C_{out}. Equation (8) can be rearranged to represent recovery as a function of perfusion flow rate as

$$\frac{C_{out}}{C_\infty} = 1 - e^{-\frac{KA}{Q}} \tag{9}$$

By plotting the left side of Eq. (8) as a function of perfusion flow rate ($1/Q$), the permeability of the membrane to the molecule of interest (the slope is KA) may be determined to characterize the system functionality.



Microdialysis, Figure 3 Schematic of the mass transfer of a two-compartment cocurrent microdialysis system

Factors Affecting Recovery

In general, it is desirable to operate microdialysis systems at the highest recovery possible. There are several factors which affect the recovery rate of analytes.

Perfusate Flow Rate

Because recovery is determined by a competition between a diffusional and perfusion convective flux, it is perfusate flow rate dependent. As demonstrated in Eq. (3), recovery increases as the flow rate decreases. Even though low flow rates result in high recovery, it is often restricted by the reproducibility of low flow rates supplied by syringe pumps and the sample volume needed for solution analysis. Therefore, extremely low flow rates are often not applicable due to limited analysis time resolution because of the long times needed to collect the appropriate solution volume for analysis.

Dialysis Membrane Area and Membrane Material

The dialysis membrane chosen plays an important role in controlling the recovery. The dialysis area of the membrane can be increased to achieve high recovery without sacrificing time resolution. Larger diffusional area can enhance recovery, but in most cases, a minimal tissue disturbance by small microdialysis probes is favored. Recovery can be improved by selecting membranes with a higher permeability, K. Overall permeability mainly depends on the properties of the microdialysis membrane, such as pore size, pore density, tortuosity and analyte particle size. Membranes are commonly available with different molecular weight cutoffs (MWCOs), which determine the size of recovered particles. Molecules beyond the MWCO are too large to fit in the microdialysis pores. Membranes with lower MWCOs usually have lower permeability to

all species due to a smaller pore size. Recovery of certain analytes can also vary by as much as 20% between dialysis membranes made from different materials with the same MWCO. Microdialysis membranes are made from organic polymers. Several different types of membrane are used: polysulfone, polyethersulfone, polyamide, polycarbonate–polyether copolymer, cuprophan, polycarbonate, regenerated cellulose, cellulose acetate and polyacrylonitrile. They come in different thicknesses, where a thicker membrane decreases the permeability and hence recovery.

Diffusion Coefficient

One of the parameters that affects recovery is the diffusion coefficient of molecules of interest, which can be estimated by the Stokes–Einstein equation:

$$D = \frac{k_B T}{6\pi \eta r} \tag{10}$$

where k_B is the Boltzmann constant, T is the absolute temperate (K), η is the viscosity of the solvent and r is the particle radius. The diffusion coefficient of molecules is approximately inversely proportional to its radius and hence to the cube root of its molecular weight. This relationship can be described as

$$\frac{D_{\text{molecule.A}}}{D_{\text{molecule.B}}} \propto \frac{r_{\text{molecule.B}}}{r_{\text{molecule.A}}} \propto \frac{\sqrt[3]{MW_{\text{molecule.B}}}}{\sqrt[3]{MW_{\text{molecule.A}}}} \tag{11}$$

Therefore most microdialysis membranes will allow the rapid passage of small molecules but usually struggle for higher recoveries of larger molecules due to their smaller diffusivity. It is also obvious that the diffusion coefficient is directly proportional to the temperature. Empirically, the diffusion coefficient for small molecules increases $1-2\%$ per degree centigrade. Thus, it is crucial to carry out the entire microdialysis experiment at a constant temperature.

Calibration Techniques

As the relative recovery will never reach 100%, the dialysate concentrations are only a fraction of the true concentration of the analyte of interest in the surrounding fluid. Before using a microdialysis probe for continuous sampling or monitoring, the true concentration of the analyte of interest in the surrounding environment and the recoveries at certain perfusate flow rates have to be obtained. There are many different methods for calibration, which are discussed in the following [1].

Perfusate Flow Rate Variation

Calibration is accomplished by placing a probe in the tissue of interest and varying the perfusate flow rate. At low flow rates, the dialysate concentration will reach a plateau, which is assumed to be near 100% recovery. Recoveries at different perfusate flow rates can then be calculated.

No-Net Flux Method

This is a method enabling the estimation of the in vivo recovery of an analyte of interest introduced by Lonnroth in 1987. The procedure involves adding the analyte of interest into the perfusion solution at different concentrations at a fixed perfusate flow rate and measuring the difference between perfusate and dialysate analyte concentration. The recovery represented by the left term of Eq. (3) can be assumed to be an unknown value P since the perfusate flow rate and resistance are left unchanged. When it is rearranged

$$C_{\text{d,out}} - C_{\text{d,in}} = -P(C_{\text{d,in}} - C_r) \tag{12}$$

By varying $C_{\text{d,in}}$ and determining $C_{\text{d,out}}$, and plotting Eq. (12) as a function of $C_{\text{d,in}}$, the x-axis intercept is the actual recovery concentration C_r and the slope reflects the recovery at the selected perfusate flow rate.

M

Retrodialysis

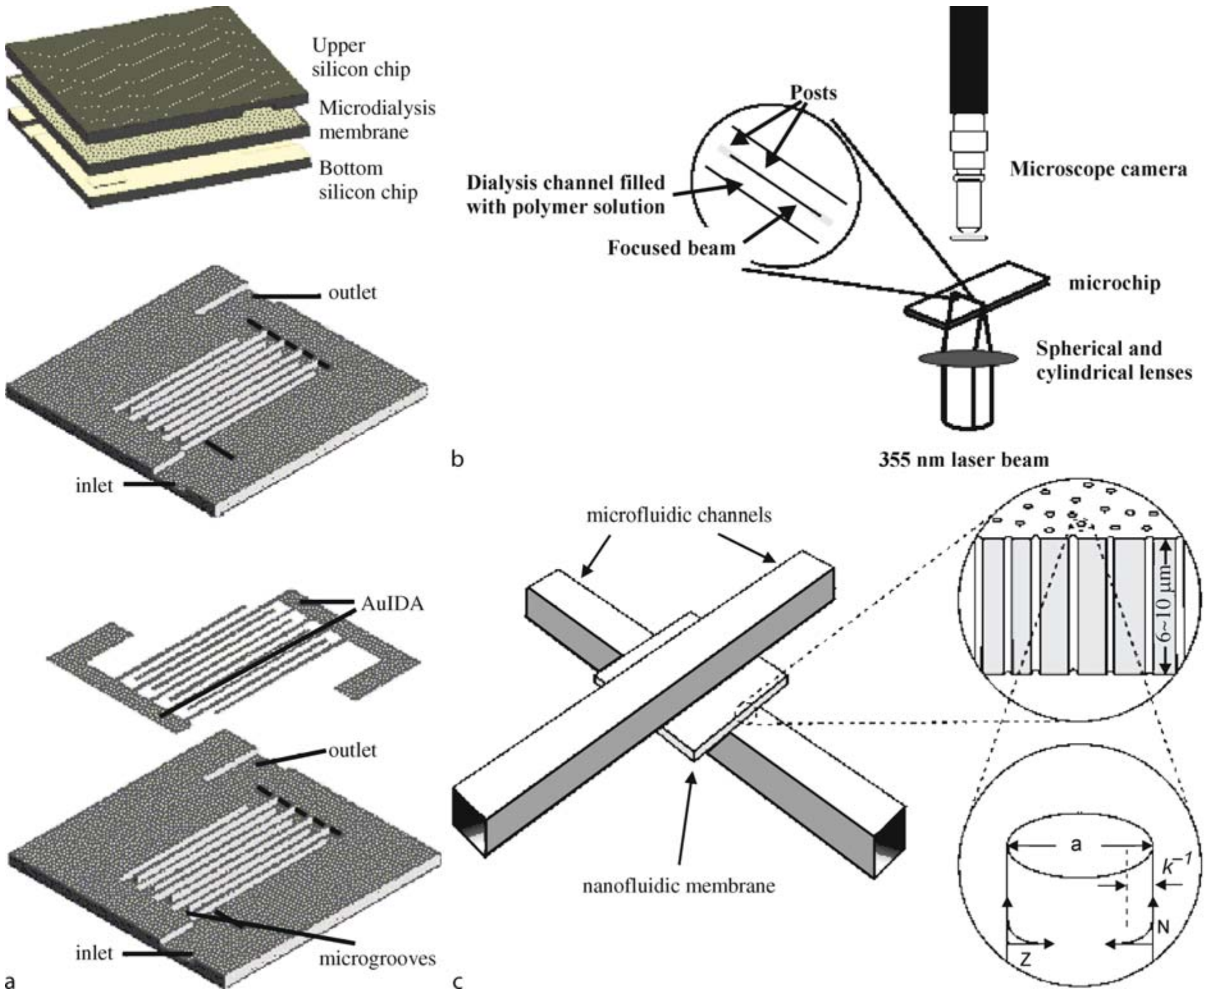
This technique is less time-consuming than those mentioned above and the recoveries can be measured continuously during the experiment. It is also called the delivery method, and is operated by using a perfusate spiked with the analyte of a known concentration. It is recommended that the perfusate concentration be at a minimum ten times greater than the concentration of the analyte around the probe since the recovery is basically determined by neglecting C_r with the assumption that it is small enough compared with the known $C_{\text{d,in}}$, as

$$\text{Recovery} = 1 - \frac{C_{\text{d,out}}}{C_{\text{d,in}}} \tag{13}$$

Another variation of this method is adding a marker or internal standard to the perfusate. The marker should match the diffusion characteristics of the analyte and therefore the recovery can be obtained in vivo by measuring its relative loss through the microdialysis process.

Key Research Findings

For the past 10 to 15 years, semipermeable membranes have been utilized in microfluidics [8]. The concept of a micro total analysis system (μTAS) was introduced by



Microdialysis, Figure 4 (**a**) Microdialysis membrane sandwiched between two etched sets of silicon microchannels with interdigitated sensing electrodes. Image taken from [10]. Widmer and colleagues in 1990, in which silicon chip analyzers which incorporate sample pretreatment, separation and detection played a fundamental role [9]. The advantages of microchip analysis include the ability to analyze minute samples, speed of analysis, reduced cost and waste and portability. Ever since, the μTAS has drawn a huge amount of attention and researchers have been attempting to incorporate a microdialysis-based continuous sampling component. Some of the devices which have been fabricated are shown in Fig. 4.

One approach towards integrating microdialysis membranes with microfluidic systems has been to sandwich a commercially available dialysis membrane between two microfluidic chips. Pan and colleagues adopted this approach for continuous glucose monitoring [10]. In their experiment a commercially available microdialysis probe was used to continuously collect glucose from an analyte solution and the dialysate from the microdialysis probe was introduced into an analysis module consisting of two sets of microfluidic channels with a patterned interdigitated electrode array separated by a microdialysis membrane (Fig. 4a). The dialysate containing the glucose is introduced into one set of channels and allowed to diffuse through the microdialysis membrane into the other set of channels containing glucose oxidase (GOx) enzyme which oxidizes the glucose into gluconic acid and hydrogen peroxide. The hydrogen peroxide is subsequently oxidized on the electrode surface to produce a working current which is proportional to the glucose concentration in the dialysate. The microdialysis membrane was sandwiched between the two sets of channels to prevent the GOx from diffusing into the glucose dialysate and being depleted from the system

Image taken from [15]

and thus improves sensor lifetime. In this system the layers are held together by mechanical pressure.

A second approach by Kirby and colleagues [11] to integrating microdialysis membranes with microfluidic channels used a UV laser photopolymerization technique to lithographically define a patterned nanoporous dialysis membrane within a microfluidic channel (Fig. 4b). A prepolymer solution is allowed to flow through the microfluidic structure and patterned by phase separation photopolymerization using a shaped UV laser beam. The microdialysis membrane was defined along a series of posts which separated to compartments within a microfluidic network. By changing polymer precursors, the degree of crosslinking could also be adjusted to affect the membrane MWCO. Countercurrent flow operation was demonstrated. The first dialysis demonstration used a membrane with a MWCO below 5700 which was designed for desalting of protein solutions. A low molecular weight rhodamine dye was observed to freely penetrate across the membrane which a higher molecular weight (MW 5700) insulin protein could not. Next, a higher MWCO membrane was defined for fractionation of a mixed protein solution. Using this membrane, lactalbumin (MW 14,000) was seen to permeate across the membrane.

A final approach to integrating microdialysis membranes with microfluidics is based on direct bonding of microdialysis membranes with the microchannel structures. One such structure was developed by Bohn and colleagues [12] and is shown in Fig. 4c. Here microchannels are defined in polydimethylsiloxane (PDMS) in the soft lithography pro-

cess, activated in an oxygen plasma and directly bonded to a nanoporous track-etched polycarbonate membrane. Bohn and colleagues used this device for electrically controlling sample manipulation after capillary electrophoresis (CE) separation of arginine and glutamate. After they were separated, either the arginine or glutamate was collected through the microdialysis membrane into a different microfluidic channel by controlling the time at which the gate was biased to collect the sample flowing through that area of the CE column.

Finally, a novel on-chip microdialysis system for glucose sensing based on direct microdialysis membrane bonding onto microfluidic channels (Fig. 5a) has been developed by Hsieh and Zahn [13–15]. The microdialysis device is designed as a miniaturized probe for direct contact between the dialysis membrane and tissue of interest. The system is designed to allow high recovery of analytes with a smaller diffusional surface area and lower flow rates resulting in a less invasive, more precise microdialysis probe. In addition, the large dialysis surface area to microchannel volume ratio and short diffusional path allow higher recoveries and faster equilibration times for higher frequency sampling rates. Hsieh and Zahn have demonstrated glucose microdialysis [13, 15] using this system. They have also integrated an in situ glucose biosensor directly with the microdialysis system (Fig. 5b, c) and demonstrated continuous sensing in a solution where the solution concentration changed sinusoidally in time [15]. The system was able to track the glucose changes with minimal phase lag at a recovery of 99% (Fig. 5c).

Future Directions for Research

Microdialysis still has great potential to impact many research areas. The designs of probes and the choice of dialysis membrane are crucial. Future research effort must be used to characterize the mass transfer characteristics of different membrane materials and their fouling properties, especially in the context of biofouling when dialyzing biological solutions such as blood. Part of the success of microdialysis is due to the development of chemical analysis methods. A combined sampling device and analytical instrument allow continuous monitoring with minimal disturbance to the surroundings. In the future, microfabrication technology holds promise to integrate these two components and improve temporal resolution with higher analytical throughput. Such systems could also be exploited to produce miniaturized reverse osmosis or ultrafiltration devices. Another area of opportunity lies in the integration of active membranes for selective separations such as the use of ion exchange membranes to allow electrodialysis to separate positively and negatively charged chemical species. The ability to perform on-chip microdialysis with electrical conductivity feedback to determine ionic strength allows very sophisticated manipulation of solution properties for biochemical reaction engineering. In this way enzymatic reactions may be tailored with feedback control to proceed effectively. By monitoring ionic concentration in the reaction chamber and enzyme reaction rate, salt may be removed or added to a reaction as needed to improve the efficiency of the enzymatic reactions. Ultimately dialysis biochips may be integrated with other microfluidic components such as micropumps, micromixers and microreaction chambers to allow real-time processing of biological materials. Finally, by utilizing the high surface to volume ratio and highly parallel fluidic channels, these devices may allow use in a low-cost, low flow rate continuous kidney dialysis module. The microdialysis devices may be assembled in a parallel fashion to fluid reservoirs to continuously filter blood and remove waste for patients suffering from kidney failure.

Micro-Encapsulation

Synonyms

Encapsulation

Definition

Micro encapsulated TLCs have a shell of polymer and are spherical particles which can be put into liquids (which do not chemically attack the encapsulation) or – with a binder – sprayed onto surfaces. Micro-encapsulated TLCs are less vulnerable to environment effects but show worse temperature indicating properties than pure TLC substance.

Micro Energy Conversion Devices

Definition

Micro energy conversion devices are miniature systems that convert available energy into a more useful form, such as the conversion of chemical, thermal, or solar energy into electrical power, propulsion or cooling. They usually integrate fluidic, thermal, mechanical, and/or electrical components on-chip to achieve the desired output. Typical energy conversion microsystems, or *power MEMS*, include micro heat engines (microturbines, internal combustion engines), micro fuel cells, vibration energy harvesters, micro rocket engines, and micro coolers.

Overview

The availability of energy in the form of electricity or storable fuels has shaped the way we live and drastically improved our quality of life. For example, energy has been an enabling factor for the industrialization of our society, has allowed the development of planes, trains, and automobiles for transportation, and provides heating, cooling, and cooking in our homes. At smaller scales however, the availability of portable power sources or propulsion is limited. Electric power sources are mostly based on electrochemical storage, such as primary and rechargeable batteries, which are characterized by limited energy density, shelf life, and disposal restrictions. A need for more compact and long lasting power sources stems from the growing range and functionality of portable consumer electronics, such as mobile phones, handheld multimedia players, and laptop computers, as well as handheld biomedical or chemical instruments. Wireless sensors are also constrained by energy requirements, which holds back the implementation of distributed sensors for pervasive intelligence and monitoring of our environment. Similarly, the applications of small mobile robots and micro air vehicles remain marginal since power sources for their propulsion can only allow short duration missions and limited autonomy.

An alternate approach to traditional batteries consists of using MEMS (microelectromechanical systems), microfabrication, and nanotechnologies to implement a variety of energy conversion microsystems. These *power MEMS* could provide electrical power, propulsion, or cooling based on traditional operating principles or on novel prin-

ciples enabled by the small scale or the semiconductor's properties. This chapter will outline the energy conversion principles available and illustrate their MEMS implementation, following a discussion on energy sources and metrics.

Energy and Power Sources

Energy is available in a wide range of forms from our environment, as outlined in Table 1. Conventional energy conversion approaches are well developed at the macroscale to provide electricity, propulsion, heating, or cooling from these sources. A power source can be defined as the combination of an energy *source* with an energy *conversion* unit. An energy *storage* element can also be included in order to accommodate differences between the rate of energy (i. e. power) required by the load and that available from the source. For example, a photovoltaic solar cell can charge a battery such that electrical power remains available after the sun sets. Storage is also required for mobile systems that are not collocated with the energy source, such as the fuel tank of an automobile. Power sources are also characterized by their centralized or distributed nature. Large-scale thermal power plants and hydroelectric stations provide power generation from a central location; the useful energy is then transported to the points of use. Alternatively, solar cells arrays powering individual homes are distributed power sources, collocated with the load.

Scale and Metrics

The size of the energy conversion element is scaled according to the power required by the load, $\dot{W}_{\text{load}}$. For watt or sub-watt level applications, such as wireless sensors and portable electronics, miniature power generation units would be sufficient, suggesting the applicability of MEMS technology to meet this need.

For systems with stored energy (batteries or fuel), the volume of storage scales with the amount of energy required between replenishments, ΔE_{fuel}. The energy required is simply the product of the average rate of energy consumption, $\mathrm{d}E_{\text{fuel}}/\mathrm{d}t = \dot{E}_{\text{fuel}}$, by the time of operation, $\Delta t : \Delta E_{\text{fuel}} = \dot{E}_{\text{fuel}} \Delta t$. For a given specific energy of the fuel, h_{fuel}, expressed in J/kg or Whr/kg (1 Whr = 3600 J), the mass of stored energy is then $m_{\text{fuel}} = \Delta E_{\text{fuel}}/h_{\text{fuel}}$. Energy density of the fuel is defined as the energy per unit volume of storage, typically expressed in J/cm^3 or Whr/cm^3, and calculated as the mass of stored energy divided by its gravimetric density.

The rate of energy consumption from the source is however greater than the power delivered to the load, since the conversion process is never 100% efficient. One can define the energy conversion efficiency, η, as the ratio of power delivered over the rate of energy consumption:

$$\eta = \frac{\dot{W}_{\text{load}}}{\dot{E}_{\text{fuel}}} \tag{1}$$

This metric is important for power sources with stored energy since low conversion efficiency will increase the energy consumption and reduce the time between replenishments, for the same storage volume and same average power to the load. From the first law of thermodynamics, the inefficiency in the conversion process will translate into heat rejection to the surroundings, either by convection, conduction or radiation:

$$\dot{Q}_{\text{rejected}} = \dot{m}_{\text{fuel}} h_{\text{fuel}} - \dot{W}_{\text{load}} \tag{2}$$

Systems that directly extract their source of energy from the environment are referred to as energy *scavenging* or *harvesting* approaches. In this case, minimal or no storage is required since the system is continuously replenished in energy. The concept of energy density becomes less relevant because the energy is not stored in the system. This has the benefit of reducing the size of the power source, but at the expense of loosing some autonomy since the energy availability is subject to changing environmental conditions. A combination of energy storage and scavenging can offer an interesting compromise.

Specific power and power density are also an important metrics, defined as the ratios of power delivered per unit mass or volume, respectively. For power sources that are not dominated in size by the storage unit, such as energy scavenging systems or high power application with short duration, the power density will define the scale of the device to meet a given power requirement.

Basic Methodology

A broad range of micro energy conversion systems can be implemented based on MEMS technology and microfabrication processes. Many large scale energy conversion systems operate using a working fluid either to implement a thermodynamic cycle or to transport thermal and chemical energy. The implementation of micro energy conversion systems based on these principles requires the miniaturization of fluidic and thermal components, raising new challenges in the related fields. Alternatively, the use of semiconductor processing introduces materials with interesting solid-state physics that can also be leveraged for energy conversion. This section will outline the underlying

Micro Energy Conversion Devices, Table 1 Available sources of energy and examples of power generation approaches

Energy Sources	Power Generation	Usable Energy
Mechanical • Wind, Hydro, Tides • Structural Vibrations • Sound	• Wind mills • Hydroelectric plants • Vibration harvesting	• Electricity
Chemical • Hydrocarbon fuels • Glucose, Biofuels • Battery chemistries	• Engines, turbines • Human body • Batteries, fuel cells	• Propulsion • Electricity • Muscular activity

principles and engineering approaches for micro energy conversion.

Direct Solid–State Energy Conversion

Photovoltaics

A photovoltaic cell is a solid-state device that directly converts light into electricity. Upon absorption of incident light, electrons in the material gain sufficient energy to rise in the conduction band, and are free to travel. When generated at the junction of a diode, the free electrons will travel only in one direction, creating a useful current. Most solar cells are tailored to absorb the sun wavelengths and are based on silicon. Efficiencies of solar to electrical energy conversion range from 6% for low-cost amorphous silicon cells to over 30% for exotic semiconductor cells with multiple junctions (each tailored to absorb and generate electrons in a distinct band of the sun's spectrum). Power per unit surface area is limited by the incident radiation, ranging from $0.1\ \mathrm{W/cm^2}$ in direct sunlight to $0.1\ \mathrm{mW/cm^2}$ for indoor lighting. For a cell efficiency of 10%, the output electrical power per unit area would be a factor of 10 lower than these values.

Photovoltaic cells are currently manufactured using silicon processing technologies and novel approaches are in development using polymers and nanostructures. By achieving cost reductions, photovoltaics are expected to take an important role in macro power generation. They can also be used as micro power sources, as long as the power and size meet the needs of the application.

Thermophotovoltaics

Photovoltaics can also be used to directly convert thermal radiation into electricity. Here, a photon emitting surface is heated in the range of 1200 – 1600 K, by combustion or nuclear reactions. It is coupled with a photovoltaic cell specifically chosen to absorb the photons in the near infrared and infrared range of the spectrum, emitted by the hot surface. This approach requires a high temperature heat source and careful thermal management and isolation.

Thermoelectrics

Thermoelectric materials generate a current or potential when they are subjected to a temperature gradient. They typically consist of heavily doped semiconductors, with free carriers that carry both heat and charge. The free carriers are electrons in an n-type materials and holes (or electron vacancies) in p-type materials. Carriers in the hot region are faster and tend to travel further, leading to a higher density of carriers in the colder region of the material. Since the carriers are charged (− electrons and + holes), the non-uniform density of carriers induces an electric potential in the material. This phenomenon was first discovered by the German physicist T. J. Seebeck in 1821. The thermoelectric power, or Seebeck coefficient, S, represents the thermoelectric potential induced per unit temperature difference:

$$S = \frac{\Delta V_{\mathrm{TE}}}{\Delta T} \tag{3}$$

The efficiency of thermoelectric power generation is the ratio of electrical power produced to the heat rate conducted through the material. The non-dimensional figure of merit typically used for thermoelectric materials is:

$$zT = \frac{S\sigma^2}{k} T \tag{4}$$

where σ is the electrical conductivity of the material and k is its thermal conductivity. Thermal power generation efficiency will be a function of the material and operating temperatures. Interesting performance is achieved typically by alloying or nano-structuring the material to scatter the phonons and therefore reduce the thermal conductivity, without affecting the carrier mobility (electrical conductivity). Such materials include heavily doped bismuth telluride (Be_2Te_3) for applications below 450 K or SiGe for temperatures up to 1300 K, which have demonstrated thermal to electrical conversion efficiencies up to 4.5% and 7%, respectively.

Thermoelectric devices can also be used for cooling. By forcing a current through the material, a temperature gradient is created. This is the inverse of the Seebeck effect, and is referred to as the Peltier effect.

Thermoelectric devices are traditionally fabricated by assembling small blocks of n-type and p-type material in an array, interconnected in series with electrodes. A successful system implementation is the radioisotope thermoelectric generator (RTG) for deep space probes. Microfabrication technologies for thermoelectric materials are however being developed to create low-cost integrated power and cooling microsystems.

Thermionics

Electrons on a very hot surface (1000 – 3000 K) can reach sufficient thermal vibration energy to overcome the electrostatic forces holding it on the surface and escape the solid. Useful electric power can be created by collecting the emitted electrons on a cooler electrode at a slightly higher potential overcome by the electrons (0.5 – 1 V).

Electromechanical Micro-Generators

Vibration Energy Harvesting

Mechanical vibrations are omnipresent in our surroundings, ranging from the large amplitude vibrations in rotating machinery to barely noticeable vibrations of windows and walls. For wireless sensor nodes or other distributed applications, these vibrations can be a constant source of energy by converting the mechanical motion into electricity. This process is commonly referred to as *vibration energy scavenging or harvesting*. Inertial harvesters use the vibration of a structure to excite a miniature spring-mass-damper system attached at one point, such as an anchored cantilever beam with an end mass. Ideally, the natural frequency of the harvester will coincide with the frequency of the excitation, such that resonance will amplify the displacement. A limitation of this approach is the need for a known and constant source of vibrations. The induced displacement is then converted to electricity through electromagnetic, electrostatic, or piezoelectric principles. An alternate approach is strain-based vibration energy harvesting, which consists of deforming a device attached to a structure by at least two points, again producing electricity according to the same principles. A disadvantage of strain-based harvesting is the need to be closely coupled to the structure. On the other hand, it can operate over a wide range of frequencies, unlike inertial harvesters.

Radioisotope

Radioactive materials can be used as energy sources for long-lasting compact power sources. The most common approach is thermal, where the alpha particles are stopped very easily and their decay energy is converted into thermal energy. Heat can then be converted to electricity using thermoelectric modules or thermodynamic micro heat engines. An alternate approach is to collect the charged particles emitted from the radioactive material on a flexible structure. The accumulated charges can induce an electrostatic force on the structure, therefore inducing a deflection. This deflection can then produce electrical power by electromagnetic, piezoelectric or electrostatic principles.

Wind Energy Harvesting

Ambient air flow or forced convection can also be a source of energy for distributed environmental sensors or similar autonomous devices exposed to a flow. The airflow can induce the rotation of a microturbine (similar to large-scale wind mills) or the oscillation of a structure. This mechanical energy can then be converted to electricity by electromagnetic, piezoelectric or electrostatic principles.

Electrochemical Power Generation

Micro Fuel Cells

Direct chemical to electrical energy conversion can be accomplished in fuel cells. Many types of fuel cells have been implemented at small scale, including low temperature ($< 100\,°C$) proton exchange membrane fuel cells (PEMFC), direct methanol fuel cells (DMFC), and formic acid fuel cells, as well as high temperature ($> 600\,°C$)

solid oxide fuel cells (SOFC). Micro fuel cell configurations are typically planar, consisting of layered cathode, electrolyte, and anode materials with flow field plates covering both electrodes. A fuel, such as hydrogen, is continuously provided to the anode, where it is oxidized to form protons (H^+) and electrons. Oxygen from ambient air is reduced at the cathode, at a different electric potential. Both half-reactions are catalytic, typically requiring the presence of a noble metal such as platinum, palladium and/or ruthenium on the electrodes. Electrons are allowed to flow from the anode to the cathode through an external circuit, providing the electrical power. The reaction is completed by allowing the ions to flow through an electrolyte that separates the anode and cathode compartments. In solid oxide fuel cells, the O^{2-} ions diffuse through a ceramic electrolyte, whereas in most other types of fuel cells, the H^+ protons travel through the polymer or liquid electrolyte. Water is formed at the cathode as a product of the reaction, as well as CO_2 at the anode for methanol fuel cells.

The performance of a fuel cell is characterized by its output voltage and current density, which is defined as the current per unit area of the cell. The fuel cell voltage drops at higher currents due to increasing catalytic activation losses, ionic and electronic resistances in the cell, and mass transport limitations. The cell efficiency is therefore proportional to the ratio of measured voltage to the ideal cell voltage (1.23 V and 1.21 V for hydrogen and methanol at 25 °C, respectively).

From a system perspective, micro fuel cell power sources must include auxiliary components in addition to the fuel cell itself. Hydrogen-based PEMFCs require high pressure hydrogen gas reservoir and pressure regulation or metal-hydride storage with temperature control. Methanol-based fuel cells can either operate by reforming the fuel in a reactor upstream to liberate the hydrogen, or directly breaking down the fuel catalytically at the anode. Either approach also requires flow supply and water management auxiliary equipment, as well as electrical circuits and/or storage.

Microbatteries

In contrast to fuel cells, batteries do not consume the reactants or emit products. The electrodes in a battery store the chemical energy and change as the battery is discharged. Microbatteries leverage thin film deposition processes to form planar configurations that can be more readily integrated with MEMS and microelectronics. Lithographic patterning and micromachining are also used create advanced electrode geometries that enhance the recharging capabilities and power densities of batteries.

Thermodynamic Micro Heat Engines and Coolers

Micro heat engines are miniature systems that implement a thermodynamic power cycle at the microscale. The approach consists of using a fluid, gas or liquid, to convert thermal energy into mechanical energy. The fluid is sequentially compressed, heated, expanded and cooled, such that more work is done by the fluid during the expansion compared to that required for its compression. The result is net mechanical power generation from the heat engine, which can be used for propulsion or electrical power generation. This output power is equal to the difference between the heat added to the fluid and the heat removed during cooling. The efficiency of a heat engine is defined at the ratio of net power output to heat rate input:

$$\eta = \frac{\dot{W}_{\text{out}}}{\dot{Q}_{\text{in}}} \tag{5}$$

The maximum achievable efficiency for a thermodynamic power cycle is that of the Carnot cycle, which adds and removes heat from the working fluid at constant temperatures, T_h and T_c respectively:

$$\eta_{\text{carnot}} = 1 - \frac{T_c}{T_h} \tag{6}$$

Work from heat engines typically scales as the product of mass flow through the engine and the change of enthalpy during the (adiabatic) expansion. Since, fundamentally, thermodynamics are scale independent, one can expect similar enthalpy changes for macro and micro scale engines. The power therefore scales as the mass flow, itself proportional to the cross sectional area of the engine (for similar flow velocities): $\dot{W} \propto \dot{m} \propto A \propto l^2$. Power density of the engine therefore scales as the inverse of its characteristic length scale, l:

$$\frac{\dot{W}}{V} \propto \frac{l^2}{l^3} \propto \frac{1}{l} \tag{7}$$

By miniaturizing heat engines, we therefore expect larger power levels per unit volume. In practice however, the technological challenges of implementing a thermodynamic cycle will differ with scale since heat transfer, friction, and leakage losses tend to be more important in microsystems compared to their large scale brethren. This would reduce the achievable power density and efficiency. Various types of micro heat engines are possible, characterized by their thermodynamic cycle and their mechanical implementation, as described next.

Micro Internal Combustion Engines (Otto Cycle)

A piston moves with a reciprocating motion to alternatively compress and expand an enclosed gas. Upon compression, fuel is burnt with the gas to release heat. The high temperature gas expands by pushing on the piston, which provides mechanical work. The combustion products are then exhausted to the atmosphere and replaced with fresh cool air before the next compression process. High temperatures, and therefore efficiency, can be achieved since heat is generated by combustion directly within the enclosed chamber. Cooling is accomplished externally to the engine, by rejecting the hot combustion products to the atmosphere. Challenges due to miniaturization include: sealing around the movable piston to allow sufficiently high pressure ratios; friction and lubrication between the movable parts given the alternating loads; mass transfer and heat transfer during the combustion process that can lead to insufficient time for combustion or quenching of the flame by heat loss to the nearby walls. Expected power densities range from 0.1 to 10 $\mathrm{W/cm^3}$.

Micro Gas Turbine Engines (Brayton Cycle)

A continuous flow of air is drawn from the ambient into a rotating compressor. The pressurized air is then mixed with fuel and burnt as it flows through a combustor. The hot gases expand through a turbine, imparting torque on it to drive the compressor, and potentially a generator, that are attached to the turbine by a common shaft. The rotating motion instead of an alternating motion reduces the mechanical complexity compared to internal combustion engines. Furthermore, the continuous flow rate and high temperatures suggest higher power densities, on the order of $1-100\ \mathrm{W/cm^3}$. High tangential speeds are however required to achieve sufficient efficiency of the turbomachinery components, to compensate the effect of scale reduction on the Reynolds number.

Micro Steam Turbines (Rankine Cycle)

Steam turbines differ from gas turbines mainly by pressurizing the working fluid in liquid state with a pump, instead of in gaseous state with a compressor. The pressurized water is then evaporated from an external heat source. The steam is expanded through a turbine, which drives the pump and a generator. Component efficiency is less critical compared to a gas turbine since pressurizing a liquid requires dramatically less power per unit flow rate than compressing a gas. Lower rotation speeds are therefore acceptable. There is however a trade-off of lower power density and efficiency since the achievable cycle temperature is limited by heat transfer to the working fluid and by the challenges of managing two-phase flow in a microsystem. Heat must also be rejected to the atmosphere through a heat exchanger since the device must operate on a closed cycle, if fresh water is not available.

Micro Coolers

Refrigeration cycles can also be implemented in microsystems. The vapor compression cycle, which is the inverse of the Rankine cycle *(Micro steam turbine)*, consists of compressing a gas and consequently rising its temperature above ambient conditions. The high pressure fluid is then condensed by rejecting heat to the surroundings. The fluid pressure is then reduced as it flows across a valve, which also drops its temperature below the ambient temperature. The fluid can then absorb heat from the region to be cooled, as it evaporates at low pressure. Challenges include developing efficient compressors at microscale and managing two-phase flows.

Micro Propulsion

In addition to power generation, microsystems can be used for propulsion in small scale applications, such as attitude control of nanosatellites and thrust for micro air vehicles. Micro thrusters or rocket engines consist of a chamber that feeds a convergent–divergent nozzle through which mater is ejected at high speed to provide thrust in the opposite direction. By applying Newton's second law to a control volume enclosing the thruster and the propellant reservoir, one can express the thrust, F, as a function of the total mass, m, and exit velocity, $\boldsymbol{V}_\mathrm{e}$. Noting that the mass decreases due to the flow rate of propellant through the nozzle, $\dot{m}_\mathrm{p}$, the thrust is expressed as:

$$\boldsymbol{F} = \frac{\mathrm{d}\left(m\boldsymbol{V}_\mathrm{e}\right)}{\mathrm{d}t} = \frac{\mathrm{d}m}{\mathrm{d}t}\boldsymbol{V}_\mathrm{e} = -\left|\dot{m}_\mathrm{p}\right|\boldsymbol{V}_\mathrm{e} \tag{8}$$

Assuming that similar exit velocities can be achieved at micro and macro scales, the thrust is proportional to the mass flow, hence to the cross section area or to the square of a characteristic length scale: $F \propto \dot{m} \propto A \propto l^2$. The thrust to weight ratio of a micro thruster is therefore expected to increase as it is miniaturized:

$$\frac{F}{mg} \propto \frac{l^2}{l^3} \propto \frac{1}{l} \tag{9}$$

Another metric for propulsion systems is the specific impulse, I_sp, which represents the thrust per unit mass flow rate of propellant. Ideally, I_sp is not a function of scale, but depends mostly on the type of propellant used. In practice, aerodynamic losses due to lower Reynolds number

flows in the nozzle and non-ideal nozzle geometries (constrained by microfabrication) can reduce the achievable I_{sp} in micropropulsion systems.

The source of energy can be in the form of a compressed gas, electricity, or a chemical fuel. Cold gas thrusters simply exhaust a compressed gas through a convergent-divergent nozzle to reach supersonic velocities at the exit. Higher thrust and I_{sp} can be achieved by heating the gas, either through resistive heating or combustion. Two types of reactants can be used for combustion: solid or liquid fuels. For space applications, fuel and oxidizer must both be carried on-board. On the other hand, air-breathing applications can use oxygen from the ambient air, leading to dramatically higher I_{sp}.

In contrast to gas thrusters, ion thrusters accelerate charged particles with an electrostatic field. This approach leads to the highest I_{sp} but typically very low thrust levels.

Thrusters can be used in either continuous or pulsed operation, according to the application. Miniature rocket launchers and micro air vehicles require a continuous thrust and are best served by a unique thruster or engine with a continuous feed of propellant. Alternatively, digital micropropulsion refers to an array of single-use thrusters that provide a small impulse (short burst of thrust) to accurately orient a small spacecraft or correct a vehicle's trajectory.

Auxiliary Components

Many micro energy conversion systems require a host of auxiliary components along with the core elements mentioned above. These can include: micro heat exchangers and combustors to provide heat; valves and flow regulators to control the flow of fuel or coolant; temperature, pressure, or speed sensors along with electronics to control the device operation; as well as power electronics and electrical energy storage.

Key Research Findings

As described above, many approaches can be taken to convert energy at small scales. This section describes some of the achievements and challenges identified in three of the most researched areas for which microfluidics are of central importance: micro fuel cells, micro heat engines, and micro thrusters. The focus will be on device implementations that leverage MEMS and microfabrication technologies.

Micro Fuel Cells

Although standard techniques can be used to fabricate miniature fuel cells, microfabrication approaches have been increasingly used to implement various components and subsystem of fuel cells power sources. Initially, most attention was devoted to microchannel flow fields for fuel and oxidizer delivery, leveraging the increase in mass transport at small scale, but at the cost of increased pressure drop. Since miniature pumps and blowers to force air through the cell are neither efficient nor small enough for watt-scale applications, air-breathing configurations driven by free convections have gained interest. Unfortunately, this configuration emphasizes the challenge of water accumulation at the cathode. Microfabrication has then been used to replace standard gas diffusion layers that cover the electrodes, such as carbon cloth or paper, by tailored silicon structures for water management. Micro and nanostructures, such as porous silicon, have also been studied to create the porous electrodes and ionic transfer media. Although to date, the best performance of μPEMFC and μDMFC have been demonstrated with traditional carbon-based porous electrodes and polymer electrolyte membranes, novel configurations enabled by micro and nanofabrication offer the promise of increased control over the multiple transport phenomena that must coexist in a fuel cell, such as gas diffusion, water removal, electronic conduction, and ionic conduction. Micro fuel cells operating in laboratory settings on hydrogen have been demonstrated up to $300\,\mathrm{mW/cm^2}$ and average voltages of $0.4-0.7\,\mathrm{V}$, while those operating on methanol have shown a maximum of $100\,\mathrm{mW/cm^2}$ and voltages in the range of $0.2-0.3\,\mathrm{V}$ [1]. Micro-DMFCs have the benefit of using a liquid fuel with high energy density, but suffer from relatively low efficiency ($< 30\%$) and power density. Methanol unfortunately has a tendency to crossover the membrane, from the anode to the cathode, so it is commonly diluted in water (to approx. 7%) to reduce this loss. To ensure proper mass transport of reactants at the electrodes, it is also important to ensure removal of the gaseous CO_2 generated at the anode and liquid water at the cathode. The management of two-phase flow and bubbles in microchannels is therefore of importance. Micro-PEMFCs have demonstrated higher efficiencies ($> 40\%$) and power densities than methanol fuel cells, suggesting more compact power sources. The main challenge for practical applications is the fuel: hydrogen. Although hydrogen has the highest specific energy (per unit mass), its gaseous state leads to very low energy density (per unit volume). Metal-hydride storage or compressed hydrogen tanks remain to be developed at small scale. An alternate approach consists of using a micro reformer to extract hydrogen from a liquid fuel. Such chemical microsystems are being studied, but face the challenge of providing sufficiently pure hydrogen to prevent poisoning of the Pt catalyst. Micro solid oxide fuel cells (SOFC) of planar, tubular, or swiss roll configurations are also under development [2]. They accept a wider range of fuels, but their high

M

operating temperatures (up to 800 °C) introduce material challenges and stringent thermal insulation requirements with the surroundings for viable implementation.

Micro Heat Engines

Two main approaches have been used to implement micro heat engines: precision machining of metals (mesoscale) or silicon-based microfabrication [3]. Mesoscale heat engines are typically miniature versions of their large scale counterparts and operate in the 10 – 1000 W range. Microfabricated heat engines must however be reinvented to comply with the geometric constraints imposed by the planar nature of lithographic and etching processes. They can be further miniaturized to meet the needs at lower power levels.

Internal combustion engines implementing the Otto cycle have been studied based on the rotary engine with a triangular rotor (Wankel), as well as free and spring loaded linear pistons. Challenges in terms of sealing, wear/lubrication, and combustion have led the research towards the mesoscopic implementation however. MEMS-based high speed rotating microturbines have also been developed for propulsion and power generation [4]. Millimeter-scale rotors in the shape of a disk are micromachined from the bulk silicon using deep reactive ion etching (DRIE) and integrated with fluid film bearings, combustors and electromagnetic or electrostatic machinery using wafer bonding. Air-driven microturbines have been operated over 1.4 million RPM, demonstrating the feasibility of air bearings, the mechanical strength of single crystal silicon, and sufficient precision to make adequately balanced rotors to reach the high speeds required for microturbomachinery [5]. Efficient combustion using hydrogen and hydrocarbon fuels has been demonstrated in microfabricated chambers of less than 1 cm^3, with complete combustion and exit gas temperatures over 1800 °C. Permanent magnet and induction generators have also been demonstrated at power levels on the watt scale and with conversion efficiencies near 50%. These building blocks require further development for stand-alone and high temperature operation. Their integration into complete microsystems is also in progress to make micro gas turbines engines (Brayton cycle, [4]) and micro steam turbines (Rankine cycle, [6]). Predicted performance levels range from 1 – 100 W/cm^3 depending on the operating conditions, with overall conversion efficiencies up to 10%. One main challenge is thermal isolation approaches and materials to prevent heat leakage between the hot and cold portions of the thermodynamic cycle. For micro gas turbines, conduction from the turbine to the compressor can dramatically reduce the compressor efficiency and the power output of the cycle. For micro steam turbine cycles, sufficient insulation must be ensured to prevent evaporation in the pump and condensation in the turbine. These thermal challenges are preponderant in microsystems due to the short length scales and the high thermal conductivity of silicon and silicon carbide. Lubrication of the rotating components must be done with the working fluid (air or steam), typically using internally pressurized hydrostatic or hydrodynamic fluid film bearings. This approach prevents solid friction and wear in steady operation, but is not unconditionally stable and requires some initial rotation to become active. Sealing is also important, but not as critical as for internal combustion engines.

Micro Thrusters

Various types of micro-thrusters have been developed, both for continuous and pulse operation. Silicon microfabricated cold gas and heated gas (resistojets) thrusters have been demonstrated with specific impulses (I_{sp}) of 66 s and 90 s respectively, at thrust levels up to 12 mN [7]. Supersonic flows in two-dimensional, deep reactive ion etched micro nozzles exhibit noticeable viscous losses due to the moderate Reynolds number ($1000 < Re_t < 3000$), which impacts the achievable I_{sp}. Liquid bipropellant micro rocket engines have also been studied to achieve higher I_{sp} and thrust, reaching 150 s and 1 N respectively [8]. These consisted of a stack of six micromachined silicon wafers that are bonded to enclose a contoured 2D nozzle with a combustion chamber and integrated cooling passages. Challenges include the temperature limitation of silicon which imposes stringent cooling requirements, as well as aerodynamics of high speed internal micro flows.

Digital micropropulsion, consisting of an array of single-shot thrusters, has also been developed to provide short impulses for attitude control of miniature spacecraft. The approach consists of enclosing an explosive or propellant between a resistive heater and a burst diaphragm that leads to a nozzle etched in silicon. Impulse levels of 10^{-4} N/s for mm^2-scale thrusters have been demonstrated, with an I_{sp} of 11 s [9]. There is potential for finer impulse levels and better fuel utilization as the combustion process is mastered.

Future Directions for Research

Most of the micro energy conversion approaches described above still require significant research and development before reaching the level of performance and reliability of a commercial product. Certain engineering challenges are common to many approaches and worth listing:

- Fluid dynamics, heat transfer, and mass transfer in developing moderate Reynolds number flows

(1 < Re < 1000) in complex microfluidic geometries

- Liquid-gas flows with phase change and capillary forces in complex microchannels
- Materials and configurations for thermal insulation in microsystems
- Novel microfabrication processes and materials to meet the needs of power MEMS, ranging from high strength and high temperature ceramics to stable hydrophilic/hydrophobic coatings.

Opportunities also arise to pursue innovative concepts and leverage micro and nanoscale phenomena for energy conversion. The MEMS tool set provides a framework to invent new concepts for energy conversion that may not be feasible or practical at the macroscale. Examples include microfluidic fuel cells that leverage laminar flow in microchannels to implement a purely diffusive, membrane-less fuel cell, and thermal expansion or phase change heat engines that can cycle at high frequencies due to low thermal mass and high heat transfer rates at microscale. Also, piezoelectrics and electrostatics principles complement more traditional electromagnetic approaches for mechanical to electrical conversion, given the established fabrication processes using MEMS technology. Opportunities also arise in the use of biochemical energy sources and biological approaches inspired from living organisms, as well as in leveraging nanoscale materials and phenomena to meet micro energy system needs.

Not only is further development required to improve the performance of core components, but significant effort is required at the system level. Integration of power generation elements with the required balance-of-plant components and the energy storage remains a technical challenge and a barrier towards commercialisation. Finally, the experimental development of power MEMS also raises unique difficulties in packaging and testing. Instrumentation development has not kept the pace with the microsystems they are meant to characterize, to the point where critical measurements inside the microsystems are replaced by external, global measurements. Only by understanding their physical behaviour will micro energy conversion systems take a predominant role in our every day lives.

Definition

Filters with pore size ∼1 μm located within microfluidic systems/channels, typically used to separate blood cells from plasma and to confine micrometer-sized beads within a microfluidic system.

Overview

Biomarkers (molecules of clinical significance) are often present in blood plasma, and the goal of many commercial systems under development is to rapidly estimate the concentration of these molecules – either in batches or continuously. Since one can draw only a limited quantity of blood from a patient for analysis, one is compelled to use as small an amount as possible for each analysis. This is especially true if one wants to either assay for multiple biomarkers, or one is interested in tracking the concentration of a particular biomarker frequently, or both.

Microfluidic systems, with their small volumes and sample requirements are inherently well suited to such tasks. In these systems, various optical, electrochemical, and electrical sensing elements are placed within microchannels. However, since the presence of particulates (like blood cells) can clog up microchannels, these systems are unable to operate for significant periods of time. Although some commercial microfluidic systems [1] have worked around this drawback by utilizing disposable systems, such disposable systems cannot be used for continuous monitoring – which is required in many cases. For instance, it is widely known [2] that during long operations like cardiac bypass surgery, a number of immunological pathways are initiated, and that these immunological responses lead ultimately to many adverse outcomes such as organ dysfunction [3]. This lack of a method to monitor the said responses in real time prevents a better understanding of the problem, and has consequently led to a lack of protocols for early corrective intervention [4]. Similarly, recent research has indicated that if the blood sugar levels of diabetic patients admitted to the intensive care unit (ICU) is kept under "tight glycemic control" [5] by measuring the blood glucose levels of patients once every five minutes and administering appropriate doses of insulin, then the mortality rate for such patients can be reduced by over 40%. Since diabetics, diagnosed or otherwise, make up a disproportionate fraction of those admitted to the ICU (as high as 56% according to one study [6]) a technology that would enable the widespread practice of tight glycemic control could have an enormous impact on overall outcomes in the ICU. In the latter case, though there are "continuous" glucose monitoring systems that rely on using cell-free interstitial fluid (ISF) already available on the market, they are not well suited for this applications on account of the time-lag between the levels of glucose in the blood and in the ISF. In cases like the former (monitoring immune response), there is a more fundamental drawback to using ISF instead of blood – i. e. that a large number of clinically relevant biomarkers may not be found in the ISF, or their concentrations there may not correlate to that in the blood in a clinically significant manner. Thus we are compelled to devise filters (and other technologies) that will remove the interfering cells prior to analysis or assay. A similar logic applies for food, environmental, and other samples – where one wishes to remove various particu-

late matter that may interfere with the detection of the target biomolecules. Another purpose for which microfluidic filters are widely used is to confine micrometer-sized beads to specific regions in a microfluidic network. These beads, typically tagged with antibodies/complementary sequences to target bioparticles or biomacromolecules, are being increasingly used in microfluidic systems on account of their high surface area (leading to better binding probability of the target species) and ease of handling [7].

Basic Methodology

In general, for diagnostic applications, the requirements for blood cell removal are extremely onerous, i. e. a 100% cell removal efficacy. Even a few cells (out of the millions present in a typical sample) have the ability to clog up microchannels and adversely affect sensitive biosensors downstream. The sensitivity of the biosensor and the concentration ranges of the target biomarkers also determine by how much the original solution may be diluted. For low abundance biomarkers, any dilution may be undesirable. At the same time, the need for continuous, or even "once every few minutes" measurements may require a throughput of the order of a few microliters per second. And finally, a filter that meets these requirements must also be such that it can be housed within a chip, whose choice of material may be dictated by other concerns, including, but not limited to, biocompatibility and the ability to fabricate and/or house the downstream sensors in the chip.

The system requirements for most other applications are much less stringent – a 5 – 10% loss of beads may not be catastrophic, and the presence of a small number of particulates may be tolerated in many assay procedures.

Despite the obvious differences in the applications for which they are designed, research in the microfilters area is directed towards answering two basic questions:

- How can one make a filter with the desired pore size distribution within a microchannel carved out in the material of choice?
- How should the filter be sized, positioned, and operated for it to meet the design objectives?

Of course, like all design questions, these two questions need not be completely independent. For instance, the ability to fabricate the filter out of a tougher material that is able to withstand a higher pressure could enable a filter of a particular design to meet more demanding design requirements. Nevertheless, they not only represent two themes on which recent investigators have tended to focus, but also provide a way to classify new designs along two axes.

Key Research Findings

Making the Filter

Given the different types of materials (glass, silicon, poly(dihydroxymethyl silicate) (PDMS), different types of other polymers) used in microchannel fabrication, various techniques have been adopted to achieve the goal mentioned above. Three broad types of filters are seen frequently:

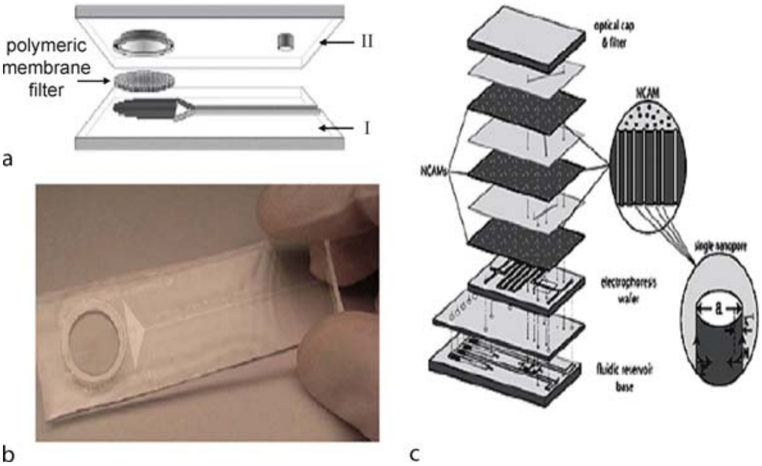
- microporous or nanoporous membranes incorporated as one of the walls of a microfluidic channel (usually the "floor" or "roof") allowing the filtrate to flow into a chamber or channel on the other side of the membrane;
- arrays of pillars, usually arranged in a regular geometric pattern, within a microchannel; and
- porous beds, with a distribution of pore sizes, embedded within a microchannel.

Porous Membranes

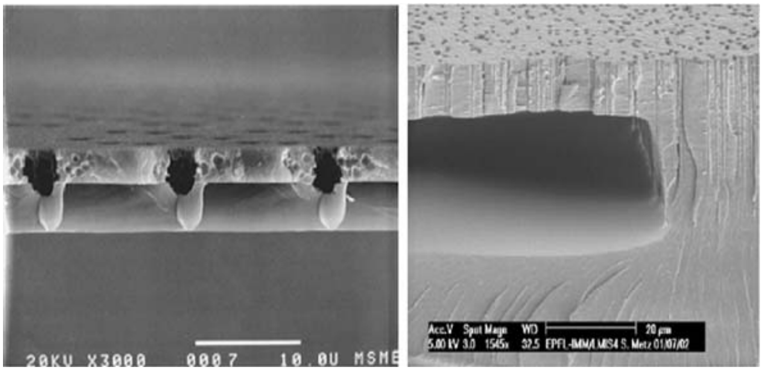
Since micro- or nanoporous membranes are routinely used in the macro- or milliscale for many of the same goals as those desired for microfluidic systems, it is not surprising that they have been incorporated into the latter. The membranes used to effect the separation in the microfluidic systems may either be manufactured specifically using microfabrication techniques, or may be bought off the shelf. Using bulk microfabrication techniques (wet etching), it is possible to obtain micrometer-sized pores in a variety of shapes in silicon nitrate membranes. These pores can also be coated with polymers (such as parylene) to impart desired physical properties such as hydrophobicicty or hydrophillicity [8]. Even smaller pore sizes (~ 25 nm) can be obtained by focused ion beam drilling [9].

These membranes, and other commercially available membranes, can be incorporated within microfluidic devices by having open channels (or ports) fabricated in two separate pieces, and then sandwiching the membrane while fusing/gluing together the former. Examples of devices obtained in this manner are shown in Fig. 1.

While these devices are often able to meet their design targets of performing a crude separation at a low cost, they are often not very well suited for complex tasks such as those involving the separation of multiple samples along multiple channels. The very fact that these devices have to be "assembled" (the membranes often being put into position often by hand) limits how many different membranes (with different pore sizes) one can incorporate within a single chip. An alternative to the above is to fabricate the "membranes" within the chip. This can be accomplished in silicon microfluidic devices using the same bulk micro-



Microfilters, Figure 1 *Left:* (**a**) schematic and (**b**) picture of a microfluidic blood filtration device [32]. The top and bottom pieces are made up of PDMS, and the membrane is a commercially available hydrophilic polypropylene filter. *Right:* schematic of another device fabricated similarly, but with multiple layers of nanoporous membranes [33]

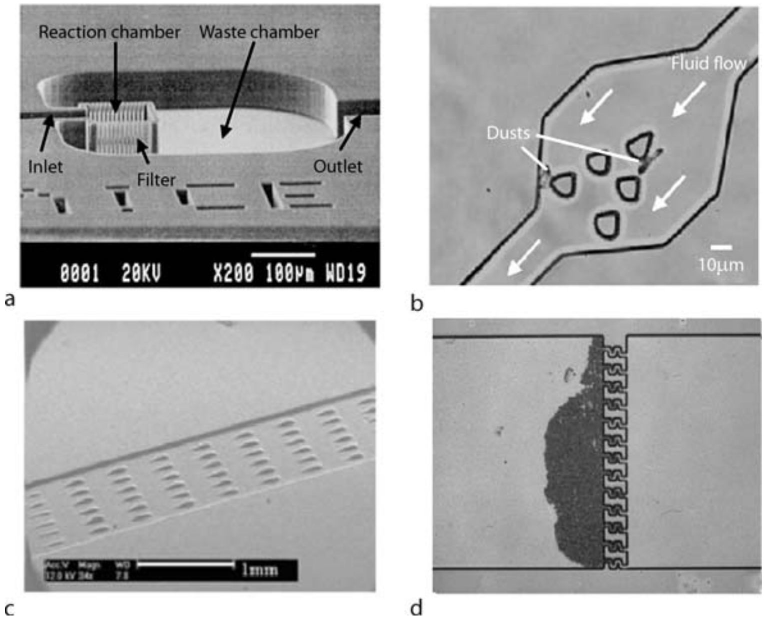


Microfilters, Figure 2 Pores fabricated on top of a channel in a silicon-based device using bulk micromachining [34] *(left)* and in a polyimide channel using track etching by lasers [35] *(right)*

machining techniques (wet-etching and deep reactive ion etching (DRIE)) that are used to make free-standing SiN microporous membranes. More advance fabrication techniques (surface micromachining) are needed to fabricate nanoporous membranes on top of selected regions of microfluidic channels housed in silicon wafers [10, 11]. Similar sized nanopores have also been fabricated by track etching polyimide microchannels (as also shown in Fig. 2). These in situ fabricated membranes are able to overcome most of the drawbacks associated with the devices that use prefabricated membranes. In addition, depending on the material, designers have a high degree of flexibility with respect to the pore size distribution of the membrane. Moreover, the location of their pores is such that these membranes can be used in a cross-flow mode – a mode of operation that (as will be discussed later in the article) is more effective than the other commonly used (dead end) mode. The main drawback is that fabricating devices with such pores is difficult and expensive. Also, and perhaps more importantly, it has been possible to fabricate such devices in only a few limited materials.

Arrays of Pillars

The *arrays of pillars* design has been adopted in microfluidic systems made out of a variety of materials, and the fabrication process adopted is formulated accordingly. In silicon-based microfluidic devices, the channels are typically formed either by wet etching or by DRIE. In either case, selective patterning of photoresist (or oxide) is used to define the channel regions. On exposure to wet etchant or reactive ion radiation, areas on the silicon wafer not covered by the resist or oxide are etched away, leaving open trenches. When the top is covered by another silicon or



Microfilters, Figure 3 "Arrays of pillars" created in different microfluidic systems. These pillars serve as filters with well-defined pore size. (**a**) 50 μm high pillars with a spacing of 2 μm obtained through DRIE of a silicon wafer [36]. (**b**) 25 μm high posts with a separation of ∼ 15 μm in PDMS [37]. (**c**) Tilted scanning electron microscopy image of trapezoidal shaped pillars (120 μm high, 50 – 200 μm wide) with a separation of ∼ 50 μm injection molded on a cyclic olefin copolymer (Topas 5013-S04) substrate [38]. (**d**) Array of complex microposts (73 μm wide) spaced by 7 μm wide tortuous channels spanning a 500 μm wide ×5.3 μm deep silicon channel [39]

M

glass wafer, and bonded to the former using anodic or thermal bonding, closed microchannel networks are obtained. Here the original resist or oxide pattern itself is used to define islands that will not be attacked by the etchant or reactive ion radiation. These islands give rise to pillars within the microfluidic trench when the channel network is formed by etching – an example of which is shown in Fig. 3a. Subsequent anodic or thermal bonding yields covered channels with pillars within them that stretch from the channel floor to the channel roof. Similar structures have been fabricated in PDMS and other materials also – and examples are shown in Fig. 3. In all these cases, the pillars are fabricated along with the main channels.

The main advantage of using this design is that one can obtain monodisperse "pores" of the desired size with ease. The lower limit of the pore size is determined by the feature size resolution of the fabrication process used to make the channels, and thus pores ∼ 1 μm can be easily fabricated. However, higher throughput microfluidic devices can require channel depths of ∼ 100 μm – and not only is making pillars with a spacing of about a micrometer in such channels difficult and expensive, but such posts, once made, are liable to buckle more easily than shorter ones. The failure of even a few posts may compromise the filtration process. The latter concern may be ameliorated to an extent by fabricating "wider" posts that run for a distance along the direction of fluid flow, and thereby effectively create smaller channels into which larger particles cannot enter. In addition (as seen in Fig. 3d) these "channels" can be designed to be tortuous to further aid the filtration process.

Packed Beds and Porous Monoliths

Packed beds consist of a large number of solid particles packed into a conduit. These particles may be either of the same material, shape, and size (e. g. latex microspheres of 1 μm diameter) or vary by size, shape, and/or material. They are typically held in place by a frit or some other structure downstream of the bed that allows fluid to flow through while holding them in place. Typically, the downstream frit is fabricated/placed first, the bed is then packed at high pressure, and finally another frit is placed upstream to hold the structure in place. A packed bed typically has a large number of interconnected pores, with a distribution of sizes, through which the particle-laden fluid is driven. The interconnected network of pores of different sizes often prevents particles whose diameter is larger than that of the modal pore size from passing through the bed. Even in the macroscopic world, packed beds and membranes are the two most common methods for filtering solutions. So it is not surprising that packed beds are also used for the

same purpose in microfluidic systems. In microchannels, in addition to frits [12], weirs [13], surface coatings [14], and channel constrictions [15] have also been used to hold the particles in place. However, placing the upstream frit (or other structure) after packing the bed in place remains a difficult task to accomplish in microfluidic channels. Hence, for practical reasons, porous monoliths are more commonly used instead of packed beds.

Porous monoliths, as the name suggests, are single pieces of porous material (like a pumice stone). When placed within conduits, they function in the same manner as packed beds and share many of their characteristics as well – primarily the interlinked network of pores with a distribution in pore size. It is possible to fabricate such materials within microchannels, and to ensure that the monolith is bonded to the wall. Thus, the need for frits (and other structures) to hold the "bed" in place is eliminated. In addition, depending on the method used for fabrication, it may also be possible to tailor the modal pore size.

It has been possible to fabricate porous monoliths within silicon [16], glass [17], and polymer [18, 19] microchannels. Within silica and glass channels, porous monoliths can be fabricated by a thermally aided sol–gel reaction. Photopolymerization of acrylate monomers in the presence of porogens (inert organic solvents) has also been used to obtain porous monoliths. By varying the composition of the monomer blend, the composition of the porogen mixture, and the ratio of monomer to porogen it is possible to control the porosity of the monolith and the modal size of its pores. In addition, if the channels are made out of acrylate polymers, or have been coated with such material, the monolith bonds to the surface, and the filter can be operated without any extra arrangements (like frits) to hold the monolith in place.

The main advantage of these porous monoliths is the ease with which they can be fabricated. The fabrication process also allows for the fabrication of multiple porous monoliths with different characteristics (porosity and pore size distribution) within the same microchannel network, and to rapidly modify these characteristics on an as-needed basis with a minimum change in fabrication procedure (changing the composition of the pre-reaction mixture used to fabricate the pores, and/or the reaction temperature and duration for the same). Figure 4 shows two different monoliths fabricated from the same material. They can also be tailored to withstand higher pressures by the simple means of increasing the bed length and/or changing its shape. There are two main disadvantages, though. Firstly, due to the large surface area of the solid, it is possible for a relatively larger number of molecules (relative to the other structures), some of which are likely to be the target molecules in the downstream analysis section of the overall device, to adsorb onto its surface – though one can physically or chemically coat the material with molecules like poly(ethylene glycol) (PEG) or its derivatives to reduce this. Secondly, the characteristic pore sizes are limited to the micrometer range. Not only is making a monolith with smaller pore sizes difficult, but a monolith with a modal pore size in the nanometer range would require extremely high pressures to drive liquid through it. However, this is not an issue for a large number of applications – including that of blood cell removal from plasma.

Operating the Filter

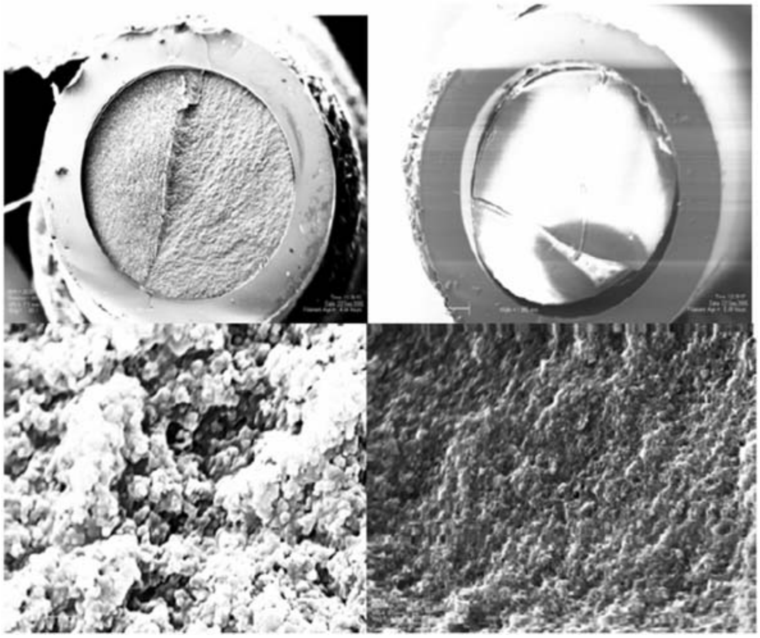
As shown in Fig. 5, there are two main modes in which a filter may be operated – the dead end mode and the cross-flow mode. In the dead end mode, the particle-laden fluid is directed normally against the filter surface. While particles of size larger than that of the pores are prevented from passing through, all of the fluid passes through the filter. The particles being excluded remain on the upstream end of the filter, and when a large number of them are accumulated, they impede further fluid flow. Hence dead end filtration is typically used for small sample volumes, or suspensions with a small number of suspended solids.

In the cross-flow mode, the particle laden fluid flows tangentially past a filter. However, by suction, or by other means, a fraction of the fluid is pulled through the filter. Like in the dead end case, particles whose size is larger than that of the pores are excluded by the filter – but unlike the previous case, are not allowed to accumulate there since the tangential cross-flow sweeps them along and away from the surface of the filter. In practice, the cross-flow is never 100% efficient in sweeping away the excluded particles, and these particles do build up over time, causing the same set of problems (increased pressure drop, damage to the filter, etc.) as in the dead end mode. But a decreased volumetric recovery efficiency of the fluid (only a fraction is pulled through the filter) buys the user a longer operating time.

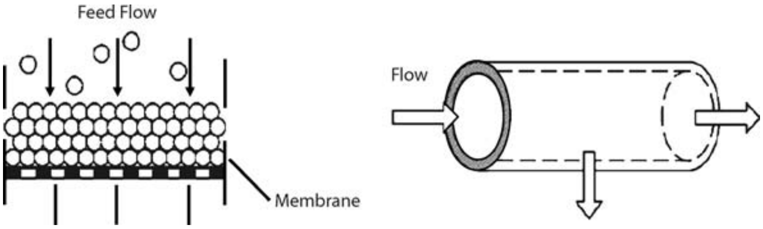
For most microfluidic applications involving beads, and for removing contaminant particulates from environmental samples, filters are operated in the dead end mode. Also to purify small volumes ($\sim 100\,\mu l$) for "one-shot" diagnostic applications [18], the dead end mode suffices. But for blood-diagnostic applications requiring continued operation and/or larger volumes (milliliters) of blood, one needs to resort to cross-flow [20, 21].

Future Directions of Research

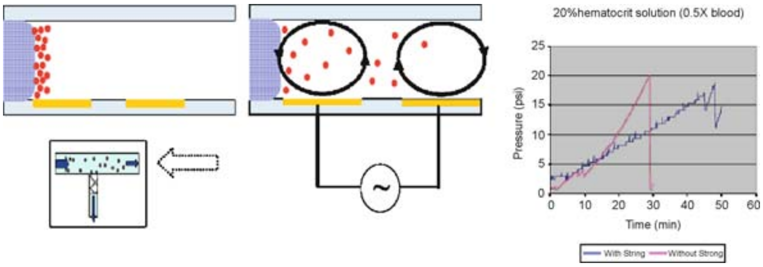
The migration of deformable blood cells towards the low shear filter region [22], however, causes the beneficial



Microfilters, Figure 4 Porous monoliths with different porosities and pore size distributions created by the photopolymerization of a blend of acrylate monomers and porgens



Microfilters, Figure 5 Dead end *(left)* and cross-flow *(right)* modes of filtration [40]



Microfilters, Figure 6 Schematic *(left)* of an AC electro-osmotic stirrer placed at the edge of a monolith filter that generates microvortices to break up the excluded red blood cell “filter cake”, and pressure buildup data *(right)* demonstrating the beneficial effects of stirring (reducing pressure buildup rate and consequent time to failure of the system)

effect of the cross-flow to be less pronounced for microfilters than in their macroscale counterparts and realized performance characteristics fall short of desired goals. An active area of research has been to explore means to enable the cross-flow to be more effective at removing the layer of excluded material on the upstream surface of the filter. Modification of the surface of the filter to make the excluded material less strongly adherent to it [23], the use of acoustic pulses to break up the “filter cake” [24], and the use of a sinusoidal flow field for the cross-flow [25]

have been tried previously to varying degrees of success. Recent research in our laboratory has focused on enhancing the rate at which excluded material can be removed by the cross-flow by placing electrodes at the edge of the filter and generating AC electro-osmotic vortices to break up the filter cake, and, as shown in Fig. 6, we have been able to extend the operation time of the filter by close to 50% as a consequence.

Additional drawbacks of using filters, especially upstream of bioanalytical procedures for detecting low-abundance molecules, include the potential losses of the target molecule due to adsorption on the high surface areas typically associated with filters. Current research has focused on reducing this problem by using thinner membranes [26] – but this general approach comes at a cost (the ability of the membrane to withstand lower pressures). Making the membrane of a stronger material (glass or silicon as opposed to polymer) can also adversely affect the overall bioanalytical goal if it may lead to increase lysis of cells, and consequent perturbation of the composition of the plasma.

To conclude, one may say that while the building blocks are largely available to build blood cell filters, a cake-free and high-throughput blood cell microfilter is still unavailable, and much work remains to be done to make it possible for blood cell filters to meet the performance desired of them in blood diagnostic chips. Other competing technologies exist (and are in development) that seek to remove blood cells and other undesired particulates from suspensions without damaging the cells and/or adversely affecting the composition of the liquid. A large number of technologies, including, but not limited to, dielectrophoresis [27], electrophoresis [28, 29], centrifugal force [30], and differential diffusion rates [31] have and/or are being explored. However, they also suffer from various drawbacks that make them individually unsuitable for the most demanding applications such separating blood cells from plasma in whole blood. One area that has not been explored is to use filtration in combination with one or more of these techniques to effect the desired separation.

Microflaps

YANDONG GAO , DONGQING LI
Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, USA
yandong.gao@vanderbilt.edu

Synonyms

Microflow actuator; Flow control

Definition

Flaps are types of flow actuators, which are hinged surfaces on the wings of air vehicles used to generate sufficient moments for aerodynamic control. The flow separation is very sensitive to small perturbations at its origin. This fact makes it possible to control vortices at the leading edge separation line by small force and/or displacement at appropriate locations. Taking advantage of microelectromechanical systems (MEMS) technology, an array of microflaps, together with a shear stress sensor, can be fabricated to manipulate the thin boundary layer near the leading edges, consequently allowing control of the global flow field [1]. Because the thickness of the boundary layer is of the order of millimeters, microflaps are typically required to be able to deliver an out-of-plane displacement of several millimeters and sustain a load of the order of several hundred micronewtons.

M

Overview

Micromachined flaps are attractive because of the possibility of integration of both microsensors and microactuators in a single device. In addition, microflaps have fast frequency responses and fine spatial resolutions with low power consumption because of their small length scales. The use of a large number of small and simple actuators also makes these systems fault-tolerant. To achieve a large actuation displacement and large output force, the most suitable actuating scheme is based on electromagnetic principles [2, 3].

Liu et al. [4] developed an integrated coil-type magnetic micromachined flap, which achieved a vertical deflection larger than 100 μm and an applied magnetic force of about 1 μN. However, the coil-type microflap requires high currents, and the thermomechanical bending strongly influences its performance due to the significant Joule heating. Liu et al. [3] developed millimeter-scale magnetically actuated microflaps moving in the out-of-plane direction based on a permanent magnet. The displacements of their microflaps achieve vortex symmetry breaking. Therefore, the rolling motion of a delta-wing airfoil could be controlled. Sherman et al. [5] presented electrostatically driven in-plane microflaps made from silicon-on-insulator wafers. Due to their small size ($60 \times 200\,\mu m^2$), they are of low power consumption ($< 1\,\mu$W) and high operating frequency ($500 - 1000$ Hz).

Microfluidic systems assembly; Microfluidic component assembly; Microfluidic integration; Microfluidic systems packaging

Definition

Microfluidic assembly refers to the realization of devices and systems for handling and analyzing microliter or nanoliter amounts of fluid through the combination of smaller subunits, including the combining of discrete microfluidic devices and components to realize complex microfluidic instrumentation. Microfluidic assembly uses various integrated and modular packaging and interfacing techniques to combine microfluidic subunits together, including bonding, mechanical press-fits, robotic manipulation, and self-assembly.

Overview

Microfluidic components and systems are utilized whenever the manipulation of microliter or (usually) nanoliter amounts of fluid is beneficial or where small size for fluidic systems is needed. Examples of microfluidic applications include the miniaturization of laboratory instrumentation for bed-side rapid diagnosis of disease; implantable monitoring and drug delivery devices such as glucose sensors and insulin pumps for diabetes; bioanalytical instrumentation for studying cells or molecules in new ways; and other Lab-on-a-Chip devices for performing complete laboratory analysis on a sample using a portable instrument. However, these and other microfluidic systems can be very complex, requiring the interfacing of many different passive and active components such as micro channels, valves, pumps, filters, and chemical reaction chambers, as well as detection systems and other sensors operating on electrical, mechanical, or optical principles. Most research in microfluidics has centered around the optimization of particular components or subsystems utilizing well-known or newly developed principles, e. g., polymerase-chain reaction (PCR) for increasing the quantity of DNA in a sample; electrode-based biosensors for determining the amount of a biological component in a sample; DNA microarrays for performing multiple DNA tests simultaneously; and microneedles for painless biofluid sampling and drug delivery. Less research has focused on efficient and cost-effective schemes for component interconnect, assembly, and interfacing between microfluidic components and macroscale devices, although such microfluidic assembly has been widely recognized as crucial to the realization of complex microinstrumentation for bed-side diagnostics and Lab-on-a-Chip devices [1].

Many individually microfabricated fluidic devices have been demonstrated and even marketed commercially. As sample volumes become smaller, and the analysis of individual cells or molecules is desired, the research instrumentation itself decreases in size and new methods of interconnection and assembly are required. Microfluidic components must often first be assembled from smaller subunits (e. g., channels, actuators) and then further assembled together to form microfluidic systems and instrumen-

tation. Although integration of subunits or components during fabrication is a worthwhile goal from the standpoint of simplicity, it is often at the cost of device performance. Methods to efficiently interconnect components that have been fabricated separately, often using vastly different techniques and materials specific to each device, are more complex but are required for full microfluidic component and systems assembly. For many components and systems, a combination of integrated and modular approaches results in the most easily packaged and best performing devices.

This article will cover the main microfluidic assembly methods for components and systems, including integrated and modular approaches, as well as key research findings and example systems from academia and industry that demonstrate these approaches in practical systems. This article will discuss relevant tools and techniques of general microsystems assembly, including bonding, robotics and fluidic microassembly. This article will also focus on interconnection and assembly between disparate materials, including silicon, glass, and polymers.

Basic Methodology

Microassembly Philosophies

Integrated Approaches

Integrated approaches seek to use a single fabrication process for the entire device or system, including all components, interconnect, and packaging. Although using a single process simplifies device interconnection, it can be at the expense of device performance, or can limit the devices and interconnect that is possible. Components cannot be individually optimized using different material platforms or technologies, although interfacing problems between different materials can be minimized.

Surface micromachining is a process whereby multiple layers of a structural material (e. g., thin film polysilicon) are separated by layers of another sacrificial material (e. g., silicon dioxide) that is removed at the end of the fabrication process resulting in free-standing structures in the structural material (see cross-referenced article on surface micromachining). In addition to mechanical structures, electrodes and other electronics can be fabricated in the same (usually silicon) substrate. Some materials combinations for surface micromachining are listed in Table 1, with materials and fabrication processes heavily dependent on the device or system function. Although widely used for more traditional microelectromechanical systems (MEMS) devices, e. g., accelerometers and resonating sensors, integrated approaches can also be employed for microfluidics provided components and interconnect can be realized in the chosen technology.

Microfluidic Assembly, Table 1 Surface micromachining materials

Structural Material	Sacrificial Material	Sacrificial Etchant
Polysilicon	SiO_2, other silicon dioxides (e. g., PSG, LTO)	HF
Al	Photoresist	O_2 plasma
SiO_2	Polysilicon	XeF_2 gas
Al	Silicon	EDP, TMAH, XeF_2 gas
SU-8	Polystyrene	O_2 plasma

Other integrated approaches rely on sequential bonding and patterning of multiple bulk layers rather than film deposition and patterning. One popular approach involves patterning all microchannels and microfluidic structures for one layer using, e. g., deep reactive ion etching (DRIE) of silicon, alternated with silicon fusion bonding of patterned or unpatterned wafers that can then be further structured in the integrated process (e. g., [2]). As with surface micromachining, such approaches can be limited in the realizable structures and are usually limited to a set number of materials.

Modular Approaches

In the macroscopic world, fluidic devices are attached together using various plumbing fixtures, and readily interfaced to electronic, mechanical, and optical devices using wires, mechanical fasteners, and lenses. Fluidic components (e. g., pumps) are also fabricated using a variety of mechanical attachments, gaskets, plumbing parts, and molded plastic or machined metal housing. On the microscale, modular approaches have employed a variety of techniques adapted to or developed for the microscale, including: microfluidic circuit boards with attachable components; gasketed stacked modules where each layer performs a specific function; permanent bonding; quick-connect modular assembly using specially developed interfacial structure between components; and cartridge-based modularity for interfacing reusable control and detection circuitry to disposable microfluidic cartridges.

Microfluidic Boards Microfluidic board interconnection technologies seek to mimic the electronic printed circuit board for ease of use, reliability, and versatility. In microfluidic board technologies, the substrate contains the passive microfluidic channels and reservoirs, with active components (e. g., sensors, valves) mounted

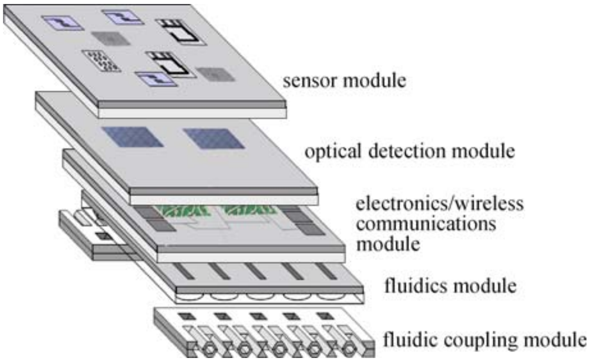
Microfluidic Assembly, Figure 1 Modular microfluidic board approach: (**a**) illustration of example board technology with electronic and fluidic routing between surface mounted components and coupling to off-chip devices; (**b**) photograph of example microfluidic board in silicon with five mounted pressure sensors, embedded microchannels, surface electronic routing, and couplers to capillary tubing [2]



Microfluidic Assembly, Figure 2 Illustration of stacked-module approach, where the microfluidic system is composed of stacked modules that each perform specific functions and are aligned and assembled together vertically in a jig

on top (e. g., [2]) (see Fig. 1) similarly to electronic components mounted on a printed circuit board (PCB) or multichip modules (MCM) in surface mount technologies (SMT). Electronic connections between components are provided on top of the board, while fluidic interconnection is usually provided in the board material itself. Microfluidic circuit boards can be made from a variety of materials, including silicon, glass, and polymers, e. g., polydimethyl siloxane (PDMS), epoxy, or polymethyl methacrylate (PMMA). Microfluidic boards can be as simple as a single packaged component socket or as complex as a full Lab-on-a-Chip analysis system, with size and complexity constrained mainly by mounting technique (e. g., bonding or adhesive) and via hole fabrication method.

Stacked Modules Microfluidic systems composed of modules, where each module forms a layer that is stacked on previously layered modules, is a simple solution to interfacing components fabricated using different materials or for producing components from alternating passive (e. g., microchannels) and active (e. g., sensors, actuators for valves and pumps) layers. Each module (layer) performs a specific function and can be interfaced to the modules above and below it electrically, optically, or fluidically, provided suitable electronic and optical interfaces and fluidic gaskets are used (see Fig. 2). The modules are usually compressed together in a jig, with modular replacement requiring complete disassembly of all modules. Stacked modules can be made of many different materials, including silicon, glass, and both thermoplastic and thermosetting polymers, provided compliant polymer gaskets (e. g., PDMS) are used to interface layers for fluid-tight seals.

Embedding of Components Most of the earliest packaging of individual microsensors centered around a concept taken directly from microelectronics: the embedding of the device in a molded polymer package with simple electronic (e. g., dual-in-line package pins or surface mount bumps) and/or optic (e. g., transparent windows for LEDs) or fluidic (e. g., access holes for pressure sensors) interconnect as needed. This concept has been extended to microfluidic systems whereby many components are assembled in a jig and embedded into a relatively inexpensive polymer package all at the same time. The most commonly used polymer in academia is PDMS as it is readily molded, easy to work with, and in use by many researchers already that utilize soft lithography, or molding against a photoresist master, as a primary method of fabrication of microdevices and systems. However, thermoplastic polymers, e. g., PMMA and polycarbonate (PC), are utilized for embedded packaging by industry and other researchers with access to techniques such as injection molding.

Cartridge-Based Modular Assembly The use of disposable, usually hard polymer cartridges containing microfluidics that are interfaced temporarily to reusable components, e. g., optics or control electronics, is an assembly approach that is widely used in industry for microfluidic systems involving DNA chips and biofluid analysis. In this approach, the cartridge containing the fluidic sample is slid into the instrument by the user, the desired tests performed on the sample, then slid out and disposed of such that the sample does not interfere with the re-usable and more expensive parts of the instrument. This also avoids washing steps, as the cartridge is the only part of the machine in contact with the liquid and is disposable. Smooth motion and lock-in-place mechanisms between the disposable and reusable portions of the instrument must be incorporated into the system design.

Structures to Facilitate Modular Assembly For many modular approaches and techniques, including microfluidic circuit boards, stacks, or freely joined modules assembled via robotic techniques, alignment keys and mechanical joints may facilitate microassembly, joint strength, or reworkability.

Alignment keys can be used for bonding of two substrates, parts, or components such that they line up in some useful manner (e. g., a through-hole lines up with the end of a microchannel or an actuator lines up with a membrane used in a micropump). Alignment keys are similar to those used for photolithography processes, although they may be larger to facilitate manual or robotic assembly. Alignment keys are widely used for assembly of both components and systems.

Mechanical joints for assembling microfluidic components and systems often involve insertion of one part into another. The afore-mentioned cartridges are a simple example, and structures must be included on both the cartridge and inside the instrument to allow smooth insertion. Such structures can include micro-rails to aid such sliding assembly on-chip. Care must be taken in choosing materials for properties such as friction and wear. Friction is defined as the force of motion or tendency toward such of two surfaces in contact, defined by the equation:

$$F = \mu N \quad (1)$$

where μ is the coefficient of friction, which is an empirical property of the contacting materials, and N is the normal force exerted between the surfaces. For surfaces in relative motion, μ is the coefficient of kinetic friction. For surfaces initially at rest relative to each other, μ is the coefficient of static friction (generally larger than its kinetic counterpart). The direction of the frictional force on a surface is opposite to the motion that surface would experience in the absence of friction.

Other structures can be used to facilitate the actual joining of parts. Such structures are based on mechanical press-fits, including simple fits of one part into another, and structures based on micro peg-in-hole or beam-spring assembly. The inserted part is held in contact with the mating part via friction and the spring force from either the beams or material compliancy holding the parts together. Prediction of how well a snap-together interface will work is based on mechanics (e. g., beam equations) and contact modeling, with mechanical materials characteristics such as Young's modulus and yield strength of paramount importance. It should be noted that polymer characteristics can be heavily dependent on processing, which complicates prediction of structure behavior. A compliant cylindrical peg inserted into a hole can provide microfluidic interconnect between two microchannel-containing substrates. Such a structure both mechanically holds the substrates together while providing fluid-tight interconnection.

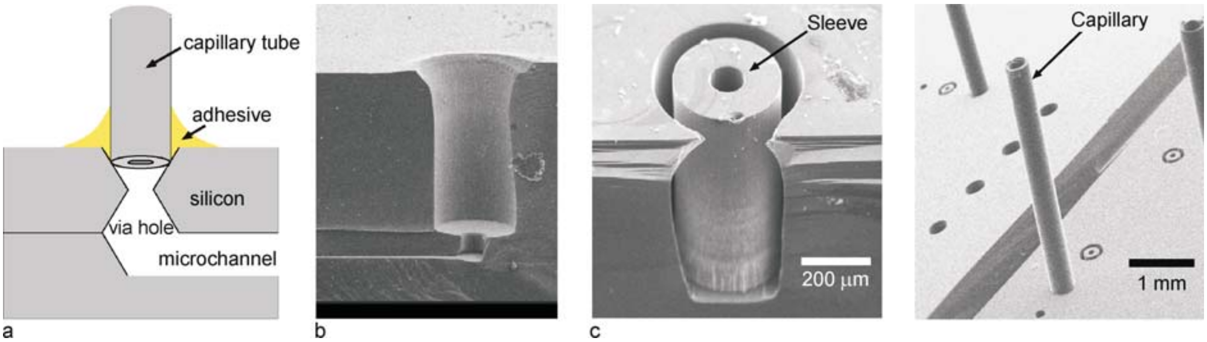
Hybrid Approaches

Many practical/commercial microfluidic systems use a combination of integrated and modular approaches for systems assembly. In these cases, portions of the system, such as capillary electrophoresis microchannels with integrated electrodes, or microsensors with integrated pumps and valves, may be combined with a modular approach towards the optics or other microfluidic elements. Such combinations of integrated and modular systems can be very effective resulting in the *best of both worlds* for a microfluidic system.

Coupling to the Macroscale World (World-to-Chip Coupling)

A major issue with many microfluidic interconnect technologies is the coupling of the fluidic circuits to the macroscopic world. Such couplers allow fluid to be pumped on-chip, and waste to be removed off-chip in a controlled manner. Couplers can be integrated into the fabrication process, or assembled to the device as a separate component.

The simplest fluidic couplers involve a tube directly glued into a hole at the end of an on-chip microchannel, e. g., fluidic couplers consisting of a capillary tube glued into an insertion channel which is etched into the silicon substrate (see Fig. 3a). These couplers do not have accurately fitted insertion channels resulting in difficult handling and leakage of adhesive into the microchannels. Couplers fabricated by more geometrically versatile techniques, such



Microfluidic Assembly, Figure 3 Examples of glued couplers between on-chip and off-chip devices: (**a**) illustrations of capillary tube glued in microchannel fabricated by wet anisotropic etching of silicon; (**b**) capillary tubing coupler with holes etched in silicon by DRIE such that the inner and outer diameters of the capillary tubing are matched; (**c**) *sleeve*-type coupler that fits inner and outer diameter of capillary tubing and prevents adhesive seeping into the microchannel [2]

as DRIE of silicon, may have high density insertion channels that accurately fit the outer diameter of capillary tubing [2] (see Fig. 3b). However, such couplers are often still sealed with adhesive.

Couplers featuring exchangeable interconnect utilize mechanical press-fits similar to press-fits used to join modules. Press-fits utilize the elastic forces of the coupling parts to seal the fluidic connection, which is adequate provided high pressure and/or very high density coupling is not required. Press-fit type couples can be designed such that the tubing fits on a coupler parallel to the on-chip microchannels, or such that the tubing couples perpendicularly to the microchannel-containing chip surface.

Microassembly Tools and Techniques

This section will cover several tools and techniques utilized for microsystems assembly, including microfluidic systems assembly, primarily of modular systems although bonding can be considered as either integrated or modular depending on how it is employed. Manual assembly is still the most commonly used microfluidic systems and microinstrument assembly method, but suffers from problems of scale-matching, reproducibility, accuracy, and speed. Manual assembly can be used successfully for prototyping if parts are large enough, although methods of batch and automated assembly are necessary for parts that are too small to be manipulated by a person or for manufacture of multiple units.

Microassembly is the discipline of positioning, orienting, and assembling of micrometer-scale components into complex microsystems [3]. Although some attention has been given to developing techniques and tools for microsystems assembly, much of this has been aimed at combining electrical, mechanical, and optical components, but not microfluidics. Thus, although the robotic and self assembly techniques discussed below are utilized for microsystems assembly, they have not necessarily been utilized for microfluidic systems assembly. Bonding, on the other hand, has been widely used to assemble both microfluidic components from integral parts (e. g., actuator membranes, channels) as well as assemble together microfluidic components into systems (e. g., components adhesively bonded to microfluidic circuit boards).

Bonding

Bonding is the joining of two materials either directly or through the use of an intermediate layer. Various bonding methods can be used for basic assembly and packaging of components fabricated on the same or different technology platforms, including silicon, glass, ceramics, metals, and polymers. These bonding methods usually result in a permanent joining of the two materials that cannot be easily reworked.

► Anodic Bonding is a method of using high voltages and elevated temperature to bond glass to silicon. The glass must contain a mobile ion, such as sodium or potassium, for the bonding to proceed. Many glass making companies sell glass wafers in conventional sizes (e. g., 4 in. diameter and 0.5 mm thick) that are suitable for silicon-to-glass bonding (e. g., Corning 7740 Pyrex, Schott 8329). Typical bonding temperature is about 400 °C, with a typical voltage of 1 kV. It is of note that anodic bonding can be performed over thin metal electrodes on the glass or silicon surface. Anodic bonding can also be used for silicon-to-silicon bonding provided an intermediate glass layer deposited by, e. g., chemical vapor phase deposition or spin-on techniques, is used. Anodic bonding is very useful in situations where channels or active devices (e. g.,

pumps, valves, sensors) have been fabricated in silicon, but it is necessary to visualize the fluid flow through the glass, or an insulating materials is desired between the silicon and its further packaging.

Silicon can be bonded to silicon using fusion bonding. This bonding results in a very strong bond and is accomplished through surface modification and heating of the silicon substrates. The surfaces are thoroughly cleaned and hydrated (e. g., using ammonium hydroxide or sulfuric acid and hydrogen peroxide) to form hydroxyl groups (OH) on the surfaces. The surfaces can be aligned and then contacted. The bonding is then accomplished through an annealing step at elevated temperatures (e. g., 1000 °C).

Glass can also be directly bonded to itself thermally. Cleaned glass wafers are soaked in a solution of water, NH_3 or HCl, hydrogen peroxide, and then thermally bonded at approximately 600 °C for 6 to 8 h.

Polymers require joining processes that are different than those for silicon and glass, and are performed at lower temperatures. In most cases, a form of adhesive bonding is used either through direct adhesion of the two polymers or using a separate adhesive intermediate layer. Other polymer bonding techniques rely on surface chemistry (e. g., plasma bonding, solvent welding) or heat (e. g., thermal welding).

Thermal polymer bonding results when two parts are heated under compression. The joining of the materials takes place by fusing them through direct liquid phase interaction. The heating can be either radiative thermal, or supplied using another method, such as ultrasonics. Some polymers are degraded and soften under radiative light energy, e. g., PMMA under UV light. This property can be exploited to realize reduced-temperature thermal bonding.

Solvent welding is another method of bonding polymers by first degrading and softening them, only in this case a solvent is used to degrade the surfaces before bonding them together.

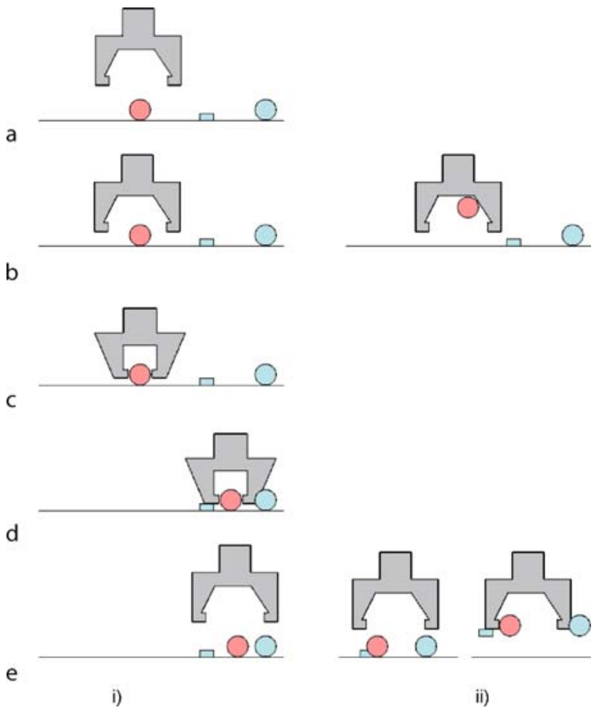
Plasma activated bonding modifies the polymer's surface to facilitate bonding. PDMS can be irreversibly bonded to itself and various other materials (e. g., silicon, glass, silicon nitride, and several other polymers) through the use of surface-oxygenation. The materials to be bonded are placed in an oxygen plasma. In the case of PDMS, this generates silanol groups by oxidation of the surface methyl groups of the PDMS structure.

Adhesive bonding is essential the *gluing together* of two materials using an adhesive such as epoxy, thermoplastic polymer adhesives, photoresists, benzocyclobutene (BCB), etc. Care must be taken to join the two surfaces while not clogging channels, producing voids, or otherwise not properly controlling the adhesive location.

Robotic Microassembly

Robotic microassembly covers both assembly by telemanipulation and automated robotic assembly such as pick-and-place or the use of a levitation table for part manipulation. Micro-grippers, -robots, and assembly tables are themselves very sophisticated microinstruments, with complex visual and/or tactile feedback to accomplish relatively simple tasks, such as pick-and-place or peg-in-hole insertion.

Manipulator-Based Robotic Microassembly Pick-and-place robotic manipulator systems employ visual and/or force feedback for precise placement of force and monitoring of micropart force interaction (see Fig. 4). These systems can either be macroscale with microscale precision, or themselves built on the microscale, although the latter results in a system that is often more complicated to assemble than the systems intended to be built by the



Microfluidic Assembly, Figure 4 Illustration of microassembly by microgripper. The first column (**i**) illustrates the desired microassembly, while the second column (**ii**) illustrates problems that can commonly occur: (**a**) approach; (**b**) close proximity positioning of microgripper. Electrostatic attraction may cause the micropart to *jump* onto the microgripper prematurely causing incorrect placement; (**c**) grasp; (**d**) moving micropart to desired location; (**e**) placement of micropart. The micropart may adhere better to the microgripper than the substrate, causing inaccurate placement or even remain attached to the microgripper after it is removed from the substrate

micro-robotic system. A combination of micro and macro components can also be used, whereby a microgripper less than a millimeter in size is precisely positioned for its task using macroscale equipment such as motors and x-y stages with micrometer precision. Relative placement of parts over the long range is monitored via a visual system, while force sensors provide precise feedback on the interactions among parts during contact.

Manipulation of microparts uses physical characteristics, such as friction, adhesion of micro-scale parts, or suction forces. Once the parts have been grabbed by the device, the components need to be assembled, and this task may require a complex control system. Adhesive forces between microgripper and micropart can be significant compared to gravitational and inertial forces and are primarily due to Van der Walls forces, surface tension, and electrostatic attraction. For example, a micropart may "jump" onto the microgripper prematurely due to electrostatic attraction, but may be difficult to release from the microgripper once in place due to adhesion forces. Electrostatic forces are due to charge accumulation or transfer during contact. Van der Walls forces are due to quantum mechanical polarization of atoms and molecules, while surface tension arises from residual moisture on the microgripper and micropart.

A good review of microassembly adhesion forces can be found in [3] by considering the force between a spherical object and the surface of a microgripper finger, which can be modeled as a plane. We repeat the analysis here for this simple yet instructional case:

The electrostatic force between these objects can be modeled as:

$$F_{\mathrm{es}} = \frac{q^2}{4\pi\varepsilon(2r)^2} \tag{2}$$

where q is the charge, ε is the permittivity of the dielectric, and r is the object radius. Very high electrostatic densities and forces can be generated on the microscale especially as r becomes very small.

The van der Walls force between a sphere and plate is modeled by:

$$F_{\mathrm{vdW}} = \frac{hr}{8\pi z^2} \tag{3}$$

where h is the Lifshitz–van der Walls constant, and z is the atomic separation between the surfaces. This formula is only an approximation in that it assumes smooth surfaces; severe corrections must be made for rough surfaces as the actual contacted area is much different.

Surface tension force in a humid environment with hydrophilic surfaces (e. g., glass, oxidized silicon) may be very high due to a thin layer of liquid present between the object and the plane of the microgripper finger. Surface tension between these objects can be modeled as:

$$F_{\mathrm{st}} = \frac{\gamma\,(\cos\theta_1 + \cos\theta_2)\,A}{d} \tag{4}$$

where γ is the surface tension, A is the shared area, d is the gap between the surfaces, and $\theta_{1,2}$ are contact angles. This can be further simplified assuming completely hydrophilic surfaces (zero contact angles) and $d \ll r$:

$$F_{\mathrm{vdW}} = 4\pi r\gamma \tag{5}$$

These forces can be compared to the gravitation force of a micropart (sphere), given by:

$$F_{\mathrm{g}} = \frac{4}{3}\pi r^3 \rho g \tag{6}$$

where g is gravity and ρ is density for the micropart (sphere) material.

Consider the case of a silicon microsphere ($\rho = 2300\,\mathrm{Kg/m^3}$), with surface tension of water $73\,\mathrm{mN/m^2}$, van der Walls over a contact area of 1% of the apparent area, and charge density of $1.6\times10^{-19}\,\mathrm{C/m^2}$. For microparts ranging in size from 1 μm to 1 mm, surface tension forces will dominate, with gravity overtaking van der Walls and electrostatic forces as micropart size increases. Thus, for microgripper/part release, it is beneficial to assemble parts in as dry an environment as possible. Care must also be taken to utilize materials and methods that minimize surface tension, electrostatic charging, and van der Walls effects, including: materials with small contact potential difference, conductive materials, and roughened materials to minimize contact area.

Telemanipulation for Microassembly Telemanipulation is the utilization of a device which allows a mechanism to be controlled by a human operator for the manipulation of remote objects. In the case of microassembly, the objects are not so much remote in location as a scale mismatch exists that facilitates the need for telemanipulation. The manipulator may be a microgripper or microneedle used to then position and assemble microscale parts and/or devices. The same problems with adhesion forces discussed in the previous section may plague teleoperated microgrippers. Usually, a camera and/or force feedback are provided for the operator who takes the place of the computer in automated robotic microassembly.

Other Robotic Microassembly Platform based micromanipulation, where parts are placed and assembled in a known environment using methods other than pick-

and-place microgripper style manipulation, is popular for microscale systems. An example of a platform-based micromanipulation approach to microassembly would be laying the parts out on a table and using levitation methods, such as an air bearing table where parts are suspended on air and moved around using, e. g., air jets or magnetic coils, to orient and combine the parts. Such systems require complex global control over the entire system and sufficient manipulation force to combine components.

Macroscale X-Y stages and needle-like micromanipulator probes such as those used for electronic test can be used to assemble microscale systems. The X-Y stage can be used to move components in two dimensions, via a macroscale robotic platform and control system, and then forces exerted to assemble the components together using the microneedle.

Micro Self-Assembly

Self-assembly is the spontaneous formation of higher ordered structures from basic units and, unlike the deterministic robotic manipulation discussed thus far, is a stochastic process. In the case of micro self-assembly, many different forces can be used to assemble components together, including surface tension, electrostatic forces, magnetic forces, and gravity. Micro self-assembly is usually performed in a fluidic environment (fluidic micro self-assembly) and often relies on a shape matching of parts, either into a crystal-like structure or components onto matched *binding sites* on a surface. Thus, micro self-assembly relies on two things: 1) a force to induce the parts to assemble and 2) a method of recognizing parts and orienting them correctly at the binding sites.

Most micro self-assembly processes are performed in a fluid medium and use gravity and/or surface tension for assembly. A prime example is self-assembly of small (submillimeter) flat parts that can be formed into a crystal-like structure on a fluid surface caused by minimization of interfacial surface tension (otherwise known in layperson's terms as the *Cheerios effect*). Another prime example is the utilization of gravitational forces to flow parts over a surface, where shape-recognition is used to place parts and surface tension and van der Walls forces hold the parts in place during subsequent processing.

Key Research Findings

Microassembly Philosophies

Integrated Approaches

Surface micromachining has been employed for integrated microfluidic systems. However, most surface micromachining processes involve deposition and patterning of thin films (limited to several microns in thickness) located only on the substrate surface. Thus, utilization of silicon-based and other thin-film surface micromachining for microfluidics has been limited in application. On example is development of an integrated closed-loop drug delivery system at UC Berkeley, with integrated microneedles, fluid manipulation, and analysis fabricated all using the same surface micromachining process.

Several new surface micromachining processes utilize the thick-film polymer SU-8 for fabrication of channels, wells, and other passive microfluidics that are integrated with electronics or optical detection devices. The development of actuation schemes and interconnect technologies may make integrated polymer microfluidic systems more attractive, although more research is needed for these components as well as the integration of the polymers with other materials to realize truly integrated systems.

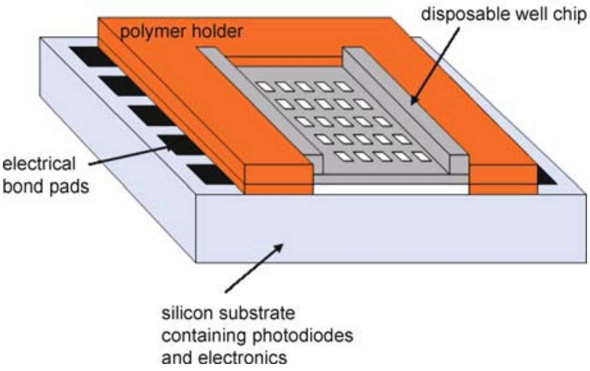
Approaches that rely on sequential bonding and patterning of multiple bulk layers rather than film deposition and patterning have been utilized successfully. Complex devices and systems have been realized by alternating DRIE of silicon and fusion bonding [2]. A variation of this approach is, of course, to pattern all the layers individually and then bond them together, an approach which can border on modular depending on the specific device or system in question and how the different layers are used. Complex microdevices, e. g., microturbines, can be realized through DRIE patterning and bonding of five different silicon wafers. Polymer example utilizes surface-activated bonding of multiple layers of patterned PDMS with through holes to build up a mutlilevel microchannel system (e. g., [4]).

Modular Approaches

Many microfluidic circuit boards have been demonstrated in epoxy printed circuit board technologies, polymers, ceramics, glass and silicon. A common problem with board technologies is that components are usually permanently mounted using various bonding techniques (e. g., anodic, adhesive), making replacement difficult. Even still, microfluidic board technologies have been utilized in the development of many microfluidic systems including chemical mixing, pH regulation, and analysis systems.

Verpoorte et al., produced one of the first microfluidic systems based on stacked silicon modules with polymer gaskets forming interfacial layers [5]. Since then, many other researchers have successfully utilized this concept for the assembly of even more complex microfluidic devices and systems.

A major drawback of the embedding of components in a package is that the assembly is usually permanent.



Microfluidic Assembly, Figure 5 Example of disposable microfluidic cartridge interfaced to re-usable instrumentation: disposable well array aligned over re-usable photodiode array using on-chip alignment structures (polymer holder). Chip is used for integrated high-speed screening by monitoring fluorescence changes as chemical reactions proceed inside the wells [7]

An example of such a system combines a small fluidic pump with a glass dielectrophoresis chip, and polymer microchannels [6]. Several other devices successfully combine microchannels with optics for fluorescent activated cell sorting, a closed-loop systems where cells that are tagged with different fluorescent markers can be sorted according to color. Fiber optics or light-emitting diodes and detectors are embedded in a polymer package containing microchannels. Other examples can be found in industry, such as the iSTAT whole blood gas analyzer, a hand held plastic device for manipulating the blood sample into which are embedded simple sensors.

Figure 5 shows an example of a cartridge based integrated high speed screening array, where photodiodes are located under each well for fluorescence detection, but the wells themselves are located on a disposable cartridge that is slid into place using on-chip polymer guides [7]. Other examples include DNA chip cartridges and blood sample analysis cartridges.

Quick-connects were developed in silicon [8] to aid in modular manual assembly. Both finger-joint interconnects perpendicular to the wafer surface, as well as peg-in-hole interconnects parallel to the silicon substrate surface (see Fig. 6b), were realized using KOH anisotropic etching along crystal planes. As these interconnects were developed in silicon, polymer gaskets were needed, complicating the fabrication process. Micro peg-in-hole assembly has been investigated for use in microfluidics, where instead of a simple peg a cylinder is used and assembled into a fluidic hole making a fluid tight connection (see Fig. 6). Fluid-tight interconnects in both deep reactive ion etched (DRIE) silicon [9] and polymers [10] have been developed and used to combine micro-channel containing substrates. The polymer interconnects represent a significant improvement over their silicon interconnects, requiring no additional gaskets and being compatible not only with silicon and glass but polymer substrates, as well, provided suitable bonding/embedding techniques are employed. Polymer interconnects are also superior in that the restoring spring force used to hold the cylinder in the hole is the result of material compliancy, rather than rigid beams, and provides a more uniform joining force [10].

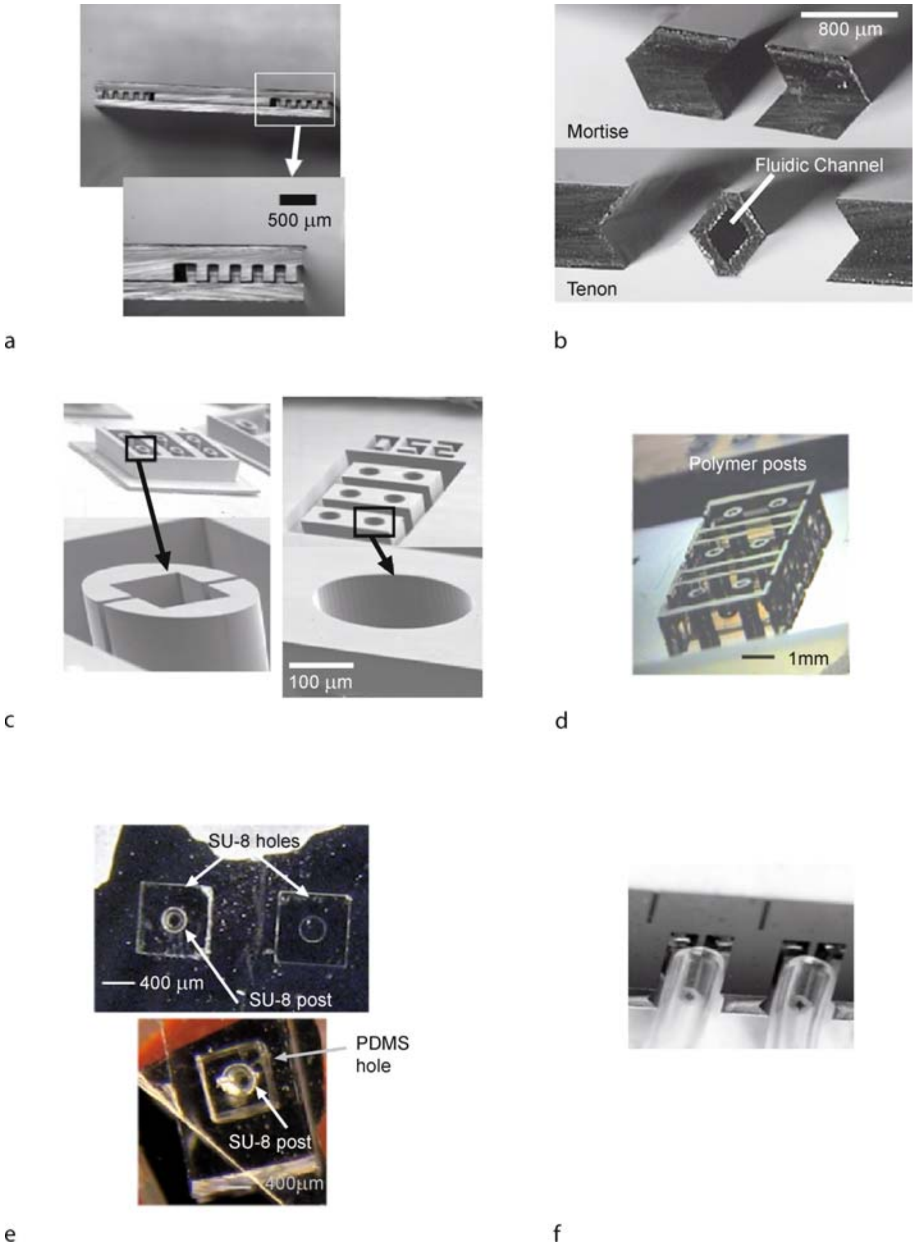
Other noteworthy examples of modular microfluidic systems approaches include 3D MCM chips [11], and multiple layers of integrated systems with electronic, fluidic, and mechanical functionality [12], with new technologies constantly being investigated.

Coupling to the Macroscale World (World-to-Chip Coupling)

Coupling between on-chip channels and off-chip devices is a scale-matching problem that seems universal in the field of microfluidics. Whether a researcher wishes to study flow through a new micromixer, or manipulate and analyze cells for Lab-on-a-Chip, most researcher eventually run across the coupling problem. As a result, a large number of solutions have been developed for providing fluid flow between on-chip microfluidic systems and off-chip devices. A few example devices will be discussed here.

Many reversible press-fit couplers have been developed. One successful design involves a press-fit between a soft tube and a more rigid microstructure on the microchip surface, such as the hexagonal ports shown in Fig. 6f. These ports are fabricated parallel to microchannel flow using KOH anisotropic etching, and have been fabricated in an array of five ports. These ports are usable as is for low pressure flows; at higher pressure flows, adhesive such as RTV silicone must be used in addition to the press-fit. Vertical tubing couplers, where the tubes are perpendicular to the substrate surface, have also be made using press-fits (see Fig. 7). A good discussion of these different couplers can be found in [13]. Example include injected molded plastic couplers, soft molded polymer couplers and compression molded couplers that can be used to hold and seal a fused silica or metal capillary tube in place. Couplers with integrated o-rings have also been developed using a combination of DRIE of silicon and molded silicone o-rings that are squeezed into place. Higher-pressure microfluidic couplers have also been developed that do not rely on adhesives for sealing.

Many glued couplers have been demonstrated, e. g., Fig. 3, where the capillary tube is simply placed in the hole



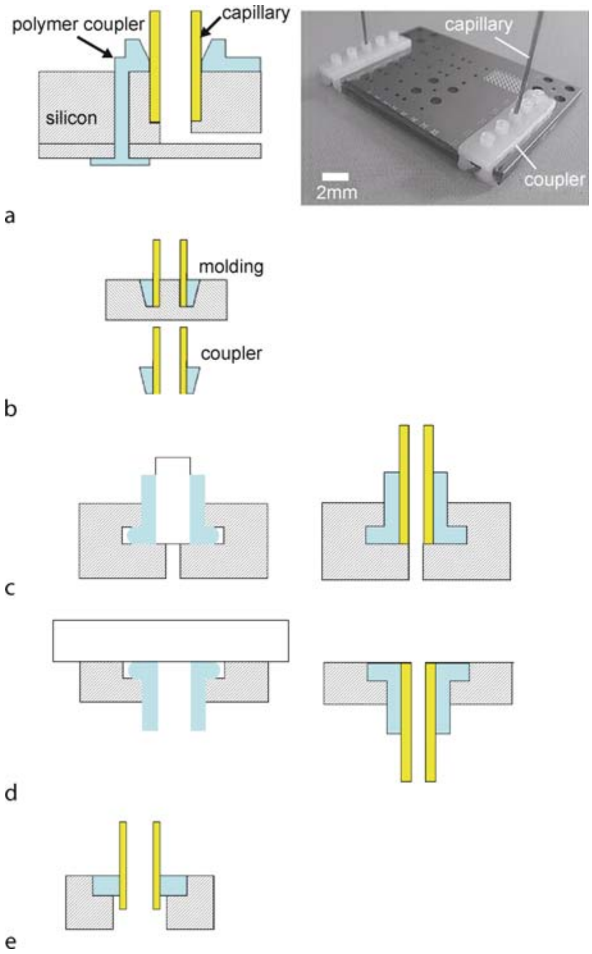
Microfluidic Assembly, Figure 6 Photographs of example press-fit interconnect structures: (**a**) arrays of interlocking silicon fingers; (**b**) silicon hexagonal interlocking interconnects; (**c**) mating silicon notched cylinders and silicon holes; (**d**) polymer cylinders do not require notches; (**e**) polymer cylinders in polymer holes; (**f**) structure in photograph 6b used instead as a soft-tubing press-fit coupler [8–10]

and adhesive used to hold the tube in place and provide a fluid-tight seal. Figure 3c shows a type made by DRIE, where the integrated sidewalls around the tube prevent leakage of the adhesive into the microchannels. A combination of surface roughening, compression molding, and adhesive bonding have also been used to make fluid-tight interconnects [13].

Microassembly Tools and Techniques

Bonding

Bonding has been a key ingredient in many successful microfluidic devices and systems. In fact, most microfluidic devices and systems involve some sort of bonding for at least one part, whether silicon-to-silicon bonding



Microfluidic Assembly, Figure 7 Illustrations of press-fit couplers: (**a**) combination silicon DRIE and injected molded polymer coupler [2]; (**b**) PDMS coupler molded to tip of capillary tube; (**c**), (**d**) flanged thermoplastic tube couplers created by thermocompression molding; (**e**) integrated o-ring coupler

to build up multiple channel layers or simple adhesive bonding to hold the system together. Only a few examples are mentioned here. Bonding has been used for microfluidic systems where multiple wafers are patterned, e. g., using deep silicon etching, with microchannels and other fluidic structures, and then bonded together using, e. g., silicon fusion bonding. Silicon-to-glass and silicon-to-silicon bonding has been used for microvalves, micropumps [14], and many other component, as well as combinations of components for complete systems. Bonding has also been used to mount components on microfluidic circuit boards. Polymer bonding of microfluidic parts and components has been similarly utilized for many microfluidic devices and systems, e. g., multiple microchannel layers in PDMS (e. g., [4]), disposable microfluidic circuits using laminate bonding and multiple fluidic and electrical connections using adhesive tape [1], and PMMA bonded microfluidic systems.

Robotic Microassembly

Many robotic microgrippers have been demonstrated, some with accompanying systems that use either teleoperation or automated microassembly. Using a vision system combined with force sensors, researchers (e. g., [15]) have demonstrated systems to automate microassembly. MINIMAN is an example microassembly system with the ability to transfer objects between robots, bond, etc., and perform task planning, which is led by a user via the graphical user interface [16]. The MINIMAN-series design is a translation from conventional macro-scale sensors and control to the micro-scale. Micro peg-in-hole insertion using microgripper has also been demonstrated.
Other robotic microassembly has successfully used air jets, magnetic actuation, or vibrational energy to supply the forces for assembly. In most instances, a global vision system is used to monitor part placement on the two-dimensional assembly grid. Yet another approach popular in Japan is the microfactory which is based on macroscale concepts of fabricating and assembling parts.

Micro Self-Assembly

Due to the difficult and slow nature of assembling complicated microscale devices and systems in a serial and/or deterministic way, self-assembly has generated a lot of research interest as a possible solution to overcome these problems. Many researchers have demonstrated self-assembly on the microscale. Some notable examples include self-assembly of optical components, self-assembly on non-planar surfaces, and self-assembly of microfluidic devices. One group of researchers in Taiwan has even proposed using a microfluidic system for the self-assembly of microfluidic components. Although self-assembly is utilized by many researchers, further research is needed before self-assembly becomes a commonplace microassembly method of microfluidic systems of increasing complexity.

Future Directions

The field of microassembly of microdevices and systems has a long way to go. The addition of the fluidic dimension that is required for microfluidic devices and systems complicates finding a solution, as not only must parts and/or components be joined together mechanically, electrically, and optically as for other systems, but fluid-tight interconnection between parts, devices, or off-chip must all be

provided. One problem is that unlike macroscale devices, systems standards for microfluidics, or a *microfluidic toolbox*, does not yet exist. The necessity for joining disparate materials and processes further complicates matters, especially as surface effects become increasingly important as scale decreases. Other issues, such as dead volume associated with sudden changes in microchannel cross-sections, problems with electrokinetics over changing surface materials, as well as microassembly adhesion force problems, require research solutions before microfluidic systems will become industrially viable.

Definition

Microfluidic bioreactors are miniaturized systems that are designed to perform a biological transformation on a sample. For instance, a bioreactor with an enzyme will convert the substrate into product when the substrate is present in the sample. Specifically, a protylytic enzyme can be placed in a microfluidic device in order to digest analyte proteins

to facilitate rapid and effective protein sequence mapping. Microfluidic bioreactors are typically fabricated by immobilizing a biologically active enzyme within the microfluidic device. The range of devices that can be made in this way include biosensors, immunoassays, affinity chromatographic stationary phase, and immobilized enzyme reactors. Microfluidic bioreactors are very useful because they have high enzymatic activity and the activity in the device is typically very stable and can be useful over a long time frame.

Overview

Microfluidic bioreactors are a variety of devices that can be made by immobilizing a variety of biologically active substrates within a microfluidic device [1]. The ability to create a variety of biologically important devices is critical to enabling the true total analytical system. The variety of devices that can be made in this way ranges from immobilized enzyme reactors to enzymatic biosensors, immunoassys, and affinity chromatographic stationary phases. In order to form a microfluic bioreactor it is necessary to immobilize the active molecule within the device; either directly onto the channel or onto a solid support within the channel such as a bead or a monolith.

Basic Methodology

The key to making a microfluidic bioreactor is immobilizing a biologically active compound in the microfluidic system. This can be accomplished in a variety of ways, but the two primary categories are covalent immobilization and non-covalent immobilization. Once a micorfluidic bioreactor is made, it can be applied to a wide range of applications including protein mapping and biosensors. In covalent immobilization techniques a covalent bond is formed between the surface of the micorfluidic device and the active molecule. The surface can be either the bare microfluidic channel or it can be a solid support within the device such as a monolith or a bead. Most commonly the immobilization of a enzyme onto a surface will involve forming a linkage between an amine group within the enzyme and a functional group on the surface of the microfluidic device. A wide range of chemical modifications can be used in order to make this covalent linkage. The chemical steps required can require a relatively simple step or it can require a multi-step synthetic strategy in order to make the linkage to the biological compound. The requirement of a synthetic route to make the covalent linkage introduces a significant level of complexity to a system such as a bare microchannel or a monolithic structure. This complexity is due to the need to perform the synthesis within the microfluidic channel, which can be extremely difficult. Beads on the other hand can be modified in a batch process and then introduced to the microfluidic system in a variety of ways.

Non-covalent immobilization typically involves the physical adsorption of a protein onto a solid support. This binding approach is based on ionic interactions, hydrogen bonding, hydrophobic interactions, etc to bind the protein to the solid support. This approach has the advantage that the active molecule is not modified in any way and will therefore retain its full activity. In addition to nonspecific binding, it is also possible to attach a bioactive species to the surface through bio-active interactions, such as an affinity adsorption. This approach is similar to that required for covalently attaching a bioactive compound to the microchip or onto a monolith or bead. The difference is that the compound attached to the microfluidic system has a strong affinity for a complexing biomolecule, which is attached to the active biological compound. The active compound can then be immobilized by passing it through the microfluidic system and allowing the affinity interactions to immobilize the biomolecule. These affinity techniques have been widely used. The advantage is that the active site is typically accessible to the solution and therefore maintains high activity. The last technique that can be used to make a microfluidic bioreactor is by physically confining the biological molecule. This is typically accomplished by encapsulating the protein in a sol–gel structure. This leaves the structure of the protein intact and allows it to maintain a high activity.

Microfluidic bioreactors have a wide range of useful applications that have been demonstrated. The most common application is for immobilized microfluidic enzyme reactors (IMER). IMERs are most commonly used for protein analysis by peptide mapping. Microfluidic bioreactors have also been widely used for biosensing applications. This typically involves immobilizing a enzyme that enables the detection of the analyte of interest. Immunoassays are also a common method to enable the detection of a specific biologically active analyte in a microfluidic system.

Key Research Findings

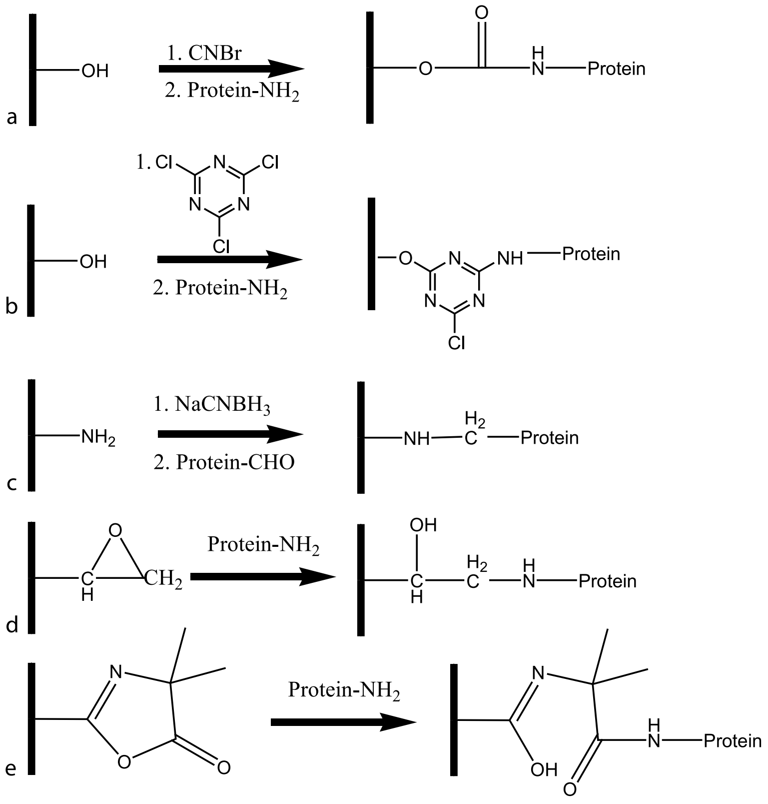
The most important factor in making microfluidic bioreactors is in the immobilization technique that is used to couple a biologically active functionality into the microfluidic system. In order to incorporate such a functionality into a system the biological compound must be attached to the microfluidic system. This can be accomplished in either an open channel or on a solid support within the microfluidic system. Immobilizing a biologically active compound to an open channel is relatively simple, however limiting

the active functionality to a specific portion of a channel is difficult. In addition, the relatively low surface to volume ratio results in a low overall activity of the bio-active functionality. In order to improve the biological activity of the system it is often necessary to use a solid support to immobilize the biological compounds to [2]. One solid support approach that has been used is monolithic materials [3]. These materials can either be formed by a porous polymer structure or a sol-gel structure. The other approach that can be used to immobilize a biofunctional compound into a microfluidic system is with beads. The great advantage of beads is that the biological functionality can be immobilized in a batch and then be incorporated into the microfluidic system. The incorporation of the beads into the system then becomes the difficult part.

One useful method that is used to immobilize biologically functional compounds into a microfluidic system is to covalently attach a protein or enzyme to the surface or onto the solid support in the microfluidic system [1]. This involves coupling the protein to the surface through a immobilizing site such as the amino, carboxyl, or thiol groups that are present in a protein. In order to make a covalent bond with these groups it is necessary to have a functional group that will be able to react. A wide variety of syntheic strategies have been developed to enable these reactions, as seen in Fig. 1. These reaction approaches include via alcohol groups, amino groups, epoxy groups, carboxylate groups, or other functionalities. Including the necessary functionalities in the microfluidic system simply involves the appropriate organic or silica chemistry depending on the support material that is used in the system. Once the surface chemistry is appropriate the immobilization reactions can be used to incorporate the biological functional compounds into the system. The greatest disadvantage of this approach is that the reactions that are required to immobilize the compounds are difficult to perform in a microfluidic system. This is why using beads, which can be functionalized outside of the system, often provide for a preferred approach to produce the microfluidic bioreactor.

The other major approach to making a microfluidic bioreactor is to use non-covalent techniques. One non-covalent approach involves non-specific adsorption of a biomolecule to the solid support in the bioreactor [4]. This relies on the non-specific physical adsorption of the protein to the surface of the solid support within the microfluidic device. This binding relies on forces such as hydrogen bonding, ionic interactions, hydrophobic interactions, van der Waals forces and so on. Because there is no chemical reaction, the bioactive molecule is not changed and it can therefore retain its full activity for use in the system. However, because the binding forces are relatively weak, the bioactive compound can also wash out of the system and therefore the activity of the system is lost because the active compound is removed from the system. Another non-covalent technique that is used to attach a bioactive species to the microfluidic system is through an affinity (bio-specific) interaction [5]. In this approach, a complimentary pair of proteins are used, with one of the pair immobilized within the microfluidic system and the other attached to the bioactive species of interest. The bioactive species can then be immobilized in the microfluidic system by placing the active compound into the system. Several bio-specific pairs have been used in this approach including Protein A, streptavidin, or the biotin-avidin technique. The great advantage of this oriented immobilization is that good access to the active site of the bioactive protein is maintained. There are other non-covalent methods of placing bioactive compounds in microfluidic system which involve the physical confinment of the protein. For instance, an enzyme can be encapsulated within a sol-gel [6]. This involves placing the enzyme in the sol solution and then forming the sol-gel through the polycondensation of the alkoxysiloxane monomers. This approach is gentle on the encapsulated protein and allows it to completely retain its structure and also maintain high activity.

A wide variety of applications for microfluidic bioreactors have been developed. One of the most common is immobilized enzyme reactors that are used for applications such as biosensors, medial diagnosis and synthetic applications. Most of the applications for immobilized microfluidic enzyme reactors (IMERs) is in protein mapping [7]. This approach is accomplished by incorporating a proteolytic enzyme into the IMER system. Using a microfluidic system for the enzymatic functionalities is ideal because it enables rapid sample handling on small samples. The microfluidic system is also ideal because it allows the reaction time to be significantly reduced, which allows the analysis time to be greatly accelerated. The enzymatic functionality in the IMER is then used to digest a protein. A variety of enzymes have been used in IMER systems including Endoproteinase, Pepsin, and Trypsin. The digested enzyme can then be analyzed in the microfluidic system. This approach can be used not only for mapping of a protein, but it can also be useful in post-translational modifications. This enables the detailed study of cellular functions that exhibit themselves as protein modifications. The real strength of IMER methods is when they are coupled with mass spectrometry methods, particularly when the IMER is coupled directly with the mass spectrometer [8]. This approach enables the identification of the peptide fragments that result when a pro-



Microfluidic Bioreactors, Figure 1

tein is digested in the microfluidic bioreactor. The identification of the peptide fragments enables the total protein to be identified and mapped. These methods are very powerful and are finding widespread use in proteomics. These IMERs can also be coupled with separation methods such as capillary electrophoresis and micro high performance liquid chromatography. Separation methods allow complex samples to be handled by introducing different proteins in the sample to the bioreactor at different times. Coupled with protein mapping techniques it is then possible to identify the proteins in a sample. It is also possible to identify post-translational modifications.

Microfluidic bioreactors have also been widely used to make immobilized enzyme biosensors. In this application the bioreactor is applied as a part of a detection device for a biologically important analyte. For instance, glucose can be detected by having a bioreactor that contains glucose oxidase immobilized in a microfluidic system [9]. The enzyme enables detection of glucose by electrochemical detection of the products of the bioreactor.

Another application that microfluidic bioreactors have been used for is in immunoassays. These are based on antigen-antibody interactions and is a powerful technique because these interactions have very high selectivity and are extremely sensitive. Typically, an immunoassay is performed by immobilizing one of the binding partners is placed within the system. The corresponding pair is then incubated within the device. The advantage of this approach is the ability to very specifically concentrate molecules on the active surface of the device. This enables enhanced reaction efficiencies, simplified analytical procedures, and reduced consumption of reagents. These immunoassay methods are often coupled with separation methods such as capillary electrophoresis in order to further increase the utility of the method [10].

The use of affinity interactions was described earlier as a method to immobilize a bioactive species within a microfluidic device. Affinity methods can also be used as a way to make a stationary phase in a microfluidic system [11]. This approach relies on the formation of strong, but reversible interactions between the analyte and the stationary phase. Because the binding interactions are reversible it is possible to concentrate the analyte of interest into a very narrow band, which further enables the introduction of high purity compounds into subsequent portions of the analytical device.

Future Directions for Research

Microfluidic bioreactors is a technology that is becoming fairly widespread. The number of applications that they are applied will continue to expand in the future. Advances will continue to be made in coupling the microfluidic within more complex microfluidic systems. This should include separation methods so that the reactions in the bioreactor can either be performed on specific analytes in a mixture or so that the products of the bioreactor can be separated to further enable analysis of the products. New and more efficient methods of incorporating the bioactive compounds into microfluidic bioreactors still will have great applicability.

Definition

A microfluidic circuit is a configuration of microscale fluidic components such as microchannels, individually addressable valves, and chambers through which fluid is allowed to flow. This definition is similar to the description of an electric circuit, which is a configuration of electronic components through which electricity is made to flow. A microfluidic circuit can control flow rates, flow directions, particle separation, mixing and reaction of chemicals, etc. on a single microdevice for lab-on-a-chip operations. Individual components of microfluidic circuits are often described using a model analogous to an electric circuit.

Overview

Like electric circuits, fluidic circuits can consist of individual components such as fluidic resistors, capacitors, inductors, and transistors. Brief descriptions of various components of microfluidic circuits are given below in this section.

Fluidic Resistance

The fluidic resistance is the pressure differential required to obtain a unit flow rate in a fluidic channel. The general formula for the fluidic resistance can be given as

$$R_{\mathrm{f}} = \frac{\Delta P}{Q} \tag{1}$$

where ΔP is the pressure difference and Q is the flow rate. Thus, by comparing Eq. (1) with Ohm's law for a DC circuit, assuming that the flow is steady and there is no energy dissipation in the system, it can be shown that ΔP is analogous to an electric potential difference, and the flow rate Q to an electric current. For a planar microfluidic conduit of length L, width W, and height H, the fluidic resistance is given by

$$R_{\mathrm{f}} = 12\frac{\mu L}{WH^3}, \tag{2}$$

where μ is the viscosity of the fluid. Fluidic resistance is also known as fluidic impedance.

Fluidic Inductance

The fluidic inductance is defined by

$$L_{\mathrm{f}} = \frac{\Delta P}{\mathrm{d}Q/\mathrm{d}t}, \tag{3}$$

where t is the time. The physical meaning of the fluidic inductance is that it describes how fast the flow rate follows the pressure signal. In a fluidic circuit, the characteristic response time can be expressed as

$$t_{\mathrm{L}} = \frac{L_{\mathrm{f}}}{R_{\mathrm{f}}}. \tag{4}$$

A typical value of the characteristic response time for water in an 800 μm capillary is approximately 20 ms, and so the typical frequencies in a microfluidic circuit are on the order of 100 Hz.

Fluidic Capacitance

The fluidic capacitance is the pressure-dependent volume change under isothermal (or adiabatic) conditions, and can be expressed as

$$C_{\mathrm{f}} = \frac{\partial \forall}{\partial P} = -\beta \forall \tag{5}$$

where $\forall$ is the volume of interest and β is the compressibility, or bulk modulus of elasticity. The physical meaning of the fluidic capacitance is that it describes how much the volume of interest changes with respect to a pressure change. The fluidic capacitance is normally used in the case of applications that involve elastic membranes and/or compressible fluids.

Fluidic Transistors

These are also known as flow field effect transistors (flow FETs). Fluidic transistors make use of the surface charge conditions to control the flow in a microfluidic chip. They are generally used with electrokinetically based microflows to modulate the zeta potential at the shear plane. Fluidic transistors can be used to control the flow both locally and globally in a microfluidic channel.

Fluidic Amplifiers

A fluidic amplifier controls the pressure and the flow rate in a microchip through the interaction of multiple fluid streams or jets. Fluidic amplifiers can be used for both analog (proportional) and digital (bistable) control. They can also be used to perform various Boolean functions in a microfluidic chip for the purpose of control logic.

Fluidic Logic

A logic circuit can be formed in a microfluidic chip by incorporating appropriate resistances and/or valves into the flow paths [1]. The various logical functionalities that can be integrated into a chip are OR, AND, NOR, NAND, conversion, and inversion. Fluidic logic can be designed to control the flow and/or mixing of droplets in a microchip.

Basic Methodology

A number of microfluidic circuits have been developed; their principles of operation depend on the mechanism of fluid flow in the microchip. In this article, we shall describe only the fluidic circuits used with pressure-driven flow and electrokinetically driven flow, as these are the two main pumping methods for continuous-flow microfluidic devices. Pressure-driven flow can be obtained by connecting the channel to a syringe pump or a compressed gas. Electrokinetic flow of an ionized electrolyte can be obtained by applying an electric field along the flow direction.

Fluidic Circuits for Pressure-Driven Flow

In a microfluidic channel, the flow becomes laminar because the viscous force is dominant over the inertia of the fluid. Hence, the effects of turbulence used to control flow in regular-scale devices cannot be applied in a microchannel. Most fluidic circuits used for pressure-driven microflow are based on fluid resistance. For

a microflow conduit, a general expression for the fluid resistance is [2]

$$R_{\mathrm{f}} = C\frac{\mu L}{A_{\mathrm{c}}^{2}}\,, \tag{6}$$

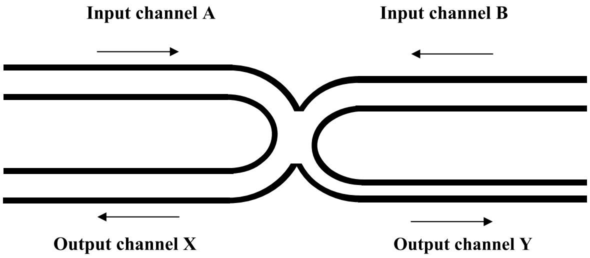
where A_{c} is the cross-sectional area, and C is a constant. Values of C for several different channel geometries are listed in Table 1.

Fluidic control can be achieved by changing the impedance of the fluid path and/or by modulating the mass flow rate of the incoming fluid streams. The working principles of some recently tested pressure-driven microfluidic circuits are presented below.

Fluidic Logic Circuit

In a complex microfluidic network, the direction of fluid or particle flow can be controlled effectively by changing the resistances of individual flow conduits. Equation (6) shows that the flow resistance of any particular channel can be modulated by changing the channel dimensions, such as the cross-sectional area and the channel length, or by varying the fluid viscosity. The fluidic resistance can also be altered by inserting a bubble or a droplet of another liquid (other than the fluid flowing in the microchannel). In this case, the interface between the two fluids (between the bubble(s) and the flowing fluid) increases the fluidic resistance. Using this principle, Parkash and Gershenfeld [3] developed a type of microfluidic logic gate called "bubble logic". In the logic circuit that these authors constructed, the binary symbols "0" and "1" were represented by the absence and presence, respectively, of a bubble in a microchannel.

The basic operating principle of a bubble logic gate [3] is shown in Fig. 1. This microfluidic circuit consists of two input channels (A and B) and two output channels (X and Y). Channel X is slightly wider than channel Y, i. e. channel X has a lower fluidic resistance than Y. Hence, if a bubble reaches the junction by way of input channel A or B then it will always take the output channel X owing to the lower fluidic resistance. But if two bubbles arrive simultaneously from input channels A and B, then the first bubble will take the output channel X. This first bubble increases the fluidic resistance of channel X and causes the other bubble to flow through channel Y. For detailed information on other microfluidic logic circuits, readers are advised to consult [3].



Microfluidic Circuits, Figure 1 Schematic view of a four-channel microfluidic logic gate [3]. The lengths and cross-sectional areas of the input channels A and B are the same. The flow resistance of the output channel Y is higher than that of X owing to its smaller cross-sectional area

Microfluidic Circuits, Table 1 Typical channel geometries used in microfluidic circuits [2]

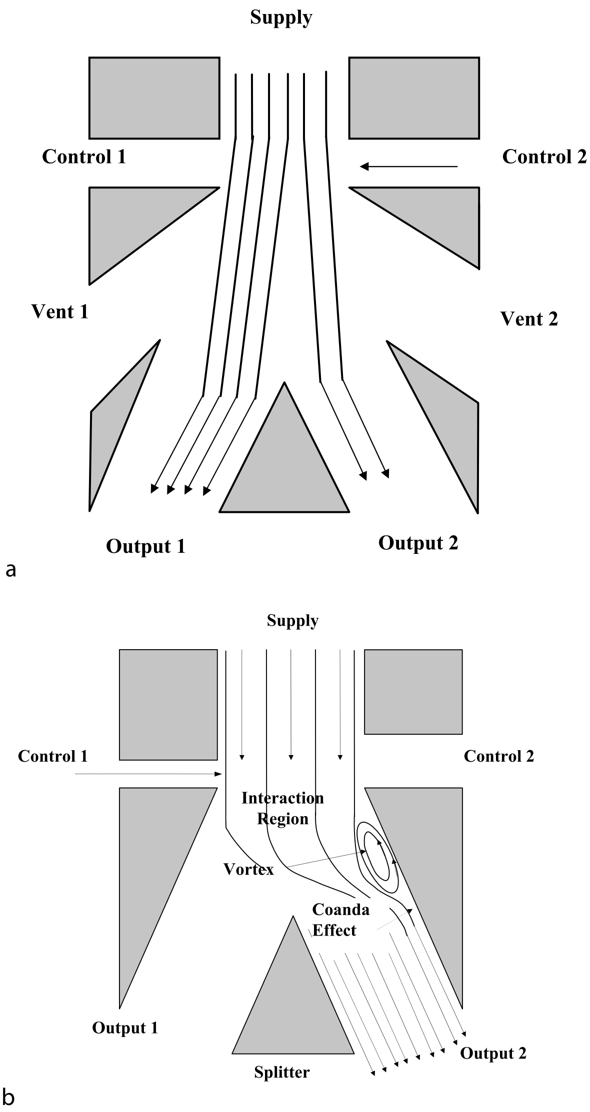
Cross section	Class	C
	Capillary tube	$8\pi = 25.13$
	Equilateral triangle	$\frac{60}{\sqrt{3}} = 34.64$
	KOH-etched triangle ⟨100⟩	35.12
	KOH-etched trapezoid	$\frac{12-1.38A_{\mathrm{c}}+4A_{\mathrm{c}}^{2}}{A_{\mathrm{c}}-0.85A_{\mathrm{c}}^{2}+0.28A_{\mathrm{c}}^{3}}$

Fluidic Amplifier Circuit

The primary goal of a microfluidic amplifier is to increase the pressure at a set of outlet ports by modulating some control pressures. Microfluidic amplifiers can be primarily classified into two types: analog and digital. The first type uses the effect of jet interaction, whereas the second type makes use of the wall attachment effect in a fluid.

A schematic view of an analog or jet interaction amplifier is shown in Fig. 2a. The device consists of a supply nozzle, two inlet (control) ports, two outlet ports, and two vents. This device is geometrically symmetric about its vertical axis. A uniform jet is supplied to the amplifier via the supply nozzle. Depending on the flow rates at the control channels, there can be three types of scenario at the output channels. First, if there is no flow through the control inlet(s), the fluid jet exiting from the nozzle will flow in a straight line, and it will be equally divided into two outlet streams. Second, if the flow rates of the control inlets are the same, the resultant jet will also travel in a straight line and will split symmetrically between the output ports. Third, if a differential pressure is applied between the two inlet ports, the resultant jet will be deflected from a straight line and the flow rates through the outlet ports will change. The difference between the pressures at the output ports will increase with increasing differential input pressure.

The digital amplifier works on the basis of the Coanda, or wall attachment, effect [4]. In 1930 Henri Coanda observed that a moving fluid has a tendency to attach itself to a surface and flow along it, even if the direction of



Microfluidic Circuits, Figure 2 (**a**) Schematic view of an analog, or jet, interaction amplifier [11]. The supply jet exits through both of the outputs 1 and 2. The ratio of the mass flow rate at output 1 to that at output 2 is determined by the control ports 1 and 2. (**b**) Schematic view of a digital, or wall attachment, amplifier and its working principle [11]. The supply jet exits through either output 1 or output 2. Switching between these outputs is guided by the control ports 1 and/or 2

curvature of the wall is away from the primary axis of flow. Figure 2b shows a schematic view of a digital wall attachment amplifier. If a constant jet is supplied from the entry nozzle, it will be attached to one of the attachment walls owing to the Coanda effect and will eventually exit through that outlet (#2 in Fig. 2b). However, the exiting jet can be toggled to the other output port if a temporary flow at a small pressure is applied through the control port next to the attached jet. Thus, this wall effect amplifier switches a large flow from one output port to the other by means of a small control flow. In this fluidic circuit, two vent ports are used to decrease the internal pressure and also to control the loading of the output by the control flow [5].

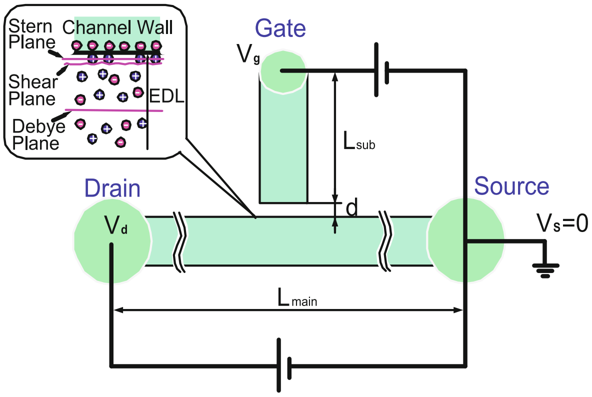
Fluidic Circuits for Electrokinetically Driven Flow

Flows in microfluidic channels are often driven by electrokinetic means. In an electrokinetic flow, an ionized liquid can be forced to move in a dielectric capillary or microchannel under the action of an externally applied field. Electrokinetic flow is an attractive option for driving samples because (a) it can be integrated within a single microchip, (b) the flow rate can be controlled very precisely using an externally applied electric field, (c) no mechanical parts are required, (d) it is useful for a wide range of electrical conductivity of the sample, and (e) the velocity distribution across the microchannel is plug-like. In a planar microchannel, the electrokinetic velocity distribution can be represented by the Helmholtz–Smoluchowski velocity as follows [6]:

$$u \cong u_{\mathrm{HS}} = \frac{\varepsilon \zeta E_x}{\mu}\,, \tag{7}$$

where ζ is the zeta or electrokinetic potential, ε is the permittivity, and E_x is the electric field. The equation above shows that the magnitude of the electrokinetic flow velocity in a microchannel can be controlled either by changing the external electric field applied along the flow direction or by modifying the electrokinetic potential at the shear plane. For control of the global flow in the entire microchannel, the applied electric field is generally altered; this method is relatively straightforward to implement in a microchannel. On the other hand, selective manipulation of the zeta potential can be implemented to obtain local flow control in a microchannel or capillary. However, this technique is quite challenging because the zeta potential depends on the solution pH, the buffer concentration, and the surface charge density.

One commonly used device for controlling the zeta potential is the flow FET [7–9]. The basic principle of the flow FET is that a constant perpendicular electric field from a side channel is used to modify the local zeta potential. A schematic of a typical flow FET is shown in Fig. 3. The device consists of a main channel and a side channel, separated by a very thin wall (nanometer to micron size). In a flow FET, the working fluid moves only through a main microchannel (horizontal) from the source reservoir to the drain reservoir. A gate potential generates a perpendicular electric field that controls the zeta potential, which locally alters the flow in the channel. The change in zeta potential



Microfluidic Circuits, Figure 3 Schematic view of a field-effect-controlled microfluidic device for application in a straight channel [9]. The main (horizontal) channel is separated from the subchannel (vertical) by a micrometer-scale distance (d). The potentials at the drain and gate reservoirs are V_d and V_g, respectively, and the source reservoir is connected to a common ground ($V_S = 0$). The inset shows the formation of an electric double layer (EDL) next to the channel surface

for a particular gate voltage V_g can be expressed as [9]

$$\Delta\zeta = \zeta - \zeta_0 = \frac{C_{total}}{C_{EDL1}} \Delta V_C = \frac{C_{total}}{C_{EDL1}} R \left(V_g - V_{g0}\right), \quad (8)$$

where ζ_0 and V_{g0} are the reference zeta potential and the gate voltage for which there is no current from the side channel to the main channel, respectively. R is a system constant that depends on the electrical resistances of the main channel, side channel, and separation wall. The total capacitance of the flow FET (C_{total}) can be expressed as [8]

$$C_{total} = \left(C_{wall}^{-1} + C_{EDL1}^{-1} + C_{EDL2}^{-1}\right)^{-1}, \quad (9)$$

where C_{EDL1} and C_{EDL2} are the capacitances of the electric double layers in the control (side) channel and in the main channel, respectively, and C_{wall} is the capacitance of the separation wall.

Key Research Findings

Microfluidic Logic Gate

A microfluidic logic gate eliminates the need for external valves to control the flow and mixing in microchannels. It also increases the speed of response of the control mechanism: this speed is about 100 times faster than that of external control devices. Figure 4 shows experimental results obtained from a bubble-based logic gate in a microfluidic chip [3]. The microfluidic channels were formed on polydimethylsiloxane (PDMS) using standard soft-lithography techniques, and a Pyrex substrate was used to cover the channel. In this experiment, water was used as the working fluid, and nitrogen bubbles (0.5 psi) were introduced into the water. In order to obtain dominant surface tension effects in the microchannels, bubbles of low capillary number $\mathrm{Ca} = \mu U/\sigma$, where σ is the surface tension and U is the flow velocity, were used. At low capillary number, surface tension dominates over viscous stress, which ensures that there is no splitting of bubbles at a point of bifurcation [10]. Three different cases of logic control, listed in Table 2, are presented in Fig. 4.

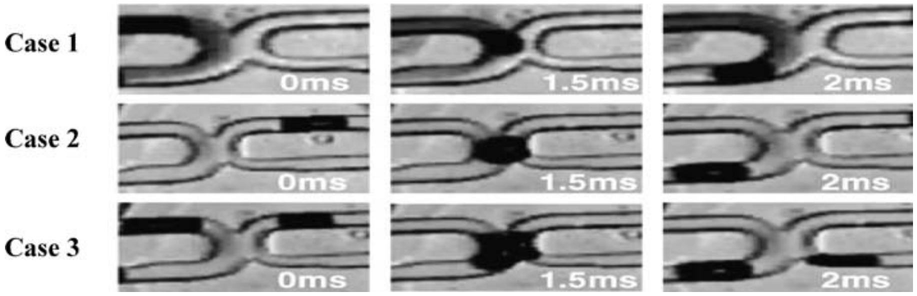
Microfluidic Circuits, Table 2 Logical outputs of AND and OR gates for various inputs in the channels A and B shown in Fig. 1. Here, the presence and absence of a nitrogen bubble in water are represented by binary states "0" and "1", respectively [3]. An AND gate returns an output of "1" if both inputs are "1". An OR gate returns an output of "1" if either or both inputs are "1"

	Input channel		Output channel	
	A	B	Y	X
			AND gate	OR gate
Case 1	0	1	0	1
Case 2	1	0	0	1
Case 3	1	1	1	1

- *Case 1 (top row).* One nitrogen bubble and water were introduced through channel A, while only water was allowed to flow through channel B. When the nitrogen bubble reached the junction it took the output channel X owing to the low fluidic resistance and low capillary number. Hence, channel X functions as an OR gate, while channel Y functions as an AND gate.
- *Case 2 (middle row).* In this case water and one nitrogen bubble were introduced through channel B, but only water was introduced through channel A. As in Case 1, the bubble at the junction took the low-resistance output channel X, and so the output of channel X was 1 and that of channel Y was 0.
- *Case 3 (bottom row).* One nitrogen bubble was allowed to flow with water from each of the channels A and B. At the junction, the first bubble took the path of the wider channel X. The presence of the first bubble in channel X increased its fluidic resistance, and so the other bubble was forced to take the output channel Y. Therefore, the outputs of X and Y were both 1.

Microfluidic Amplifier

Schomburg et al. [11] have demonstrated the feasibility of a microfluidic-based jet interaction amplifier. A scan-



Microfluidic Circuits, Figure 4 Operation of four-channel bubble logic (AND and OR) gates, from Parkash and Gershenfeld [3]. Reprinted with permission from AAAS. The nomenclature used to identify channels *A*, *B*, *X*, and *Y* is identical to that used in Fig. 1. *Left column:* a bubble is flowing through an input channel (*A* and/or *B*) towards the four-way junction. *Middle column:* the bubble reaches the junction of the two input channels. *Right column:* the bubble travels through output port *X* or *Y*, depending on the flow resistances in the output channels. The images for the left, middle, and right columns were taken at 0 ms, 1.5 ms, and 2.0 ms, respectively [3]

ning electron microscope (SEM) image of a microscale analog jet interaction amplifier is shown in Fig. 5a. This microamplifier was formed on PMMA using the well-known LIGA process. Figure 5b shows experimental results [11] obtained using nitrogen gas. A jet of 20 hPa pressure and 45 m/s mean velocity was supplied by the main nozzle. The flows through the control ports were varied to obtain a pressure differential at the outlet ports. Figure 5b shows that the output differential pressure varied linearly within a certain range of the differential control (input) pressure. The amplification of the input pressure in this amplifier depends on discharge of the supply jet.

The same research group also introduced a microfabricated digital wall attachment amplifier [11] for bistable control of flow. An SEM image of a microscale digital wall attachment amplifier formed on PMMA is illustrated in Fig. 6a. The pressure in one of the output ports (opposite to the control port used) is shown in Fig. 6b for various values of the control port pressure. The output pressures were measured at output 2 while the input control pressure was varied at inlet 1. In the experiment, a jet of 330 hPa pressure was supplied through the main nozzle, while the pressures at the control ports were varied from 0 to 12 hPa. The experimental results showed that if the jet was attached to the wall next to a control port, then temporary application of pressure (12 hPa) to that control port guided the jet to the opposite wall. The jet continued to flow along that wall after the removal of the control jet. A minimum supply pressure was needed for the action of this amplifier. The experimental results also showed that the supply pressure had no effect on the pressure recovery (ratio of maximum output to input pressure) and flow recovery (ratio of maximum output to input flow) in this amplifier.

Flow Field Effect Transistor

A schematic of a flow FET for a T-junction is presented in Fig. 7a. The drain and gate reservoirs were connected to positive voltages, while the source reservoir was grounded. The branch channel reservoir was electrically floating. Initially, the pressure head at each reservoir was maintained at the same value so that there was no movement of the fluid before an external electric field was applied. Figure 7b shows the fluid flow behavior for the no-control scenario. In this case, the drain, source, and gate potentials were 48, 0, and 25 V, respectively. The streamlines shown in Fig. 7b indicate the direction of the flow in both the main and the branch channel for the above-mentioned electrical conditions. These streamlines imply that a pressure is induced along the main channel owing to an electrokinetic pumping action, and the balance of pressure among the three reservoirs is broken.

To control the flow, we intentionally created a leakage current by changing the value of the gate voltage from its equilibrium state. This leakage current modified the zeta potential in the controlled region. The change in the zeta potential on one side of the channel wall resulted in a transverse electric field, which created a cross-stream velocity component. Figure 7c shows the velocity vector distribution in a control case for which the gate voltage was 18 V ($\Delta V_g = -7$ V). In this case, almost no sample enters the branch channel, and this specific scenario is particularly useful if one desires to transport a sample such as protein or DNA through a T-junction with minimum band distortion. Here, the effect of the field on the flow at the T-junction acts like an electroswitching valve using the benefits of the crossstream velocity component [9].

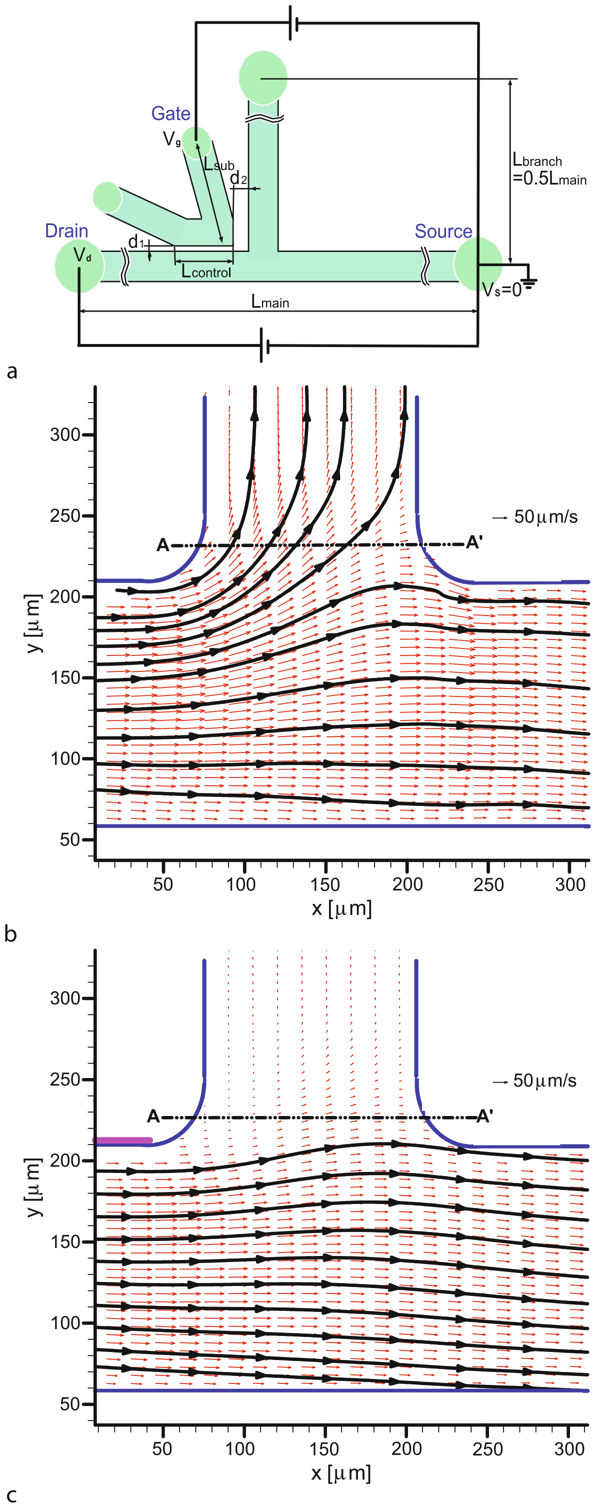
Future Directions for Research

Microfluidic circuits have enormous potential for the control of flow and ionic concentration, separation of proteins and DNA, and sensing of single molecules in a complex microfluidic chip. For instance, the microfluidic transistor presented in Fig. 7 could be used to control the flow rate in a number of branch (side) channels. Moreover, an array of flow FETs could be used to dynamically modify the zeta potential along a channel during an electrophoretic separation process. However, to maximize the effects on the zeta potential via an externally applied gate voltage, a very thin channel wall (which acts as an insulator or capacitor) is needed because the wall capacitance is inversely propor-



Microfluidic Circuits, Figure 7 (**a**) Schematic view of experimental setup for local flow control at a T-channel junction [9] (reproduced by permission of the Royal Society of Chemistry). Microchannel structures and a flow FET were formed on PDMS using soft-lithography techniques. The length, width, and height of the main channel are 2 cm, 150 µm, and 10 µm, respectively, and the geometric parameters are $d_1 = 50$ µm, $d_2 = 125$ µm, $L_{sub} = 3$ mm, and $L_{control} = 1$ mm. The drain voltage was set to $V_d = 48$ V. (**b**), (**c**) Vector plots of flow velocity in T-channel junction for (**b**) $V_g = 25$ V and (**c**) $V_g = 18$ V. The streamlines (black solid lines) show the net flow direction in the microchannel

tional to the thickness of the wall (in the case of a rectangular channel). Recently, Karnik et al. [12] examined the effects of the perpendicular electric field originating from the gate voltage in a nanofluidic channel. These authors found that both the zeta potential and the ionic concentration were influenced when the channel size was comparable to or smaller than the Debye length. In addition, a number of research groups have been working on nanofluidic diodes using the flow FET concept.

Definition

Tissue Engineering

Tissue engineering collectively refers to efforts used to augment, repair or replace tissue or organ using cellular substitutes that have appropriate structural organization and function behavior. This is a highly inter disciplinary field and has received significant contributions from researchers from various fields of engineering and life sciences. Several interpretations of phrase *tissue engineering* exist today, including commonly used definitions coined by *Skalak* and *Fox*

> "Tissue engineering is the application of the principles and methods of engineering and the life science toward the fundamental understanding of structure-function relationships in normal and pathological mammalian tissue and the development of biological substitutes to restore, maintain or improve functions,"

Langer and *Vacanti*

> "an interdisciplinary field that applies the principles of engineering and life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function or a whole organ, and"

MacArthur and *Oreffo*

> "understanding the principles of tissue growth, and applying this to produce functional replacement tissue for clinical use."

In this chapter however, we will limit our discussion to microfluidic devices used to engineer tissues.

Microfluidics

Microfluidics deals with the behavior, control and manipulation of microliter and nanoliter volumes of fluids. The behavior of fluids at the microscale differs significantly from fluidic behavior at the macroscale. At these scales (channel dimensions of around 10 to 100 sμm) some interesting and unintuitive properties appear primarily due to the fact that the Reynolds number which is the ratio of inertial forces to viscous forces, becomes extremely small resulting in highly organized laminar flow and diffusion, becomes the primary mechanism of mixing. Surface to volume ratios also become extremely large. Factors such as surface tension, energy dissipation, and fluidic resistance begin to play an important role whereas effects due to other factors like turbulence, inertia and friction that dominate fluid flow in the macroscale become negligible. Microfluidics is the study of how these behaviors change, understanding the effects of this change and then exploiting them for new applications. In this chapter, the discussion of microfluidic devices extends beyond devices used primarily for fluid flow and includes all types of devices and microscale technologies used for various types of fluidic manipulations.

Overview

Within the body there are different levels of structural organization and complexity. The lowest level of organization is *molecular*. In our body we have a wide variety of *molecules* with different structures and functions including proteins and nucleic acids. The size ranges of the different biomolecules vary from 5 to 100 nm. *Cells* are the smallest independent units of living matter capable of sustaining life. Our bodies are made up of millions of different cells that perform different structural and biological functions. Cells are typically in the size range of a 2 – 30 μm. In complex organisms such as humans, cells with similar structures and functions are typically found together in our bodies forming *tissues*. Cells that make up a single tissue typically interact with each other to function synergistically to perform specific functions. *Organs*, the next level of complexity are made up of different tissues and perform specialized bodily functions. Examples of organs include the kidney, liver, pancreas and the heart.

Further, different organs and tissues work together as a *system* to carry out one or more functions essential for the survival of the organism. Finally, the *organism* relies on the proper functioning of all the different systems in the body to sustain life.

As a field, tissue engineering emerged in the early 1990's through efforts in Robert Langer's laboratory, primarily based on initiatives by chemical and biomedical engineers. The earliest approaches focused on development of suitable scaffolds for cell attachment and culture. These approaches were successful in generating basic tissue constructs but stopped short of achieving tissue complexity in terms of vasculature and innervation into the engineered tissue. The nervous system and the circulatory system are the predominant mechanisms via which the body maintains homeostasis. Successful engineered tissues to date include non-angiogenic tissue including bone and skin. More complex tissue requires integration of vasculature and nervous tissue to achieve exact replication of in vivo tissue architectures. More recently, several efforts have focused on generation of blood vessels in vitro. However, integration of blood vessels and nerves with functional engineered tissue requires technology that can ensure exact replication of in vivo tissue architecture along with delivery of signals with sub-cellular resolution.

Microfluidics deals with the behavior, control and manipulation of microliter and nanoliter volumes of fluids. In most cases microfluidics involves the use of microfabricated systems that contain channel networks, reservoirs, cell culture areas, electrodes for stimulation, temperature controllers, sensors and detectors. The primary advantage of microfluidics over macroscale technologies is the ability to control interactions at the cellular and molecular level. Tissue and organs require well defined architectures, precise control over molecular and chemical signals and controlled microenvironments with appropriate extracellular matrix (ECM). Cellular events such as proliferation, differentiation, migration or apoptosis are facilitated via multiple surface cues from the extra-cellular environment and soluble signals triggering transmembrane signaling proteins, which in turn, activate intracellular signaling pathways. In organisms that reproduce sexually, a sperm fertilizes an egg cell resulting in a cell called the zygote. In the early stage of development (embryonic stage), the embryo can be considered the ultimate microfluidic environment for tissue engineering.

The zygote exists in an extremely well-defined microenvironment with necessary extracellular matrix (ECM) for support, signals with micro/nano scale spatial and temporal resolution, resulting in its development into different germ layers, tissue, organs and finally a mature organism. Microfluidics technology provides us with the tools to accomplish all of these tasks, most of which cannot be accomplished in the macroscale. Microfluidic approaches for tissue engineering work primarily at the molecular and cellular levels of complexity through which we use a bottom up approach to tissue engineering similar to early stages of development in the body. Using fluidics technology at these size scales, we can accomplish a wide variety of functions which will be discussed in detail in this chapter. We can organize cells spatially using microfluidic printing technologies by placing one cell at a time at defined locations; create extra cellular matrices (ECMs) at precisely defined locations for cellular attachment; pattern cells side-by-side to mimic the architectures in the body; create vasculature for continuous supply of nutrients and essential factors while at the same time providing a mechanism for removal of toxic metabolic wastes; and, deliver signals with the spatial and temporal resolution necessary for differentiation and development of certain progenitor cell types. Overall, the type of control and manipulation possible using microfluidic technology is not possible using conventional techniques.

Use of microfluidics technology for tissue engineering has a lot of advantages. However, a lot of work still needs to be done before tissues generated via this technology can be used as a functional replacement or augmentation in the body. Tissues generated in microfluidic devices are, in most cases, too small to be of functional value. Additional technology must be developed that will combine the precise microenvironments available through microtechnology together with a process to reliably scale up the production of useful engineered tissue.

Basic Methodology

We begin with an introduction to microfluidic technology available for creating controlled microenvironments (i. e.) surface modification for cell attachment and techniques for delivery of soluble signals to cells. Construction of the extracellular environment is extremely critical. Small variations in shape, size and composition of surfaces to which cells attach, changes in growth medium, soluble signaling factors, arrangement of neighboring cells as well as the temporal control over delivery of signals can play a huge role in the survival, function, proliferation, and differentiation of cells. The first step towards creating a controlled microenvironment is patterning of cells and ECM proteins to mimic the architectures in the body. Several microfluidic patterning techniques exist that can be used to accomplish cellular and extracellular patterning. Following establishment of a suitable environment, biochemical signals in the fluid medium, including soluble factors, need to be delivered with high spatial and tempo-

ral resolution. This chapter will detail techniques currently employed, that strive to achieve biomimetic patterning of cells and extracellular matrices (ECMs) followed by techniques to deliver biochemical signals with high spatial and temporal resolution as seen in the body.

Cells, Extracellular Matrix (ECM) and Soluble Biochemical Signals

Spatial Resolution

Microfluidics technology offers unparalled spatial resolution for the creation of cellular and extracellular microenvironments that cannot be reproduced with conventional technology. Using micropatterning techniques like photolithography, microcontact printing, microfluidic printing, stencil printing etc., spatial cues in the form of ECM proteins and ligands can be presented to cells with micrometer/sub-micrometer resolution. Growth medium, soluble signaling molecules and growth factors can be presented to cells by taking advantage of fluid flow behavior at the same size scales as present in the body. In tissue, different cells, and sometimes even different locations in a single cell, are exposed to multiple biochemical signals with high spatial resolution An attractive feature of microfluidic platforms is the ability to design systems that can deliver multiple signals simultaneously with similar cellular and/or sub-cellular resolution. Thus, these microfluidic platforms can be valuable tools for investigating or mimicking processes responsible for different cellular functions such as cell proliferation, differentiation, migration, apoptosis, etc.

2D and 3D Cell and ECM Patterning Techniques

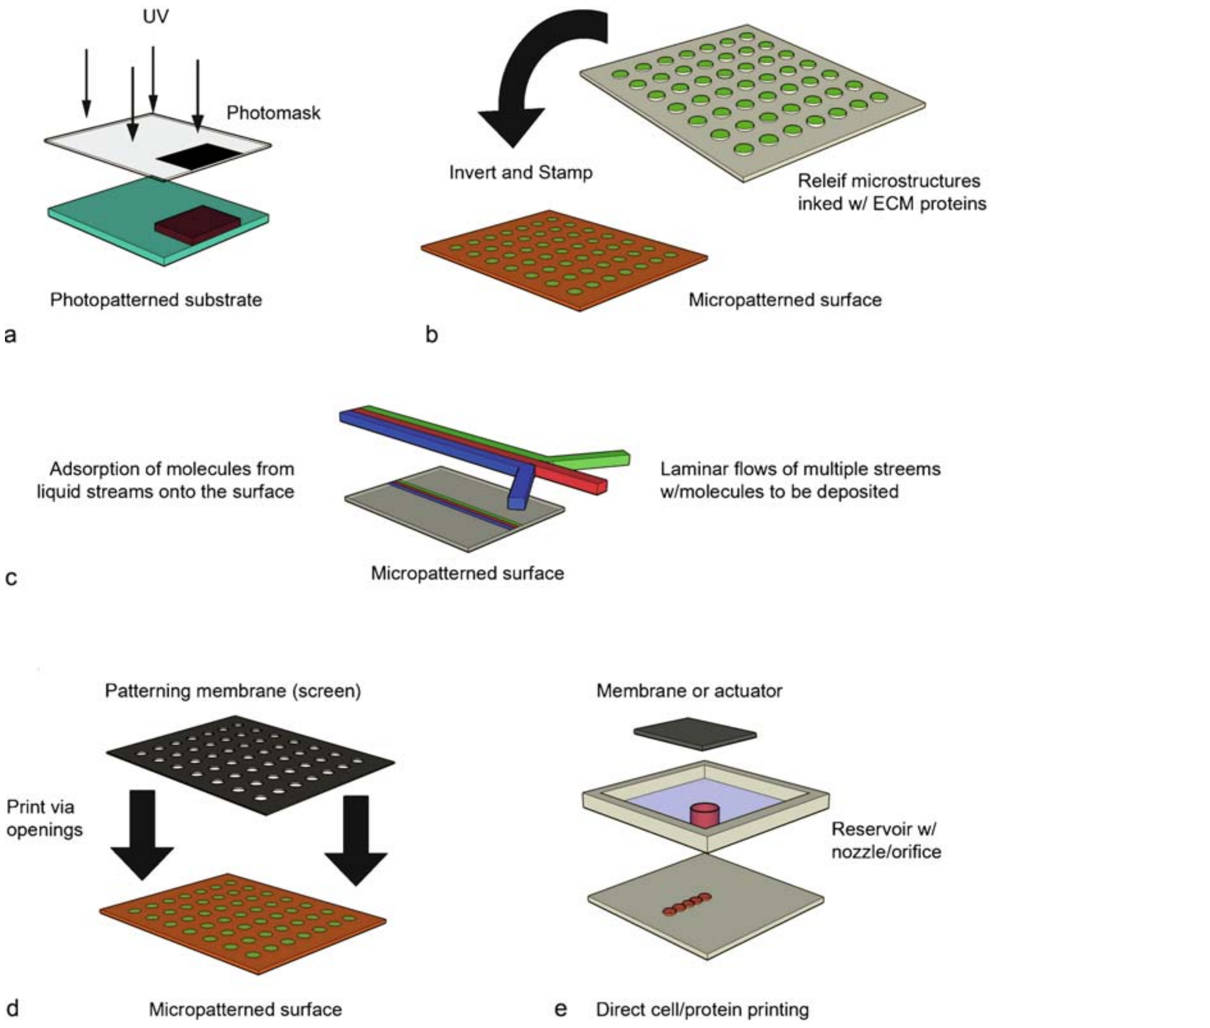
Cellular patterning relies heavily on the generation of surfaces favorable for cell attachment (typically coated with ECM proteins), in conjunction with, the ability to ensure that the surface regions where attachment is undesired suppress non-specific interactions between the proteins and the cells. Advances in surface chemistry have made possible the synthesis of biologically inert surfaces which minimize or eliminate the non-specific adsorption of proteins and other biomolecules from biological fluids such as cell culture media as well as cell adhesion. Surfaces that promote cell adhesion are typically charged, hydrophilic surfaces. Biocompatible hydrophilic surfaces are often patterned with ECM proteins like agrin, collagen, fibronectin and vitronectin as well as other molecules like poly-L and -D lysine. Hydrophobic surfaces, on the other hand, typically inhibit cell attachment and prevent the adsorption of proteins. Molecules such as carbohydrates (e. g. agarose and mannitol) and proteins (e. g. albumin) generally reduce the adsorption of proteins at the surface. To overcome limitations with respect to efficiency and stability of naturally occurring biomolecules, a number of synthetic materials have been developed. The most commonly used molecule is poly (ethylene glycol) or PEG with the monomeric repeat unit [–CH_2–CH_2–O]. Other approaches include the use of lipid bilayers tailored with different charged lipids, embedded with peptides and proteins, and polyelectrolytes deposited using layer-by-layer assembly techniques.

The advent of the printing press has been hailed as one of the most significant technological advances in human history. Modifications of those same techniques have found their way into microfluidics technology for patterning surfaces and structures for the creation of cellular and extracellular microenvironments. Much of these techniques and their adaptations for cell and protein patterning are a result of technology developed in George Whitesides's laboratory at Harvard University. Several other researchers have also contributed to development of surface patterning technology pertaining to ECM and cell patterning [please refer to review articles by Andersson [1], Folch [6], and Kane [7] for additional information related to these techniques]. A summary of these different techniques is presented below.

M

Photolithographic Patterning Photolithography involves the formation of geometric features in a substrate through the use of light and a mask in a fashion similar to photography (Fig. 1a). The patterns on the mask (equivalent to a film negative) are transferred via UV illumination onto the substrate (similar to photography paper) which is coated with a photosensitive polymer (called photoresist). The substrates are coated with the photoresist by spinning the substrate at a predetermined speed to achieve the desired thickness of photoresist. Some biocompatible molecules like PEG can be modified to become photosensitive in order to directly pattern surfaces using photolithography techniques. Other biological molecules are patterned indirectly using a lift-off process (the removal of unwanted material on the surface of a photoresist by dissolving the photoresist). Following photoresist patterning, the open spaces are back filled with the molecules of interest. The remaining photoresist is subsequently removed using a solvent, such as acetone, together with sonication. Depending on the application and biomolecules involved, exposure to solvents might not be desirable since denaturation or scission of the biomolecules may result in some cases.

To circumvent the above mentioned limitation, photolithographic patterning can be extended to accomplish generation of selective, molecular assembly patterning. For



Microfluidic Devices in Tissue Engineering, Figure 1 Commonly used micropatterning techniques for creation of precisely defined cellular and extracellular microenvironments. (**a**) Photolithography, (**b**) Relief or Microcontact printing, (**c**) Microfluidic Patterning or Liquid Phase Printing, (**d**) Stencil or Screen Printing and (**e**) Inkjet or Droplet Printing

example, metal oxides, like titanium dioxide or silicon dioxide, can be patterned using a combination of thin film deposition, lithography and etching. The non-patterned regions can be treated with oxygen plasma to become hydrophilic, modified with molecular linkers, and linked with the molecules of choice. Alternatively, metals like gold or platinum can be patterned the similarly, so molecules like thiols, or modified-thiols with different tail groups, can be self-assembled onto the patterned metal layer.

Relief or Microcontact Printing Microcontact printing is the most widely used technique for surface modification (Fig. 1b). Though primarily intended for microelectronics applications, microcontact printing has been successfully adapted to cellular patterning. This technique is simple, cost effective, and flexible, while at the same time, capable of producing patterns with sub-micron resolution. First, an elastomeric stamp (generally constructed from polydimethyl siloxane (PDMS) material) is formed by casting a liquid-phase polymer over a patterned master (e. g., silicon). After curing, the stamp is released from the master and inked with a solution containing the molecules of choice. Next, the desired surface is stamped by transfering the ink to the substrate. The substrate is patterned with the molecular ink and the geometry of the patterned surface is determined by the geometry of the micropatterned stamp. A bonus feature of this technique is the ability to backfill

the empty spaces between patterned areas with a second molecule to further promote selectivity of the surface.

Microfluidic Patterning or Liquid Phase Printing Microfluidic channels can also be used to selectively pattern surfaces (Fig. 1c). In microfluidic patterning, channels are used to selectively deliver fluids to specific areas of the substrate based on channel geometry. The substrate with the fluidic channels can be reversibly bonded to the substrate to be patterned. The channels are filled with a fluid containing the molecules of interest that can be deposited onto the substrate at specific locations. This technique is similar to microcontact printing, except for the fact that the fluid is delivered via microchannels instead of ink on a stamp. This type of microfluidic arrangement allows for sequential and combinatorial delivery of different molecules in solutions which can be delivered to the desired locations through the proper alignment of the microfluidic channels. Further, this method can draw on the advantages of laminar flow and controlled diffusion in microfluidic channels to pattern gradients of different molecules to mimic similar signaling mechanisms in the body that use gradients to control different cellular activities. Diffusion of molecules can be accurately determined using Fick's Law (1) where J the diffusive flux is dependent on the diffusion co-efficient and concentration of the molecule. The biggest disadvantage to this technique is its limitation to closed network structures.

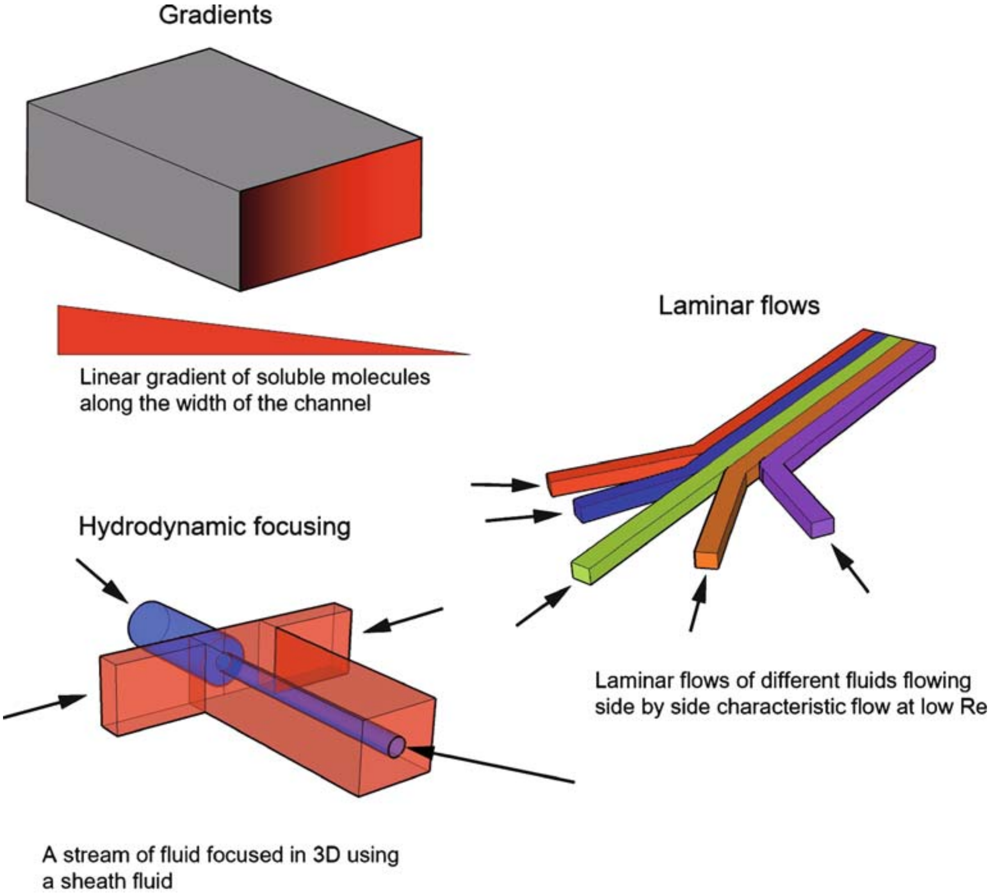
$$J = -D\left(\frac{\partial \phi}{\partial x}\right) \tag{1}$$

Stencil or Screen Printing Stencil Printing involves the generation of patterns through the use of a rigid or flexible sheet or membrane with openings through the sheet in the shape of the desired patterns (Fig. 1d). When the stencil is brought in close contact with the substrate, it can be used to locally modify the surface while the areas covered by the sheet or membrane material remain protected. The stencil can be used to add material to a substrate via mechanisms similar to microcontact printing or microfluidic patterning followed by a wash step and removal of the stencil. Stencils can also be used to selectively remove material from a substrate to yield specific patterns via chemical etching or physical ablation. Most commonly used stencils are constructed from thin layers of PDMS. Major advantages of PDMS stencils include their ability to be easily aligned and reversibly bonded to the substrate while used for patterning. This technique is also amenable to sequential and combinatorial deposition of different molecules to create complex 3D structures more accurately representing in vivo architectures.

Inkjet or Droplet Printing Technology used in commercial ink jet printers is amenable for use in tissue engineering to directly print or write molecules and proteins onto surfaces in a rapid and controlled fashion [3] (Fig. 1e). Recently, this technology has also been employed to directly print or write cells, but cell death, due to dehydration, has been associated with this technique. However, this issue has been addressed via printing cells in larger droplets. Spatial arrangement, with micron scale resolution, is also possible via ejection from more than one nozzle. 2D architectures as seen in the body can be replicated in vitro via printing, using a combination of molecular and cellular deposition nozzles. This technology potentially represents a step forward since molecular and cellular architecture can be precisely printed and replication of the cellular microenvironment is possible, as opposed to molecular surface patterning followed by self-assembly of cells.

Laser Guided Positioning of Cells or Optical Tweezers Optical tweezers are capable of manipulating nanometer and micrometer-sized dielectric particles by exerting extremely small forces via a highly focused laser beam. The beam is typically focused by sending it through a microscope objective with the narrowest point of the focused beam, known as the beam waist, containing a very strong electric field gradient. Cells and particles are attracted to the region of the strongest electric field, known as an optical trap. The cell can be moved by spatial movement of the laser relative to the substrate and the cell can then be released at any specified location. It is also possible to continuously propel cells along a light path, $\sim 300\,\mu m$ in length, and to create clusters of cells on a target surface. This technique is slow, complicated and time consuming; however, precise alignment can be accomplished one cell at a time.

Layer-by-Layer Assembly Most techniques discussed above are restricted to generation of 2D surface or cell patterning. A simple procedure to generate 3D tissue architecture is the layer-by-layer approach. A surface can be patterned with proteins or other molecules in liquid phase to create cell specific regions using any of the techniques described above, followed by cell patterning which self-assembles to form 2D tissue. This layer, with live cells, can be preserved by cryopreservation or biopreservation, or maintained alive via encapsulation in a hydrogel-like collagen gel or commercially available matrigel. Different layers patterned in 2D can then assembled on top of each other resulting in the desired 3D architecture.



Microfluidic Devices in Tissue Engineering, Figure 2 Due to low Re numbers in microfluidic systems it is possible to accomplish (**a**) controlled and predictable diffusion, (**b**) laminar flows and (**c**) hydrodynamic focusing of streams of fluids

Stereolithography of Biodegradable Polymers Stereolithography is a commonly used tool for layer by layer direct writing of polymers for rapid prototyping of machine parts. This technique can be used to accomplish direct writing of a biodegradable scaffold onto which cells can then be seeded. During the process of writing the scaffold can be modified with compatible surface modified techniques discussed above to define areas for cell attachment and self assembly.

Delivery of Soluble Signals

Thus far we have limited our discussion to microfluidics technology for patterning of ECM proteins and cells. Tissue culture is a dynamic process where a basic tissue construct is first assembled and then continuously remodeled until it resembles in vivo tissue architecture with cellular and extracellular organization. The surrounding extracellular (aqueous) environment provides the necessary signals for tissue remodeling. In static macroscale cultures it is often not possible to deliver these soluble signals with cellular/subcellular resolution necessary to accomplish delivery of multiple molecules, gradients of molecules and simultaneous delivery of two or more molecules to different locations of the same cell. To accomplish this we can use microfluidics technology that exploits flow phenomenon at these size scales to deliver complex signals with extremely high spatial resolution.

Control Using Flow Phenomenon in the Microscale In channel structures with dimensions < 200 mm (microfluidic devices) fluids (liquids) follow predictable laminar paths characteristic of low Reynolds numbers. This allows two or more layers of fluid to flow next to each other without any mixing other than by molecular or particulate diffusion. As a result of this property it is possible to have multiple inputs into a single channel and have them flow side by side in an orderly fashion (Fig. 2b). Since

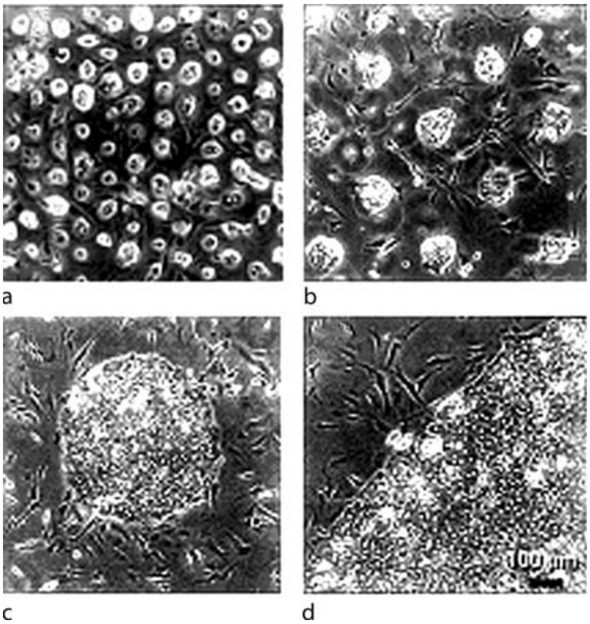
the channels dimensions in many cases are comparable to the size of single cells we can use laminar flow patterning to expose subcellular regions to specific signals. Also it is possible to allow different regions of the same cell to different conditions.

A consequence of laminar flows and the fact that mixing in microfluidic channels is almost exclusively due to molecular or particular diffusion is the development of devices that can generate stable gradients of different solutions and molecules. Based on the size and shape of a molecule or particle a diffusion coefficient for that particle can be calculated. Based on this coefficient, length of channels necessary for complete diffusion can also be estimated. Several devices using passive structures or networks for combinatorial splitting and mixing of fluids have been developed to generate both linear and non-linear gradients (Fig. 2a). Several cellular processes like cell migration and alignment that respond to molecular gradients can be accomplished using microfluidic technology. Generation of microfluidic gradients can also be accomplished via controlled diffusion of molecules in conjunction with porous or biodegradable materials. These materials can be used to pattern reservoirs, channels or passive structures to contain and deliver at predetermined rates gradients of different molecules, with the highest concentration closest to the structure.

Further exploiting laminar flows in microfluidic systems, a stream of fluid can be focused in 2D and 3D using additional focusing fluids in what is called hydrodynamic focusing (Fig. 2c). Buffers can be used to focus a stream of solution containing signaling molecules. The width of this stream can be controlled to dimensions much smaller than that of the channels itself obtaining 2 or 3D positioning a delivery of signals.

Temporal Resolution

Microfluidic Control Sequential and combinatorial delivery of signals to cells or tissue in microfluidic devices can be accomplished by using built-in control systems. Several microfluidic tools including valves, pumps, mixers, fluidic oscillators, fluidic diodes, etc., have been developed to accomplish fluidic control in these devices. These components can either be passive or active. Examples of passive elements include one way valves (flap, ball) and hydrophobic patches which take advantage of the interaction between the chemical surface properties of the substrate and liquid. Active elements, on the other hand, typically require some type of actuation mechanism. Several mechanisms for force transduction in microfluidic devices include mechanical, thermal, electrical, magnetic, and chemical actuation systems as well as and the use



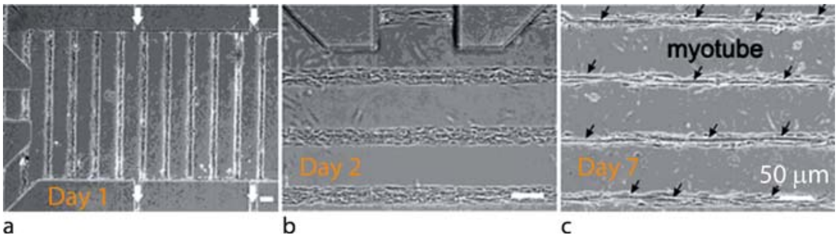
Microfluidic Devices in Tissue Engineering, Figure 3 The figure shows at different magnifications co-cultures of hepatocytes with surrounding stromal cells (fibroblasts). Co-culture is necessary to establish the necessary heterotypic interactions for performance of liver specific functions. Hepatocytes and fibroblasts were patterned using microcontact printing [12]

of biological transducers. There has been a significant amount of work in this area that has been presented in a review by Erickson and Li [5].

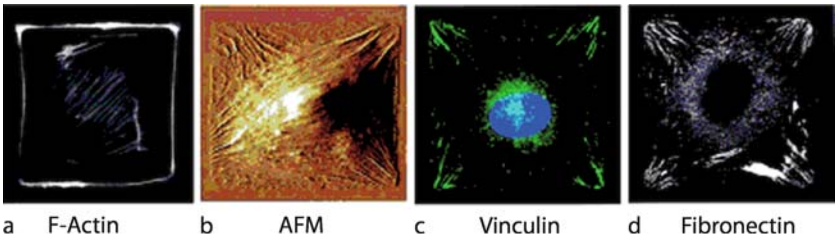
Stephen Quake's laboratory at Caltech and more recently at Stanford, developed a technique for creating pneumatically controlled valves and pumps. This technique involves the use of thin microstructured membranes which employs pneumatic force for actuation. Using this technique, valves (normally open or close), pumps (peristaltic), fluidic oscillators, etc., have been fabricated. More recently, complicated microfluidic circuits have been realized using techniques similar to large scale integrated circuits. These technologies and several others, offer the ability to accomplish switching and change in flow or culture conditions rapidly (in the order of milliseconds). Microfluidics, therefore, can not only accomplish delivery of signals with subcellular resolution but also with extremely high temporal resolution.

Integrating Feedback Mechanisms via Electrodes, Sensors and Detectors

Microfabrication technologies originated from the microelectronics industry and these techniques have been extensively applied to other fields including microfluidics and



Microfluidic Devices in Tissue Engineering, Figure 4 The formation of skeletal muscle tissue in vivo requires initiation of precursor cells into the myoblastic pathway. To accomplish this, alternating cell-adhesive and cell-repellent microdomains are patterned for attachment of precursor cells which mimics in vivo spatial cues for muscle cell assembly through fusion of myoblasts into aligned, isolated multinucleated myotubes. Figure shows differention of precursor cells into smooth muscle cells constrained in micropatterned regions over a period of 7 days [13]



Microfluidic Devices in Tissue Engineering, Figure 5 ECM islands of defined size and shape on the scale of individual cells separated by non-adhesive regions allow cell types adhere and spread on these islands, but extend only up to the limiting boundary along the periphery. By physically constraining cells to square islands, the formation of cell focal adhesions can be controlled. Culture of cardiomyocytes on these islands results ensures that cytoskeletal tension necessary for beating is available to produce a 2D, cellular electrophysiological model of cardiac muscle. Figure shows cardiomyocytes on patterned ECM islands [14]

microelectromechanical systems (MEMS). MEMS technologies have been widely used to develop sensors and detectors to monitor pressure, shear stress, temperature, pH, oxygen, glucose along with many other chemical and biological molecules. Our body has several feedback mechanisms including the circulatory system and nervous system to obtain feedback to constantly adjust its physiological functions in response to alterations in its environmental conditions. In vivo tissue culture typically lacks these feedback mechanisms. By integrating sensors and detectors within microfluidic systems, the tissue microenvironment can be monitored to enable a closed feedback loop to constantly modify the culture conditions. Again, the review by Erickson and Li provides a good overview of integrated microfluidic systems [5].

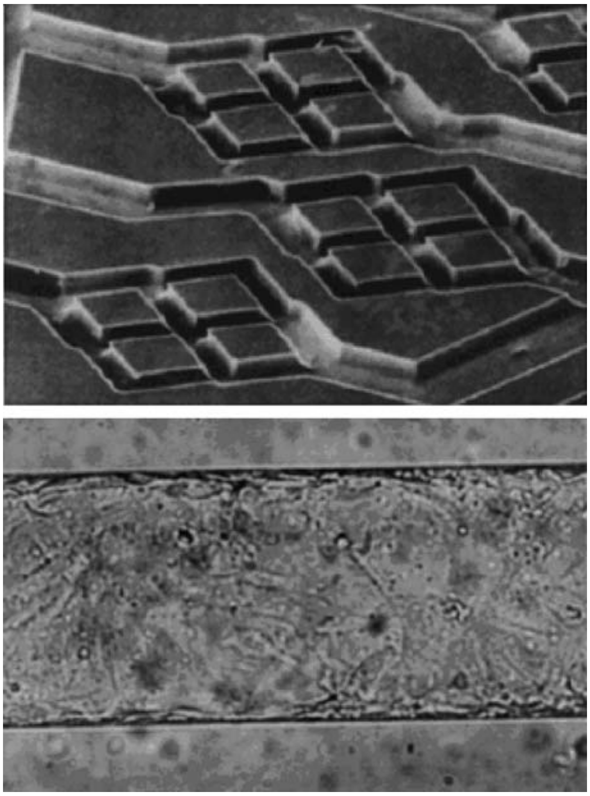
Key Research Findings

Hepatocyte – Stromal Cell Co-Cultures

Bhatia and colleagues [2] used microscale techniques to exert spatial control over cell adhesion at the 1 – 100 μm scale to study diverse phenomena in hepatocytes such as the effect of cell spreading on cell behavior and surface topology on cell migration. They developed a photolithographic cell patterning technique to study the relative role of homotypic (hepatocyte-hepatocyte) and heterotypic (hepatocyte-stroma) interactions on the stabilization of liver-specific functions in vitro (Fig. 3). Co-cultures were created in which the heterotypic interface varied over three orders of magnitude, while keeping the ratio of cell populations, as well as total cell number constant. It was found that identical cell populations (co-cultivation of hepatocytes with stromal cells (i. e. fibroblasts)) when rearranged spatially can produce different levels of function in the resultant tissue. Arrangement of co-cultures of hepatocytes and fibroblasts mimics in vivo architecture and helps maintain hepatocyte function and phenotype in vitro as determined by urea and albumin synthesis.

Microfluidic Smooth Muscle Cell Culture and Differentiation

The formation of skeletal muscle tissue in vivo involves the determination of precursor cells to the myoblastic pathway, fusion of myoblasts into multinucleated myotubes, and maturation into muscle fibers. Tourovskaia and colleagues [10] have developed a microfluidic cell culture system for myogenesis studies that provides control over the external environment to fully recapitulate myogenic differentiation in vivo and allows the manipulation of subcellular domains within mature myotubes for simulation of postsynaptic differentiation and further modula-



Microfluidic Devices in Tissue Engineering, Figure 6 Microfluidic channels in many ways resemble the vascular network in our body. Microfluidic networks made out of degradable materials like PLGA can be used to provide a structural backbone for seeding and culture of endothelial cells with perfusion and further construction of complex 3D organ and tissue architectures. Shown are the microfluidic network and endothelial cells seeded within the network [15]

tion of muscle differentiation. They accomplished spatial organization of the myotubes to resemble in vivo morphology, grew well-defined, isolated myotubes within the microfluidic channels and demonstrated the selective surface receptor tagging. The cells were successfully cultured for 2 weeks under constant perfusion at a low flow rate and no significant change in the growth rates was observed compared to the traditional non-microfluidic control cultures (Fig. 4).

Cardiomyocyte Model for Electrophysiological Studies

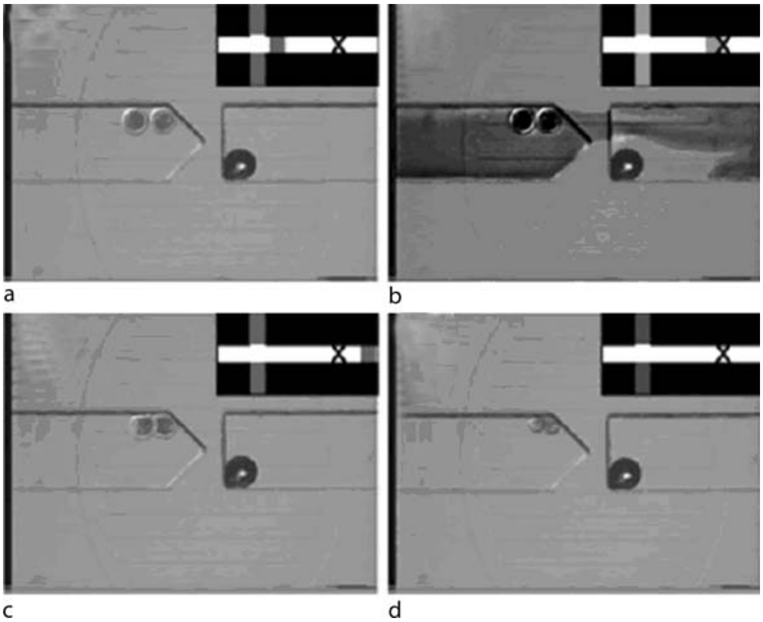
Parker and colleagues [9] used a microcontact printing approach to create adhesive ECM islands of specifically defined size and shape, on the scale of individual cells, separated by non-adhesive regions. They found that various cell types adhere and spread on these islands, but extend only up to the limiting boundary along the periphery (Fig. 5). Individual cells were shown to take on the shape of the island which they adhered to, although the cells were able to locally extend lamellipodia over the non-adhesive boundary regions. Whereas, cells on symmetrical circular islands extended new cell processes at random along their periphery. Cells on square islands were found to extended lamellipodia, filopodia, and microspikes at the corners. By physically constraining cells to square islands, the cells were able to consistently reorient themselves to where their focal adhesions formed, which tension on the exerted cytoskeletal. This structural reorientation resulted in consistent control of the direction of lamellipodia extension: cell processes were redirected to the corners of these cells where the greatest tractional stresses were observed. Application of this technique to cardiomyocytes resulted in a cellular-level model for functional electrophysiological studies of cardiac muscle.

Vascular Tissue Engineering

Borenstein and colleagues [4] developed a microfluidic device for vascular tissue engineering. Using standard photolithography and a replica molding process, they developed a biodegradable scaffold made of poly (lactic-co-glycolic acid) or PLGA with microfluidic channels for seeding with endothelial cells. Endothelial cells were successfully seeded and cultured in the PLGA channels for periods as long as 4 weeks, demonstrating that these cells successfully attach, proliferate and migrate in small channels with closed geometries (Fig. 6). The endothelial cells were maintained in culture under constant perfusion using an external pump. This work is considered a critical first step towards development of microvasculature for enabling bulk organ tissue engineering.

Microfluidic Embryo Cultures

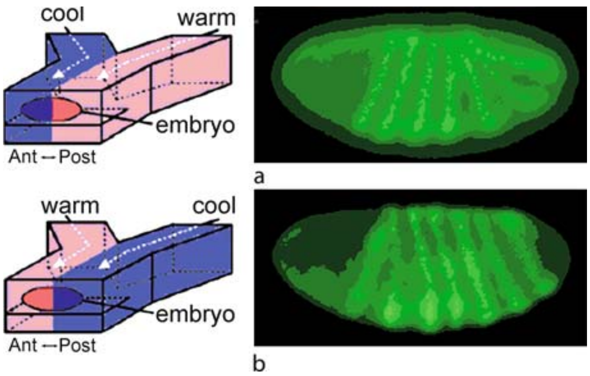
Microfluidic systems have also been used for in-vitro fertilization (IVF) and subsequent embryonic development by Zeringue and colleagues [11]. Using their device, the oocyte was anchored within a microfluidic channel (Fig. 7). The surrounding microenvironment was manipulated using microfluidic channels to deliver medium, molecular signals and growth factors. Microfluidic systems have been used to accomplish various oocyte manipulations including in-vitro maturation (IVM), in-vitro fertilization (IVF), in-vitro embryo culture (IVC), embryo biopsy, and nuclear transfer. In addition to providing a more in vivo-like culture environment, microfluidic technology was demonstrated to be more ideally suited for complex embryo manipulations, such as removal of the zona pellucida and stripping of the cell cumulus.



Microfluidic Devices in Tissue Engineering, Figure 7 Microfluidic systems have also been used for positioning, manipulation, fertilization and development of embryos for in vitro fertilization. Shown in this figure are different stages involved in stripping of the cumulus from a captured embryos using a lysis plug [16]

Drosophila Embryonic Development

Lucchetta and colleagues [8] have developed a technique for generating radical temperature variations using laminar flows and microfluidic channels to expose one-half of a drosophila embryo to one temperature and the other half of the embryo to a different temperature to investigate the effects of temperature on embryonic development (Fig. 8). They found that the warmer region initially experienced a more rapid development when compared to the colder region as evidenced by the higher rate of cell division. However, the embryo was found to have compensatory mechanisms in which normal embryonic development was still achieved when the embryos were returned to normal body temperature, even after a 2.5 h exposure to temperature differences.



Microfluidic Devices in Tissue Engineering, Figure 8 Biochemical networks in cells and tissue are sensitive to external factors such as temperature. Shown is a microfluidic device used for thermal patterning of a drosophila embryo with hot and cold liquid. Warmer regions show faster development when compared to the colder regions as shown by the staining of nuclei [17]

Future Directions for Research

Microfluidics provides the bioengineering and life science communities with an unprecedented opportunity to engineer tissues at the cellular and molecular level by creating microenvironments with extremely high spatial and temporal resolution. Microfluidic devices for tissue engineering are still in their infancy. Application of techniques and exploitation of phenomenon that occur at these size scales have been used to create complex cellular architectures and deliver spatial cues and soluble signals, but to date, generation of functional tissue using these devices and approaches has not been realized. Rather, these tools have served to help us understand at a molecular and cellular level, heterotypic and homotypic cell–cell interactions, cell–ECM interactions, cell–scaffold interactions and the effects of complex spatial and soluble signals. In terms of integrating more complexity into the engineered tissues, nervous and vascular tissue structures similar to

architectures seen in the body must be incorporated into the engineered tissues to ensure similar functional and structural characteristics of tissue found in vivo. To date, available technology in terms of integration of feedback mechanisms that utilize sensors, detectors and electrodes to monitor and provide information similar to homeostatic mechanisms in our own body have not been exploited. Microfluidics, therefore, provides tools and devices to start building from the bottom up, complicated cellular and extracellular architectures and environments necessary to enable the construction of tissues and organs. However, these techniques will need to be integrated with supporting technology to accomplish 3D architectures and scaled-up to produce functionally viable tissue that can be used to repair, replace or augment tissue in our bodies.

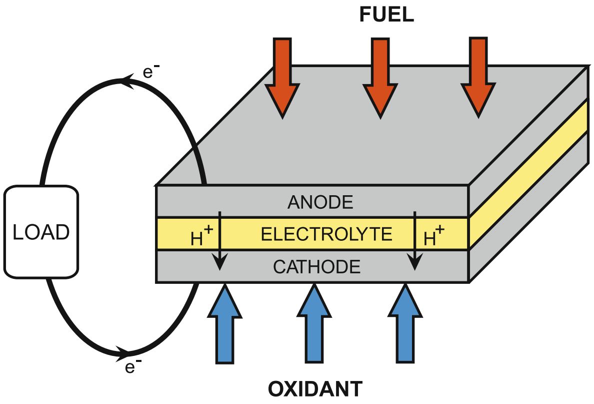
Laminar flow-based fuel cells; Membraneless fuel cells

Definition

Small ►fuel cells are considered a strong candidate for the next generation of portable power supplies. A microfluidic fuel cell is defined as a fuel cell with fluid delivery and removal, reaction sites and electrode structures all confined to microfluidic channels. This type of fuel cell can use both metallic and biological catalysts and normally operates without a physical barrier, such as a membrane, to separate the electrodes. Other types of small fuel cells, such as microstructured polymer electrolyte membrane-based fuel cells, will not be covered in this entry.

Overview

A fuel cell [1] is an electrochemical device that converts chemical energy stored in a fuel and an oxidant into electrical energy. The fundamental difference between a fuel cell and a battery is that fuel is supplied from outside the reaction chamber and waste products are removed. The heart of the fuel cell contains an anode and a cathode, separated by an electrolyte, as shown in Fig. 1. Its operation is conceptually straightforward. The fuel is oxidized at the anode, releasing protons (H^+ ions) and electrons. The protons travel through the electrolyte, which conducts ions but is electrically insulating, and recombine with the oxidant at the cathode. The electrons, that are required for the cathodic reaction, are conducted from the anode to the cathode through external wiring, thereby generating an electrical current used to drive a load. The electrochemical reactions are heterogeneous and facilitated by an electrochemical solid-liquid interface. Fuel cell electrodes are commonly made porous in order to establish three-phase contact: the solid phase that conducts electrons to or from the electrode, the liquid or gaseous fuel



Microfluidic Fuel Cells, Figure 1 Basic fuel cell design showing its core components: anode and cathode separated by an electrolyte and connected to an external load

or oxidant phase, and the liquid or solid polymeric electrolyte phase; all three phases need to be in contact at the active sites to facilitate heterogeneous electrochemical reactions that produce a useful current. Although energy is released in a fuel cell, the reactions are typically slow and have large activation energy that needs to be supplied for the reactions to proceed. There are three main ways to enhance the reaction rates: the use of catalysts, raising the temperature, and increasing the effective electrode area by incorporating microstructured materials. Most fuel cells operate at low temperatures and therefore require an electrochemical catalyst to reduce the activation energy of the chemical reactions. The choice of catalyst depends on the fuel or oxidant. Platinum is arguably the best electrocatalyst available for a wide range of reactants, in particular for hydrogen and oxygen. Other transition metals such as palladium and ruthenium, or combinations of these with platinum, provide good catalytic properties for formic acid and methanol oxidation. The performance of a fuel cell is normally quantified in terms of cell voltage (ΔE_{cell}), and current density (i). Cell voltage is defined as the difference in electrochemical potential between cathode and anode, with a maximum at the reversible open-circuit voltage ($E_{\text{cathode}} - E_{\text{anode}}$). This maximum voltage can be calculated from the Gibbs' free energy of the reactants and products at their standard states. The actual cell voltage achieved is in practice significantly lower than the reversible potential due to various losses (also referred to as overpotentials). The operational cell voltage is determined by Eq. (1)

$$\Delta E_{\text{cell}} = (E_{\text{cathode}} - E_{\text{anode}}) - |\eta_{\text{anode}}| - |\eta_{\text{cathode}}| - iR_{\text{cell}} - \eta_{\text{trans}} \qquad (1)$$

where the last four terms correspond to losses caused by activation overpotentials due to irreversibilities at the electrodes (η), ohmic resistance of the cell (R_{cell}), and concentration overpotentials from mass transport limitations (η_{trans}). Power density (mW cm^{-2}), which is an overall measure of fuel cell performance, is obtained by multiplying cell voltage and current density (current output divided by the geometrical surface area of the electrode).

Fuel cells that utilize biological catalysts are collectively termed ►biofuel cells [2, 3]. There is a common misunderstanding that biofuel cells are named as such because they use biological fuels, which is ambiguous as the same fuel (e. g., methanol) can be produced from both biological and non-biological sources. That said a biofuel cell mimics electrochemical processes occurring in nature to harvest a useful electrical current, without the use of precious electrocatalysts such as platinum. The oxidative metabolism of ethanol in the human liver, principally catalyzed by the alcohol and aldehyde dehydrogenase enzymes, exemplifies a bioanodic process. There are two main categories of biofuel cells: microbial biofuel cells and enzymatic biofuel cells. Microbial fuel cells utilize entire living cells or microorganisms combined with redox intermediates to catalyze the oxidation of a fuel. Enzymatic biofuel cells, on the other hand, catalyze the chemical reactions by biological redox enzymes that can be isolated and purified from suitable organisms, thus extracting the actual part of the cell that enables catalytic operation. Batches of enzymes can be produced by standardized methods from naturally abundant organisms using low-cost fermentation techniques. The enzymatic type of biofuel cell is preferable from an engineering perspective, due to its relatively high power density, compatibility with fluidic networks, and ease of miniaturization. Redox enzymes have an important advantage compared to traditional electrocatalysts: their selectivity towards a specific substrate (fuel). Each enzyme is coupled to the decomposition of a particular substrate, and the presence of other substances in its vicinity does not (in general) influence the turnover rate (the rate at which it oxidizes or reduces the substrate). The specific nature of biocatalysts is particularly attractive from an engineering perspective as both fuel and oxidant may share a fluid delivery manifold. Further advantages include: biocatalytic enzymes are available for a variety of substrates; the optimum temperature for enzymatic activity is near ambient; and the inherent overpotentials for biocatalysis are generally low.

Many different types of fuel cells are currently under development, with a variety of targeted applications ranging from miniature power supplies to large-scale combined heat and power plants. With the exception of limited small scale commercialization of some stationary units, most of

these fuel cells have not yet been commercialized past the field trials stage. Small fuel cells for portable electronic equipment are considered rather close-to-market for a number of reasons: it is unlikely that the technical development of batteries will keep pace with the accelerating power demands; small, microstructured fuel cells have higher energy density than batteries; and the market for portable electronics has an inherently higher cost tolerance. There are still some technical challenges, though, related to small fuel cell development. Hydrogen-based fuel cells require hydrogen storage units that are currently too bulky for portable device applications, and alcohol-based fuel cells, with compact fuel storage solutions, suffer from reduced cell voltage due to fuel crossover from anode to cathode.

In this entry, we describe how established fuel cell principles can be combined with microfabrication techniques and microfluidic networks to develop alternative microfluidic fuel cells using both metallic and biological catalysts, and how they can be operated without polymer electrolyte membranes.

Basic Methodology

Microfluidic fuel cells, sometimes called laminar flow-based fuel cells or membraneless fuel cells, describes a group of fuel cells capable of operation within the framework of a microfluidic chip. This type of fuel cell utilizes the laminar flow characteristic of microfluidics to delay convective mixing of fuel and oxidant. Two aqueous streams, one containing the fuel (anolyte) and one containing the oxidant (catholyte), are allowed to flow side-by-side down a single microfluidic channel (see Fig. 3, 4). The lack of convective mixing ensures the separation of the streams without the use of a physical barrier such as a membrane. The anolyte and catholyte also contain supporting electrolyte that facilitates ionic transport within the streams, thereby eliminating the need for a separate electrolyte. Mixing of the two streams occurs by transverse diffusion only, and is restricted to an interfacial width at the center of the channel. This inter-diffusion region has an hourglass shape, with a maximum width at the channel walls scaling as the cube root of diffusion coefficient (D), channel height (H), downstream position (z), and inverse mean velocity (U):

$$\delta_x \propto \left(\frac{DHz}{U}\right)^{\frac{1}{3}} \tag{2}$$

Anode and cathode are integrated on the walls of the manifold sufficiently far away from the co-laminar inter-diffusion zone in order to prevent fuel crossover. As will be discussed later, the placement of the electrodes also influences fuel utilization as well as ohmic resistance in the channel.

The microfluidic fuel cell design avoids many of the issues encountered in polymer electrolyte membrane-based fuel cells: membrane humidification and degradation, water management, and fuel crossover, to name a few. In addition, the co-laminar configuration allows the composition of the anolyte and catholyte streams to be chosen independently, thus providing an opportunity to improve reaction rates and cell voltage. The open-circuit voltage can thereby be increased by tweaking the reversible half-cell potentials by pH modification of individual streams. For example, the reversible potential (E) of the oxygen reduction reaction

$$O_2 + 4H^+ + 4e^- \longleftrightarrow 2H_2O$$

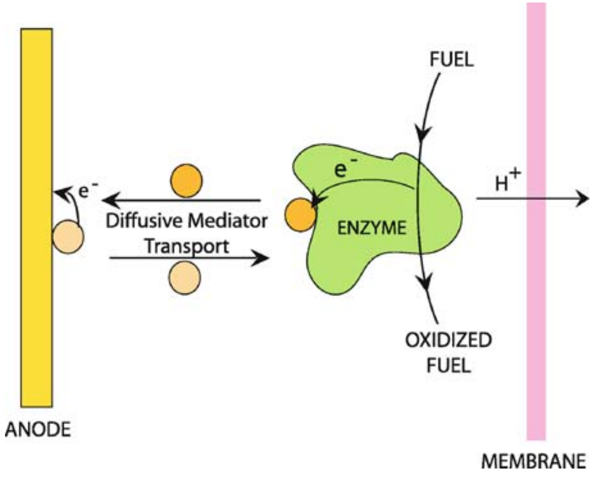
depends on pH according to the Nernst equation [1]

$$E = E^0 - \frac{RT}{F}\ln\frac{\coprod_{\text{products},i} a_i^{\upsilon_i}}{\coprod_{\text{reactants},j} a_j^{\upsilon_j}} = E^0 - \frac{RT}{F}\ln\frac{1}{a_{O_2}(a_{H^+})^4} \tag{3}$$

where E^0 is the reversible potential at standard state and a the activity of each species ($a = 1$ at standard state), which for aqueous species can be approximated by the concentration. By reducing the pH of the cathode stream (adding more H^+), the cathodic reversible potential becomes more positive and thereby yields larger open-circuit cell voltage.

In addition to compactness, miniaturization of fuel cells has a further advantage: since electrochemical reactions are surface-based, the performance of the fuel cell benefits from a high surface-to-volume ratio, which scales as the inverse of the characteristic length. The most prominent benefit related to microfluidic fuel cells, however, is the economical aspect. Microfluidic fuel cells can be manufactured by inexpensive, well-established micromachining and microfabrication methods and the cost associated with membrane and auxiliary systems, which is significant for most other fuel cells, is eliminated.

Currently, microfluidic fuel cells are typically fabricated using standard photolithographic and soft lithographic methods, see for example Kjeang et al. [4] for a detailed description. In short, this fuel cell consisted of two layers: a structurally rigid base layer containing the electrodes, and a polymeric top layer containing the channel structure. A standard photolithographic technique using UV-light, transparent photomasks and spin-coated layers of photoresist was applied to etch custom gold electrode patterns on



Microfluidic Fuel Cells, Figure 2 Anodic half-cell of a biofuel cell based on biocatalytic enzyme proteins, fuel and redox mediators in solution

a commercial gold slide, used as the base layer. Catalyst was plated on the gold patterns by traditional electrodeposition, and electrical wiring was attached using conductive epoxy. Similar photolithography was used to produce a master with a positive imprint of the channel network patterned on a glass slide, and a copy of the master was cast and cured into a slab of PDMS to mold actual channels for the top layer. Holes were punched in the polymeric layer for fluid delivery and the two layers were plasma treated which renders hydrophilic surfaces and creates an irreversible seal upon assembly of the fuel cell.

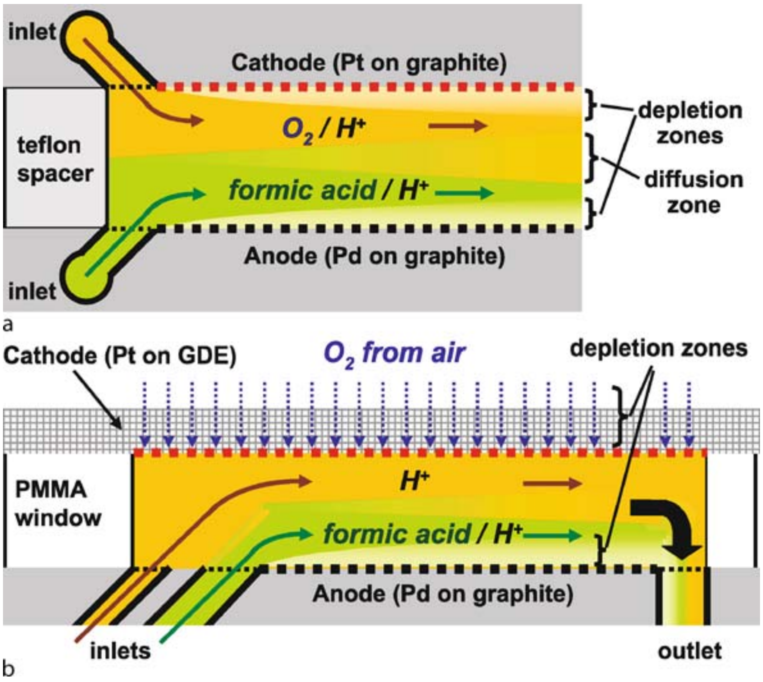
The microfluidic fuel cell design may also be implemented for biofuel cells based on enzyme catalysis. Enzymatic biofuel cells are traditionally compartmentalized into two half-cells separated by a salt bridge or ion exchange membrane [2]. Figure 2 shows the anodic half cell of a two-compartment biofuel cell based on mediated electron transfer. Enzyme proteins, fuel, and redox mediators are all dissolved in an ion-conducting electrolyte. In simplified terms, the enzyme (in the anodic compartment) oxidizes the substrate (fuel), thereby harvesting electrons. The enzyme cannot accumulate electrons internally. Instead, each oxidation event requires the docking of a cofactor (or redox mediator) in the proximity of the active site. The electrons are transferred to the cofactor, which is then released into the solution and allowed to diffuse to the electrode. This shuttling of electrons from the enzymes to the electrode can be carried out directly by the cofactor or in a relay with additional redox mediators. Depending on the type of redox mediator, the electrode may need to be functionalized with a self-assembled monolayer or film capable of oxidizing the redox mediator at low overpotentials.

Biofuel cells based on enzymes in solution are largely limited by the rate of diffusion of the intermediate species [2]. Furthermore, the lifetime of enzymes in solution is typically only a few days. These limitations can be addressed by immobilization of the enzyme directly on a conductive support (carbon or gold). Many immobilization schemes have previously been developed for biosensors including the following: self-assembled monolayer-functionalized electrodes with redox polymers and/or conductive polymers bound to the enzyme by covalent linking or affinity interactions combined with cross-linking; or direct encapsulation of enzymes in hydrogel films. Upon conformational fixation of the enzyme attributed to its immobilization, the stability (lifetime) may be extended to weeks or even months. Biofuel cells have more advanced requirements than biosensors however (fast electron transfer, low overpotentials, and maintained enzymatic activity), which makes the development of efficient immobilization schemes more challenging. Only certain types of enzymes, with active sites located on the periphery of the enzyme, are capable of direct electron transfer to the electrode without redox mediators [3].

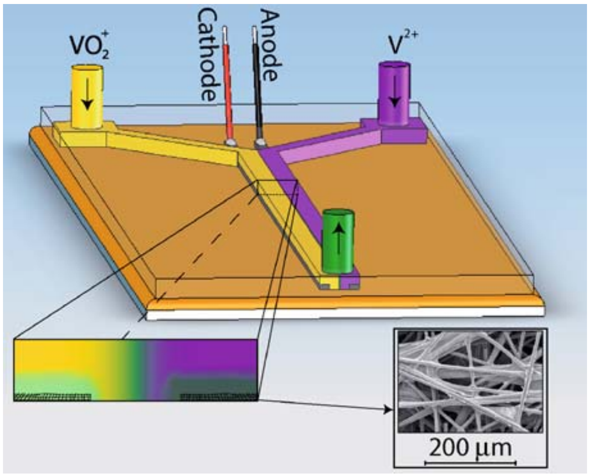
The immobilization of enzymes on conductive supports enables integrated microfluidic biofuel cell designs. Biofuel cells with non-selective electrochemistry, i. e. cells using diffusional redox mediators, can utilize the co-laminar microfluidic fuel cell design previously described, which also enables the tailoring of independent anolyte and catholyte compositions. Full selectivity of both anodic and cathodic half-cells, i. e. co-immobilized redox relays and enzymes based on suitable linking schemes with electronic coupling, allows microfluidic biofuel cell operation in a single, combined fuel and oxidant channel with mixed reactants.

Key Research Findings

Proof-of-concept microfluidic fuel cells have been developed based on hydrogen, methanol, formic acid, hydrogen peroxide and vanadium redox species as fuel. The majority of these devices employed a Y- or T-shaped channel design featuring two aqueous co-laminar streams with fuel and oxidant dissolved in a supporting electrolyte, similar to the one shown in Fig. 3a, with electrodes on opposite channel walls parallel to the inter-diffusion zone. The power density of these fuel cells was predominantly limited by the rate of mass transport to the active sites, typically in the cathodic half-cell. For cells using dissolved oxygen in the cathodic stream, the maximum power density reported to date, 5 mW cm^{-2}, was primarily restricted by the low solubility of oxygen (2 – 4 mM). One way to avoid this limitation is to integrate an air-breathing porous cath-



Microfluidic Fuel Cells, Figure 3 Microfluidic fuel cell designs with oxygen-saturated catholyte (**a**) and air-breathing cathode (**b**) Reproduced with permission from [5])



Microfluidic Fuel Cells, Figure 4 Schematic of a microfluidic vanadium redox fuel cell with porous carbon electrodes, using aqueous V^{2+} fuel (purple, dark grey in the print version) and VO_2^+ oxidant (yellow, light grey in the print version) (Reproduced with permission from [6])

ode structure that allows gaseous oxygen transport from the ambient air, a source of oxygen that has significantly higher diffusivity and concentration than dissolved oxygen. Jayashree et al. [5] introduced the first microfluidic fuel cell with integrated air-breathing cathode, shown in Fig. 3b. This cell used a graphite plate anode covered with Pd black nanoparticles and a porous carbon paper cathode covered with Pt black nanoparticles. Peak power density, 26 mW cm^{-2}, was achieved with 1 M formic acid in 0.5 M sulfuric acid anolyte and a blank 0.5 M sulfuric acid catholyte. The cathodic electrolyte stream was required to maintain an inter-diffusion zone with sufficient separation from the cathode and to facilitate ionic transport to the cathodic active sites.

The use of alternative oxidants, soluble at higher concentrations than dissolved oxygen, provides another avenue towards improved performance of mass-transfer limited microfluidic fuel cells. Kjeang et al. [4] evaluated the feasibility of a formic acid anolyte combined with a hydrogen peroxide catholyte. The electrodes consisted of Au strips that were plated with high-surface area dendritic structures of pure Pd (anode) and Pt on Pd (cathode) by potentiostatic electrodeposition. The power densities obtained with the hydrogen peroxide cell was similar to that of the air-breathing cell. An interesting side effect is the decomposition reaction of hydrogen peroxide into oxygen and water that occurs spontaneously on Pt and Pd, causing gaseous oxygen evolution on the cathode. This feature creates an instability leading to unsteady current generation. Interestingly, it also leads to enhanced time-averaged mass transport and reaction rates, and provides an alternative

source of oxygen that is not restricted by the solubility limit.

A microfluidic fuel cell design based on soluble vanadium redox species was recently introduced (Fig. 4). Vanadium redox fuel cells utilize two different aqueous vanadium redox couples, V^{2+}/V^{3+} and VO^{2+}/VO_2^+, as fuel and oxidant, respectively, dissolved in dilute sulfuric acid. This combination of vanadium redox pairs offers several advantages for microfluidic fuel cell operation: they provide well-balanced electrochemical half-cells in terms of reaction rates and transport characteristics; they have high solubility and enable relatively high redox concentrations up to 5.4 M; they have a large difference in formal redox potentials resulting in a high open-circuit voltage (up to ∼1.7 V at uniform pH); and the reactions are facilitated by plain carbon electrodes without requiring precious metal catalysts such as Pt or Pd. These advantages, together with the use of inexpensive microfabrication methods, enable very cost-effective fuel cell units with relatively high performance. Kjeang et al. [6] investigated the effects of high-surface area porous carbon electrodes for a microfluidic vanadium redox fuel cell (Fig. 4), and found that its performance was significantly improved compared to an otherwise similar cell with planar electrodes, attributed to enhanced rates of transport and increased active area. Using 2 M vanadium in 2 M sulfuric acid, a peak power density of 70 $mW\,cm^{-2}$ was obtained at 1 $mL\,min^{-1}$ flow rate per stream, which is the highest power density for microfluidic fuel cells reported to date. The fuel cell was operated at flow rates spanning four orders of magnitude, showing operational flexibility and durability. Operation in the low-flow rate regime (1 – 10 $\mu L\,min^{-1}$) resulted in single-pass fuel utilization up to 55%, with a corresponding decrease in power density. This high rate of fuel utilization was attributed to the high-aspect ratio geometry with electrodes perpendicular to the inter-diffusion zone (Fig. 4) and effective use of low-range flow rates. A consequence of the high-aspect ratio geometry is that the ohmic resistance in the channel is proportional to the average charge transfer distance between anode and cathode. For this reason, ohmic resistance in microfluidic fuel cells is generally higher than in membrane-based fuel cells due to a larger separation of the electrodes, but can be reduced by increasing the concentration of the supporting electrolyte.

The development of enzymatic biofuel cells has mostly focused on the immobilization of redox-active enzymes on conductive supports and the corresponding electron transfer mechanisms. It is common practice to present biofuel cell research findings based on individual bioanodes or biocathodes (versus a more conventional non-biological counter-electrode), and to extrapolate their feasibility towards fuel cell applications. In this entry, we focus on complete biofuel cells as well as advanced bioanodes and biocathodes developed exclusively for fuel cell applications. For more information on enzyme immobilization and linking schemes, see for example Katz et al. [2] and Bullen et al. [3].

Biofuel cells based on enzymes *wired* to tiny carbon fibers (7 μm diameter) have recently been introduced [7]. Cross-linked electrostatic adducts of enzyme were wired to the carbon fibers within a redox hydrogel comprising conductive polymer with complexed osmium redox centers. Glucose was oxidized by glucose oxidase at the anode and oxygen was reduced by bilirubin oxidase or laccase at the cathode. Operation of the fuel cell was shown in a non-compartmentalized configuration in a physiological buffer solution as well as in a grape with naturally available reactants inside its skin. The highest power density achieved was 0.48 $mW\,cm^{-2}$ at 0.60 V (in physiological buffer), which provides a good benchmark for biofuel cell development. The stability, however, was limited to the order of weeks. The laccase-based biocathode was also shown to outperform Pt as an oxygen reduction catalyst, due to its lower overpotential. The current generated by this biocathode was 90% limited by mass transport of oxygen at only −70 mV overpotential when operated in pH 5 citrate buffer.

Moore et al. [8] developed a bioanode based on NAD-dependent alcohol dehydrogenase enzymes immobilized in a tetrabutylammonium bromide treated Nafion membrane. A thin film of methylene green, which is an electrocatalyst for NADH oxidation, was electropolymerized onto a carbon ink electrode, upon which the enzyme/Nafion mixture was cast. The bioanode was assembled on a glass substrate under a PDMS microchannel that was used to deliver the fuel solution containing ethanol and NAD^+ in phosphate buffer. NADH was produced during the oxidation of ethanol by alcohol dehydrogenase in the presence of NAD^+. The NADH diffused through the membrane to the methylene green layer, where it was oxidized back to NAD^+ while transferring two electrons to the carbon electrode. The bioanode produced an open-circuit voltage of 0.34 V and a maximum current density of 53 $\mu A\,cm^{-2}$, expected to be limited by the rate of diffusion of NADH within the membrane, while operated versus an external Pt cathode. This performance was later enhanced by adding aldehyde dehydrogenase and NAD^+ to the previously described Nafion casting mixture suspended on a high-surface area carbon felt electrode. Power densities up to 2.0 $mW\,cm^{-2}$ were reached in a two-compartment U-cell setup with a Pt cathode. This bioanode was also paired with a bilirubin oxidase-based biocathode in a noncompartmentalized complete biofuel

cell arrangement [9]. The biocathode was assembled using a similar procedure with bilirubin and bilirubin oxidase suspended in the Nafion membrane together with preconcentrated $Ru(bpy)_3^{2+}$ redox mediator. The open circuit potential and maximum power density obtained with the membrane-less system (0.51 V and 0.39 mW cm^{-2}) were lower than for the corresponding two-compartment cell with a membrane separator (0.68 V and 0.83 mW cm^{-2}), due to incomplete specificity of the system. Enzymes encapsulated in a modified Nafion membrane are expected to have a lifetime of more than 90 days, though the lifetime of the biofuel cells was reduced to about 30 days due to the degradation of $Ru(bpy)_3^{2+}$.

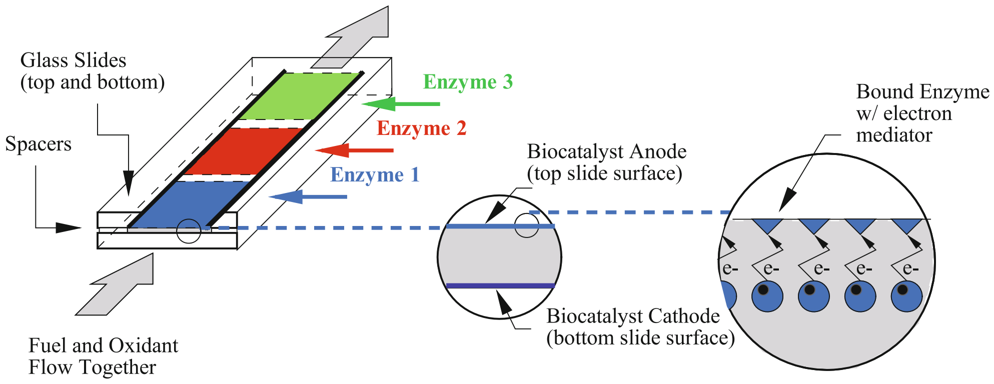
A swell of research interest in biocatalysis and biofuel cell technology is apparent from the large number of recent contributions in this area. The overall objective of biofuel cell research is still, however, to determine whether biofuel cells are real contenders for practical use. Some future directions for research in this area are described in the next section.

Future Directions for Research

The development of co-laminar microfluidic fuel cells to date has been tremendous, given that it is a relatively new invention. Research so far has resulted in operational devices with promising performance in terms of power density and open-circuit voltage, but little has been done in order to design practical, efficient and competitive devices with high energy density and high fuel utilization. The most prominent constraint identified for current microfluidic fuel cells is their low energy density, defined as energy output per system volume or mass. The core physics of the co-laminar flow configuration requires that both streams are liquid and contain an electrolyte. Although reactants may be added to the system at high concentration, the energy density of all devices presented hitherto has been low compared to other small fuel cells due to the impractical single-pass use of liquid electrolyte without any form of recirculation or recycling. The implementation of a recirculation system for the electrolyte is a challenging task, not only due to the space constraint. Dual outlets can partly solve this issue, but there will always be some degree of mixing of unused fuel and oxidants at the outlet(s) that would influence the open-circuit voltage negatively upon recirculation. Moreover, although fuel utilization data up to 55% per single pass have been presented, the fuel utilization at practical flow rates with useful power generation is generally less than 10%. Reaching overall fuel utilization beyond 20 – 40% is quite a challenging issue that may require an innovative system for separation and recycling of unused fuel and oxidant. In addition, there is a lack of engineering solutions for important functions such as the integration of fuel and oxidant storage solutions, waste handling, and low-power microfluidics-based fluid delivery (normally driven by a syringe pump via external tubing) using integrated micropumps and microvalves. In this context, the microfluidic fuel cells based on vanadium have an important advantage: the opportunity of regeneration. Provided that all reactants and products are vanadium redox species, the waste solutions could be collected from the outlet reservoir and transferred to an electrolytic cell that regenerates the initial fuel and oxidant species by an applied current (recharging), and when fully charged, transfer them back to the fuel cell for another discharge cycle. This technology would benefit from further research into the on-chip integration of a regeneration system with on-board reactant storage.

Another important engineering challenge is the scale-up and tailoring of electric current and voltage output from microfluidic fuel cell systems to meet the specific power requirements of target applications. Most research so far has been directed entirely towards the development of single cells, which despite a lack of optimization, is quite mature. The feasibility of scaling up a single cell, i. e. increasing the geometrical area of electrodes and microchannel, is mainly restricted by structural constraints introduced by flexible materials (e. g., PDMS), increasing inter-diffusion width, and escalating ohmic losses if the average distance between anodic and cathodic active sites becomes large. Stacking of multiple cells may be performed in both planar and sandwich configurations, and wired in either series or parallel configurations to match power and voltage specifications. Finally, the successful integration of well-developed and inexpensive microfabrication methods and MEMS technologies in order to reduce the cost of batch production is a key component for the development of competitive microfluidic fuel cells.

None of the biofuel cells presented to date have utilized microfluidic channels, despite the opportunity of improved performance by the addition of convective transport. Microfluidic designs would be particularly well-suited for biofuel cells using efficient oxygen-reducing biocatalysts, previously shown to be limited by the rate of oxygen transport. Furthermore, microfluidic networks enable the patterning of multiple, consecutive enzymes for the complete decomposition of fuels such as methanol to carbon dioxide. Figure 5 demonstrates a possible configuration. Kjeang et al. [10] projected in a modeling study of enzyme kinetics coupled with multi-component species transport in a microfluidic channel that consecutive enzymatic reactions may be engineered by strategic electrode patterning of multiple enzymes. A mixed enzyme pattern-



Microfluidic Fuel Cells, Figure 5 Microfluidic biofuel cell with consecutive reactions catalyzed by an array of different enzymes (Reproduced with permission from [10])

ing strategy that accounts for individual turnover rates was recommended, as intermediate fuel becomes available from previous reactions in the direct proximity of the consecutive enzymes further down the chain. A microfluidic system would also be favourable for stability studies since the reactant concentrations can be kept constant by continuous flow. Future research would benefit from an experimental study that demonstrates the capabilities of microfluidics with respect to biofuel cell development.

The performance of current bioanodes and biocathodes must be improved in order for microfluidic biofuel cells to reach their full potential and become competitive on the small fuel cell market. Improved immobilization and redox mediation schemes, more efficient wiring, improved alignment and orientation; all can help increase both stability and current density. Another possible avenue would be to identify and develop new enzyme proteins with higher turnover rates by genetic engineering. From a practical perspective, it is important to realize that early applications are going to be limited to specialized systems where the specific advantages of biocatalysis come into play. For example, biofuel cells are promising candidates for certain biochemical applications related to labs-on-chip or micro total analysis systems since they can use existing solutions specifically to generate power on-chip. Given their compatibility with physiological conditions, biofuel cells are also considered for low-power in vivo biomedical applications such as self-powered glucose sensors and power supplies for prosthetic valve actuators as well as skin-patch-based power sources for receiver-amplifier-transmitter units and miniaturized drug delivery systems. Implantable biofuel cells have effectively infinite energy capacity when utilizing blood-supplied glucose and oxygen available in the subcutaneous interstitial fluid. Unlike batteries, these devices can be miniaturized without packaging and sealing due to their non-compartmentalized operational characteristics. The combination of inexpensive microfabrication, low-cost enzymatic catalyst, and the absence of precious metals and other expensive components, would enable integrated biofuel cell units that can be disposed of and replaced at the end of their lifetime. Pending on the success of these specialized demonstrations, biofuel cells may be scaled up to meet the power and lifetime requirements of more widespread applications.

Definition

Mixing is the process by which uniformity of concentration is achieved. Depending on the context, mixing may refer to the concentration of a particular component or set of components in the fluid.

Overview

Importance of Mixing

A mixer is one of the basic building blocks in microfluidics, along with components such as pumps and valves, and is a critical component in several microfluidic devices. For example, mixing of reaction components is essential for providing homogeneous reaction environments for chemical and biological reactions. The efficiency of many devices such as biosensors depends on mixing. In other applications, rapid and controlled mixing is essential for studying reaction kinetics with much better time resolution as compared to microscale techniques. Microfluidic mixers are thus integral components essential for proper functioning of microfluidic devices for a wide range of applications.

Fundamentals of Mixing

In the context of microfluidics, mixing is the process through which uniformity of concentration is achieved. Depending on the application, the concentration may refer to that of solutes (ions, small molecules, biomolecules, etc.), solvents, or suspended particles such as colloids. Microfluidics typically involves incompressible aqueous or organic solutions, and we will consider only these systems here.

Molecules in solution undergo random motions, giving rise to the process of diffusion. Under a concentration gradient, diffusion results in flux (J) of molecules that tends to homogenize the concentration (c) of that molecular species.

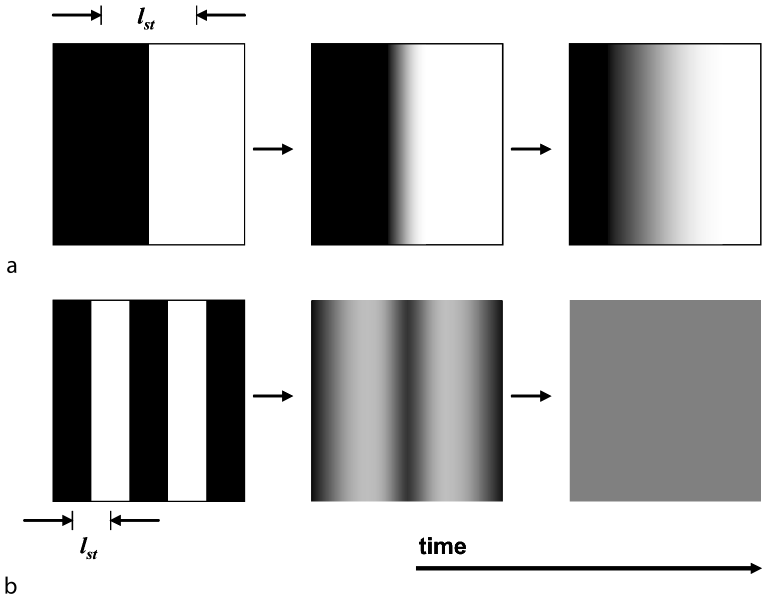
$$J = -D\nabla c \qquad (1)$$

Here D is diffusivity of the species under consideration, and varies from approximately 10^{-9} m^2/s for small molecules and ions to 10^{-11} m^2/s for large biomolecules. Therefore, an isolated system with non-uniform concentrations ultimately achieves a state of uniform concentration, i. e., it will be completely mixed. The mixing time depends on the diffusivity (D) and length scale over which diffusion must act in order to homogenize the concentration, known as the striation length (l_{st}). The mixing time is then given by

$$t_{mix} \sim \frac{l_{st}^2}{D} \qquad (2)$$

From this equation, it is clearly seen that for rapid mixing, it is necessary to reduce the striation length (Fig. 1). This concept leads to two ideas intimately connected with the process of mixing: (a) the process of decreasing the distance over which diffusion must act, and (b) the process of diffusion itself. The former process of decreasing the striation length is accomplished by stretching and folding of the fluid or by breakup and rejoining. These processes decrease striation length and increase the area across which diffusion takes place, thus enabling diffusion to rapidly homogenize the solution.

Mathematically, the concept of mixing is rather unwieldy, and is built upon the concepts of ergodicity and dynamical systems theory. The reader is referred to [1] for an introduction to the mathematical treatment of mixing, and



Microfluidic Mixing, Figure 1 Striation length (l_{st}) and mixing time. The striation length characterizes the distance over which diffusion must act in order to homogenize the solution. (**a**) An unmixed solution with a large striation length takes time to mix by diffusion alone. (**b**) A 5-fold reduction in the striation length decreases the mixing time 25-fold

to [2] for a comprehensive treatment. Here we describe two types of flows or transformations with a mathematical basis that aid in understanding and designing mixers: The Baker's transformation is useful for understanding mixing involving the process of breakup, and blinking flows are useful for understanding the process of mixing in designs that do not involve breakup.

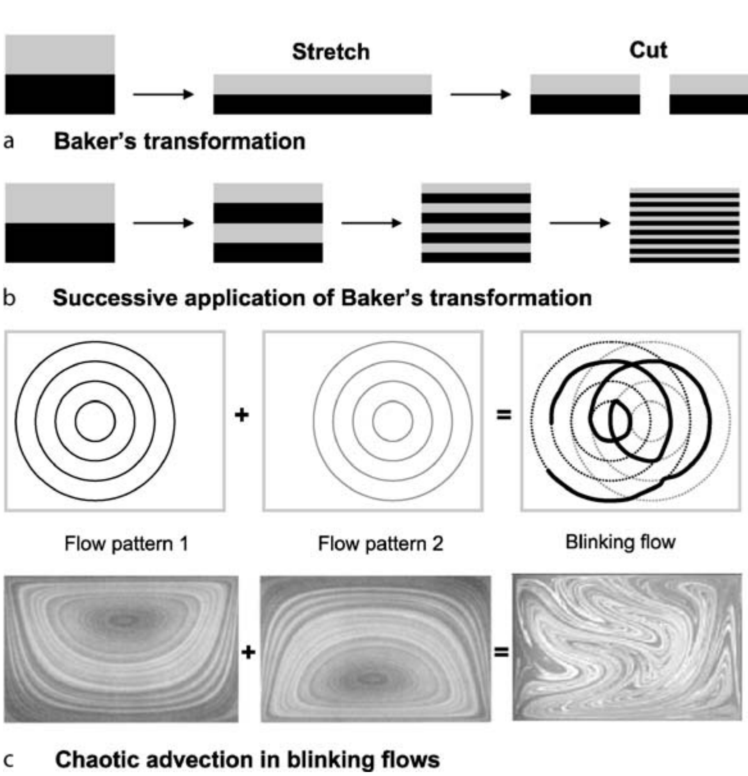
Consider a rectangular domain, with half of the domain marked with black points (Fig. 2a). The Baker's transformation consists of stretching, cutting, and rejoining such that the striation length decreases uniformly everywhere in the domain. In the first step, the domain is stretched uniformly in one direction. In the second step, the domain is cut and rejoined. The striation length decreases by a factor of two each time the transformation is applied, therefore an exponential decrease in the striation length is achieved (Fig. 2b). Mixing achieved in this transformation satisfies the strongest mathematical definition of mixing and is therefore highly desirable [1]. The Baker's transformation illustrates how the process of breakup can be used to exponentially decrease the striation length, and is useful for designing systems where fluid streams or droplets split and rejoin.

In a seminal paper in 1984, Aref [3] pointed out that simple time-varying two-dimensional flows can result in non-integrable particle trajectories, beautifully illustrated in the book by Ottino [2] (Fig. 2c). This concept was the starting point of what is now widely called chaotic advection. While chaotic advection is not precisely defined, it is associated with exponential stretching and folding of the fluid. Aref considered mixing in an idealized bounded two-dimensional domain with blinking flows. Blinking flows switch instantaneously from one streamline pattern to another in a periodic fashion. The relevance of this idealized concept to continuous-flow mixing in microfluidics is that flows transverse to the primary flow direction can be made to switch between two patterns as the fluid travels along the channel. Thus, a three-dimensional steady flow with periodicity in space may be understood in terms of a two-dimensional blinking flow with periodicity in time. An intuitive design criterion for such flows is that effective mixing corresponds to maximum crossing of streamlines of the two flows of the blinking flow. The mathematical basis of this design criterion is the linked twist map, described by Wiggins and Ottino [1]. Proper design of mixers incorporating the principles of chaotic advection can result in striation lengths that exponentially decrease in time.

Basic Methodology

Mixing in Microfluidics

The design and implementation of mixers in microfluidics differs considerably from than that on the macroscale. The small length scale leads to different physical phenomena being dominant at the microscale: First, inertial effects



Microfluidic Mixing, Figure 2 (**a**) Baker's transformation consists of stretching, cutting, and rejoining the domain. After each transformation, the striation length decreases by a factor of 2. (**b**) Successive application of the Baker's transformation results in exponential decrease of the striation length. (**c**) Blinking flows alternate periodically between two flow patterns. While each flow pattern exhibits simple streamlines and particle trajectories, the blinking flow itself exhibits chaotic advection and non-integrable particle trajectories. Images of cavity flow are reproduced from [2]

that typically result in turbulence and good mixing on the macroscale are weak in microfluidics, while methods of actuation based on electrokinetics, surface tension or other phenomena that are not relevant on the macroscale become feasible on the microscale. Secondly, many mechanical designs such as stirrers that can be easily implemented on the macroscale are very difficult to implement on the microscale. A useful mixer is therefore often the one that is simple to fabricate and integrate with other microfluidic components.

The Reynolds number (Re) characterizes the relative importance of inertial to viscous forces, and is given by

$$\mathrm{Re} = \frac{\rho U l}{\eta} \tag{3}$$

Here ρ is the density, U is flow velocity, l is the characteristic length scale (e. g., channel height), and η is the dynamic viscosity of the fluid.

In macroscale systems, the effect of inertia is often significant, resulting in a large Re and turbulence, which can be harnessed for mixing. However, due to the small channel size (l), microfluidic flows are characterized by a low Reynolds number, typically in the range of 0.01 to 100, and the effects of inertia are often negligible. Turbulence is therefore typically not encountered and microfluidic flows are usually laminar. Mixing due to diffusion alone is also not sufficient for rapid mixing in microfluidics. For example, a small molecule with a diffusivity of $10^{-9}\,\mathrm{m}^2/\mathrm{s}$ will take approximately 10 s to diffuse across a 100 µm microchannel, while a large macromolecule with a diffusivity of $10^{-11}\,\mathrm{m}^2/\mathrm{s}$ will require about 1000 s.

The Peclet number (Pe), a dimensionless number that characterizes the relative importance of diffusion to convection, is often used in the context of mixing of continuously flowing streams. The Peclet number is given by

$$\mathrm{Pe} = \frac{l^2/D}{l/U} = \frac{t_{\mathrm{diff}}}{\tau_{\mathrm{conv}}} = \frac{lU}{D} \tag{4}$$

Here D is diffusivity, l is the characteristic length scale (typically channel height) and U is the flow velocity. The Peclet number can thus be viewed as the ratio of characteristic time for diffusion (t_{diff}) to the characteristic convection time (τ_{conv}). When mixing occurs only

via diffusion in a microchannel with a flat velocity profile, $t_{mix} = t_{diff} = \tau_{conv}\mathrm{Pe}$. The channel length required for mixing (l_{mix}) is then given by

$$l_{mix} = U\,t_{mix} = l\,\mathrm{Pe} \qquad (5)$$

A linear relationship between the mixing time and the Peclet number implies that the channel length needed for mixing increases linearly as the flow velocity is increased, or as the diffusivity is decreased (for different species). In order to minimize the channel length required for mixing, it is desirable to design mixers in which the mixing time increases only weakly with the Peclet number. For a microchannel with $l = 100\,\mu\mathrm{m}$, the Peclet number is 1000 for diffusivity (D) of $10^{-9}\,\mathrm{m^2/s}$ (typical of small molecules) and flow speed of 1 mm/s. If mixing occurs purely due to diffusion, the channel length must be 1000 times the channel height for two streams to mix in the channel, i. e., the channel length must be 10 cm. However, if larger biomolecules with a diffusivity of $10^{-11}\,\mathrm{m^2/s}$ are to be mixed, the required channel length increases 100-fold to 10 m!

Clearly, in the absence of turbulence, other methods of microfluidic mixing must be devised. Since mixing ultimately occurs by diffusion, the goal of all mixers must be to decrease the striation length across which diffusion takes place in order to mix more efficiently.

Mixer Performance

The criteria used to measure mixing vary widely. One of the more common measures for mixing known as the mixing variance coefficient (MVC) [4] is based on the concentration distribution inside the channel or volume. For this purpose, the volume under consideration is divided into sub-volumes, and the deviation of concentrations in each sub-volume from the average concentration in the volume is computed as follows:

$$MVC = \frac{1}{N}\sum\left(c_i - c_{avg}\right)^2 \qquad (6)$$

Here N is the number of sub-domains, c_i is the concentration in the ith sub-domain, and c_{avg} is the average concentration for the entire domain. MVC approaches zero when mixing is complete. Division of the domain into sub-domains for computing the MVC is shown in Fig. 4a.

Experimentally, a commonly used method for characterizing mixing uses chemical reactions with fast kinetics. Such reactions may include reactions such as ion-binding fluorescent dyes that change fluorescence intensity upon binding the ion or pH indicators that change color. However, it must be noted that mixing characterized using these methods depends on reactant concentrations as well as diffusivities. Therefore, care must be exercised when attempting to evaluate mixing of the molecular species of interest using other species as indicators.

The criteria for evaluating the performance of microfluidic mixers vary widely depending on the application. However, for many applications, the most important criterion that determines the usefulness of the mixer is ease of fabrication. Mixers that can be easily incorporated with other microfluidic components are more likely to be used than those that require special fabrication procedures. Active mixers are generally more difficult to fabricate than passive mixers, and therefore find use only in certain applications. Apart from ease of fabrication, different applications may have different requirements that may be used to judge the performance of the mixer. Applications such as study of reaction kinetics demand rapid mixing and ease of observation of the ensuing reaction. Here, the primary consideration is usually mixing time. For combinatorial synthesis or other applications, it may be necessary to have a small space footprint and ease of integration with other components. In certain cases, pressure drop in the mixer may be important.

Key Research Findings

Mixer Classification

Mixers are broadly classified as active or passive mixers based on the method of actuation. Active mixers employ *active* elements such as external pressure perturbations, small actuators, or other methods in addition to the applied pressure that drives flow. Passive mixers rely solely on the pressure gradient (or other mechanisms such as electroosmosis) that drives the flow in combination with *passive* elements such as channel geometry or other properties in order to achieve mixing. Note that the definition of passive mixers applies only to continuous flow systems, and mixers that mix stationary and bounded volumes of fluid are typically active mixers. Some passive mixers may operate at moderate Reynolds numbers and use inertial effects for mixing, while others use channel geometry or other effects to mix effectively at low Reynolds numbers. Typically, passive mixers are easy to fabricate and more robust than active mixers, and are therefore more widely used by researchers. Other methods of classification may be based on the physical phenomena driving the flow (electrokinetics, magnetohydrodynamics, ultrasound, inertia, etc.), single phase or multi-phase flows, fabrication complexity, continuous flow versus discrete volumes, etc. The following sections classify mixers as active/passive and further based on flow patterns, and other classifications are either self-evident or pointed out in specific cases of interest.

Passive Mixers

Passive mixers may be broadly classified as focusing/injection mixers, lamination mixers, and chaotic advection mixers. Focusing/injection mixers rely on diffusion alone to cause mixing. These mixers are effective if one stream with a small flow rate is to be diluted into another stream with a large flow rate. Lamination mixers typically split the streams to be mixed into multiple streams that are then interdigitated and brought together. Splitting into several streams decreases the striation length and therefore enhances mixing. In these cases, the striation length remains fixed during the process of mixing, and mixing time is approximately independent of the flow rate. Chaotic advection mixers, on the other hand, cause exponential thinning of the striation length. Achieving chaotic flows in passive microfluidic mixers typically requires three-dimensional channel geometry, use of weak inertial effects, or two-phase flows.

Focusing/Injection Mixers

Focusing or injection mixers are not true mixers; rather, they are very efficient at diluting one stream in another. In the hydrodynamic focusing mixer, three streams converge and flow into one microfluidic channel. Fig. 2a shows a cartoon of the hydrodynamic focusing mixer [5]. The inlet stream can be focused into a very thin stream by the adjoining side streams, either by controlling pressures of the three streams or by controlling the flow rates of each stream using a syringe pump. Sub-micron focusing of the inlet stream enables species from the side streams to rapidly diffuse into the focused stream. Homogeneity of concentration is achieved as far as species in the adjoining streams are concerned. However, species in the focused stream take much longer to distribute uniformly across the channel cross section. Mixing time in this mixer depends only upon the width (w_f) of the central focused stream, which defines the striation length in this case:

$$t_{mix} \sim \frac{w_f^2}{D} = \left(\frac{w_f}{l}\right)^2 \tau_{conv}\mathrm{Pe} \qquad (7)$$

It is seen that mixing time scales linearly with the Peclet number. However, the mixing time is decreased dramatically since $w_f \ll l$. For $D = 10^{-9}\,\mathrm{m^2/s}$ (typical of small molecules or ions) and $w_f = 100\,\mathrm{nm}$, the mixing time is only $10\,\mu\mathrm{s}$. This mixer is a very effective tool for rapidly changing the chemical environment of species in the central focused stream, at the same time consuming a smaller sample volume due to the low flow rate of the inlet stream. Hydrodynamic focusing mixers find applications in the study of fast kinetics such as protein folding.

Injection mixers are similar to flow focusing mixers in that they also dilute one stream into another stream; however they differ from focusing mixers in that a small aperture is used to inject a thin stream into another stream. These mixers enable multiple flow streams to be injected, and may be more desirable when flow rates or pressures cannot be controlled. Mixing time depends on the method of injection and device geometry. However, construction of small apertures or the use of a membrane with apertures is required, making injection mixers harder to fabricate compared with focusing mixers.

Lamination Mixers

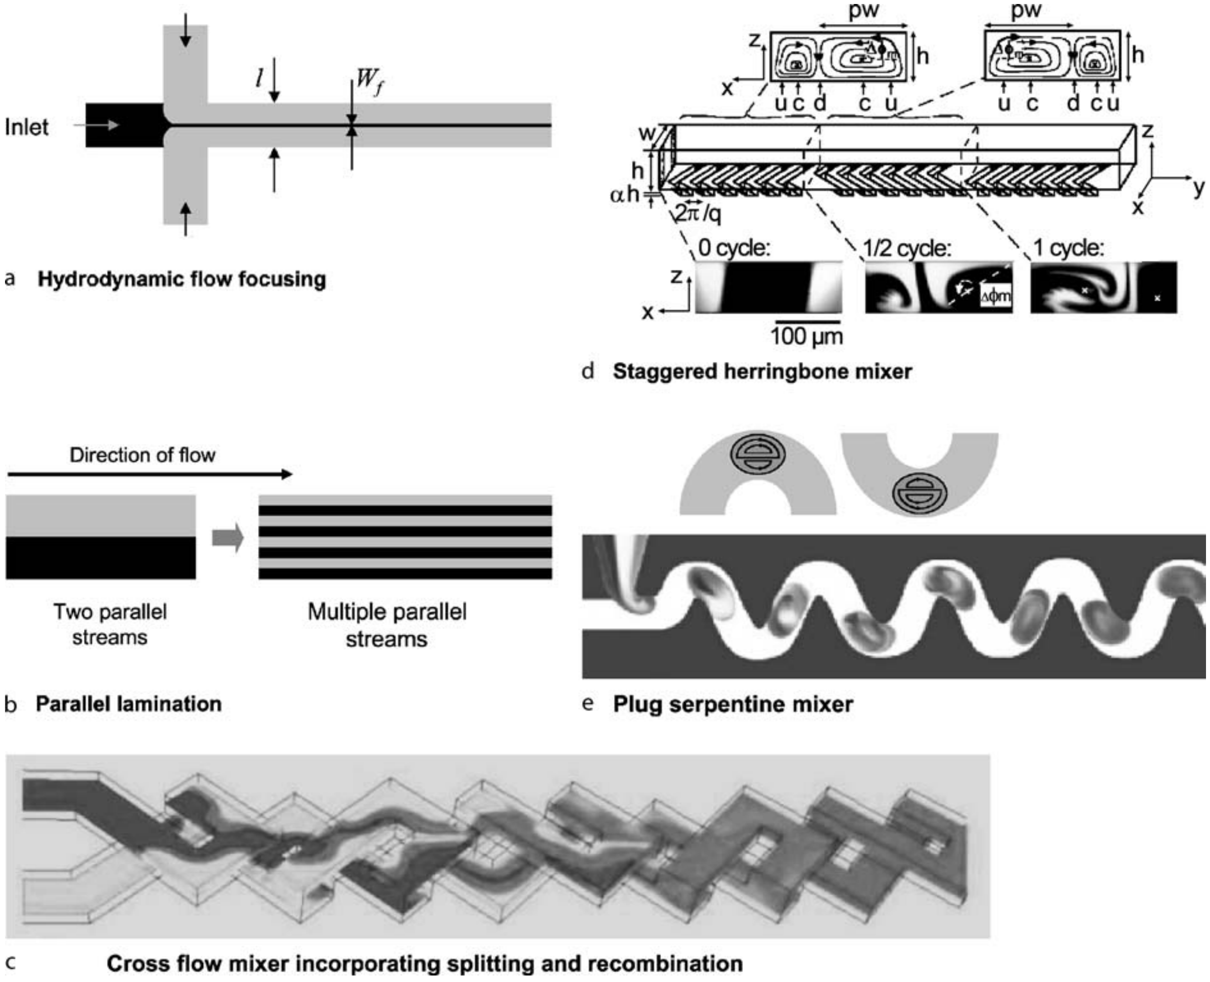
Lamination mixers employ parallel lamina across which diffusion can take place. The simplest mixer is the classic T-mixer that brings together two fluid streams and allows diffusive mixing as they flow parallel in a channel. In the absence of turbulence, the effective striation length is of the order of the channel size. Therefore, the mixing time in this case is given by

$$t_{mix} \sim \frac{l^2}{D} = \tau_{conv}\mathrm{Pe} \qquad (8)$$

Mixing time scales linearly with the Peclet number, and mixing time is equal to the characteristic time for diffusion across the channel cross-section. This mixer requires long mixing times, but is very simple to implement and hence becomes a practical multi-purpose mixer in cases where there are no severe demands on mixing time and channel length. An improvement over the T-mixer is the parallel lamination mixer (Fig. 2b). This mixer splits the streams to be mixed into multiple streams, which are interdigitated and recombined. If each stream is split into N streams, the striation length is decreased by a factor of N and mixing time is consequently decreased by a factor of N^2.

$$t_{mix} \sim \frac{(l/N)^2}{D} = \frac{\tau_{conv}\mathrm{Pe}}{N^2} \qquad (9)$$

For example, with $D = 10^{-9}\,\mathrm{m^2/s}$, $l = 100\,\mu\mathrm{m}$, and $N = 10$, the mixing time decreases from approximately 10 s to just 100 ms, and the channel length required for mixing also decreases by two orders of magnitude. This mixer is therefore more effective than the T-mixer, even though mixing time scales linearly with the Peclet number. However, interdigitation involves crossing over of channels, requiring a two-level fluidic architecture that is harder to fabricate than the single-level fluidic architecture of the T-mixer.



Microfluidic Mixing, Figure 3 (**a**) Hydrodynamic flow focusing mixer. (**b**) Concept of parallel lamination. Rapid mixing is achieved by splitting two streams to be mixed into multiple parallel streams, thereby decreasing the striation length. (**c**) A passive chaotic advection mixer employing splitting and recombination. (from [7]) (**d**) Staggered herringbone mixer uses grooves on channel walls to drive chaotic advection in microchannels. Alternating groove patterns result in asymmetric circulating flows similar to blinking flows. (from [8]) (**e**) Plug serpentine mixer uses a curved microchannel to induce chaotic advection inside plugs (droplets). Inset cartoon depicts alternating flow patterns inside individual plugs as they traverse through the channel. (from [9])

Passive Chaotic Advection Mixers

Proper design of mixers incorporating the principles of chaotic advection can result in striation lengths that exponentially decrease in time. Since steady two-dimensional flows cannot exhibit chaotic advection [1], passive chaotic advection mixers need either three-dimensional geometries or use of weak inertial effects in order to achieve chaotic advection. Alternatively, flow in the third dimension can be imparted using two-phase flows in channels with two-dimensional geometries (i. e., obtained by extrusion of a two-dimensional pattern). Continuous flow chaotic advection mixers usually consist of repeating units that perform stretching and folding or breakup and rejoining operations in each unit. After each unit, the striation length decreases by a constant factor (e. g., by a factor of 2), and exponential decrease in the striation length is achieved as the fluid stream traverses multiple units. The mixing length scales only as the logarithm of the Peclet number, making chaotic advection mixers highly effective in mixing at high Peclet numbers (low diffusivity or high velocity). For example, consider a mixer in which the striation length decreases by a factor of two after every unit. If τ_{conv} is the time required to traverse one unit of the mixer,

$$l_{\mathrm{st}} = l\, 2^{-t/\tau_{\mathrm{conv}}} \tag{10}$$

Mixing may be said to be complete when the time required for diffusion across the striation length equals the time

required to traverse one unit of the mixer [6].

$$\frac{l_{st}^2}{D} \sim \tau_{conv} \tag{11}$$

The mixing time and mixing length are then given as follows:

$$\begin{aligned} t_{mix} &\sim \tau_{conv} \log \mathrm{Pe} \\ l_{mix} &\sim l \, \log \mathrm{Pe} \end{aligned} \tag{12}$$

It is thus seen that mixing time now scales logarithmically with the Peclet number instead of linearly as in the case of the T-mixer or flow focusing mixer.

Low Reynolds Number Chaotic Advection Mixers Microfluidic mixers can be designed to mix using the principles of chaotic advection even in the purely viscous flow regime. Xia et al. [7] reported a mixer that splits, reorients and recombines flows using crossing channels (Fig. 3c). While several mixers with three-dimensional geometries mix flows at intermediate Reynolds numbers, this mixer is one of the few mixers that can mix in the regime of purely viscous flow. The three-dimensional architecture is essential for reorienting the fluid elements before recombination. The mixer was fabricated using two-level microchannels using PDMS, a silicone polymer commonly used for fabrication of microfluidic devices. Good mixing was possible at very small Reynolds numbers down to 0.01.
Stroock et al. [8] reported a staggered herringbone mixer that uses grooves on channel walls to drive transverse flows. An asymmetric herringbone groove structure results in two asymmetric circulating flows in the channel. Circulating flows that alternate periodically along the channel are established by alternating the herringbone pattern (Fig. 3d). Effectively, it results in a time-dependent two-dimensional blinking flow with intersecting streamlines, resulting in chaotic advection. In this mixer, the mixing length was shown to scale logarithmically with Peclet number over a range of 6 orders of magnitude of the Peclet number. Unlike other chaotic advection mixers that require a two-level fluid architecture, this mixer only requires grooves on the substrate, greatly simplifying the fabrication process. This mixer has therefore found wide application in microfluidics.

Two-Phase Flow Mixers Three-dimensional geometries are inherently more difficult to fabricate than two-dimensional channel geometries. However, steady two-dimensional viscous flows are inherently integrable, and chaotic advection is not possible. Two-phase flows overcome this obstacle by introducing circulating flows inside fluid segments or droplets, which can be used to convert the inherently two-dimensional flows to three-dimensional chaotic flows under suitable conditions. The serpentine mixer reported by Song et al. [9] is the most prominent mixer in this category (Fig. 3e). This mixer consists of a wiggly serpentine channel in which droplets of one phase (usually aqueous) flow in another continuous phase (usually oil). When the droplets occupy nearly the entire channel cross-section, they are termed as plugs. As a plug traverses a serpentine channel, the flow inside each plug alternates between two flow patterns with crossing streamlines. This flow pattern results in chaotic advection and rapid mixing. The same principle can be applied to mix liquid segments separated by gas bubbles. Millisecond mixing timescales are possible with this mixer, and sub-millisecond timescale kinetics can be probed, making the it one of the fastest mixers for mixing fluid streams in any given flow ratio. While increasing flow speed can decrease mixing time, this mixer is limited by break-up of the plugs/fluid segments that occurs at high flow speeds. In order to sustain plug flows without breakup of the plug or bubble, surface tension (γ) must be sufficiently large compared to shear forces. This phenomenon is characterized by the Capillary number:

$$\mathrm{Ca} = \frac{\eta l U}{\gamma} \tag{13}$$

For $\mathrm{Ca} > 1$, plugs may be sheared into smaller droplets that destroy proper flow in the mixer. Two-phase mixers are well-suited for studying reaction kinetics because each plug or fluid segment acts as an individual reactor, and there is no dispersion along the flow direction. With increasing use of two-phase systems, this mixer has found wide application in areas ranging from chemical synthesis to biochemistry.

Intermediate Reynolds Number Mixers Based on Weak Inertial Effects While turbulence sets in at Reynolds numbers greater than about 2300, even at low Reynolds numbers inertial effects can induce transverse flows that impart three-dimensionality to a flow that is otherwise two-dimensional at lower Reynolds numbers. At still higher Reynolds numbers, inertial effects can produce flow separation, vortex formation, and vortex shedding. These effects can be harnessed for mixing, and proper design can even lead to chaotic advection at intermediate Reynolds numbers. The simplest mixer in this category is the serpentine mixer that consists of a zigzag channel. Sharp bends in the mixer create cross-flows that enhance mixing. Mixing is due to diffusion alone at Reynolds numbers below about 80, and it improves at higher Reynolds

numbers [5]. Another class of mixers based on Tesla structures employ in-plane splitting and recombination of streams and can mix at Re > 5 [5]. Liu et al. [5] reported a three-dimensional serpentine mixer that uses C-shaped segments. The device has two fluidic layers, and was fabricated in silicon and glass. Chaotic advection was found to occur at Reynolds numbers higher than 20. Mixers operating at intermediate to high Reynolds numbers are especially useful when comparatively high flow rates are required, such as in chemical synthesis. However, these mixers are typically not used for biological applications, where the samples are usually smaller and more expensive.

Mixers Based on Other Instabilities Mixing in turbulent flows that occur at high Reynolds numbers is an illustration of mixing due to instability induced in the flow by inertial effects. Similarly, other phenomena may lead to instabilities in microfluidic flows and may be harnessed for mixing. The only known examples of mixing using other instabilities are the electrokinetic instability mixer and the viscoelastic instability mixer [6]. The electrokinetic instability mixer uses instabilities induced in the charged region at the junction of two fluid streams with differing ionic compositions when an electric field is applied parallel to the junction. The viscoelastic intability mixer exploits non-Newtonian fluid properties in order to achieve mixing.

Active Mixers

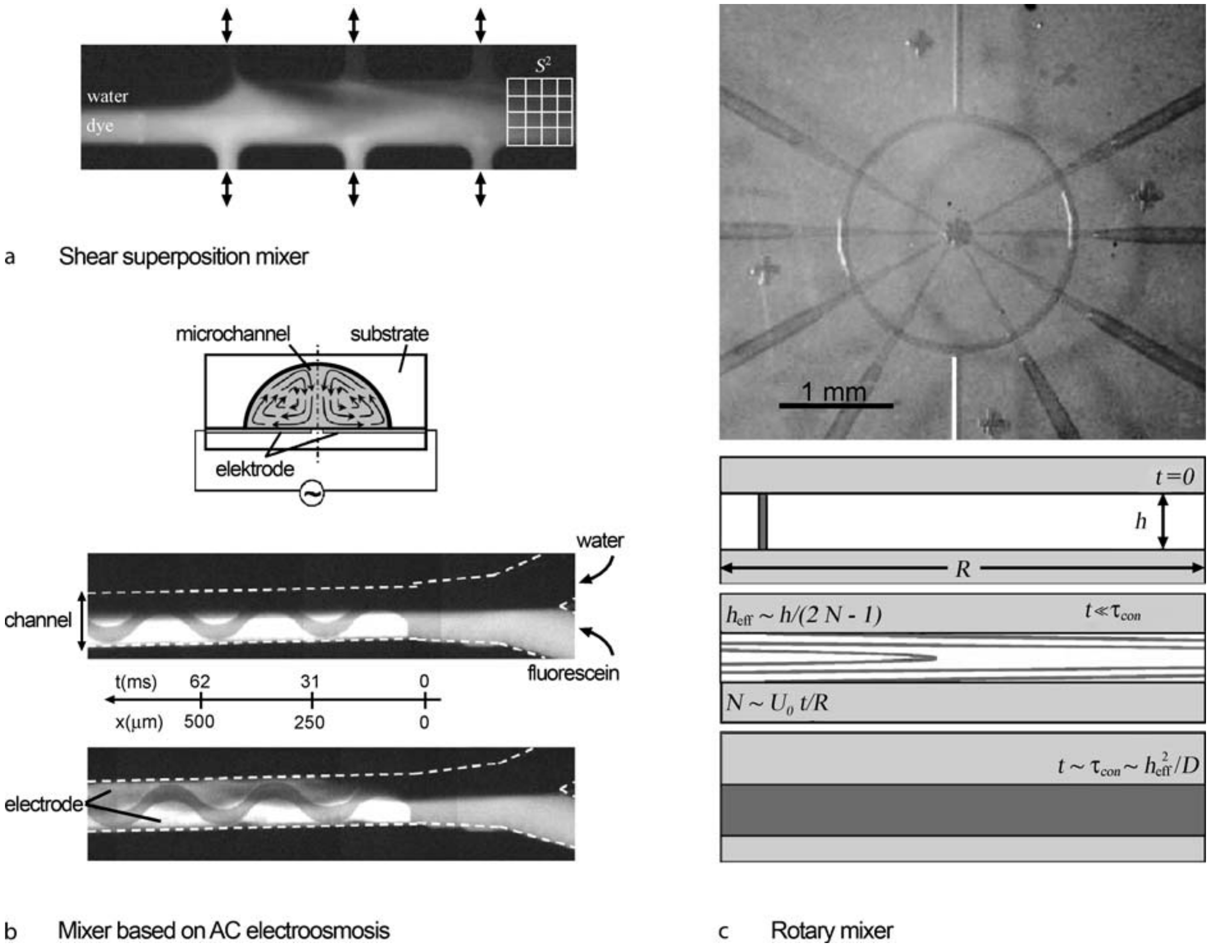
In addition to pressure gradients and inertial effects, several other mechanisms can be used to drive fluid flow for mixing. These mechanisms can range from simple pressure disturbances to more complicated systems utilizing miniature actuators.

Pressure/Velocity Field Disturbance Mixers These mixers rely on external pressure or velocity disturbances to change the flow pattern inside the channel and thereby enable faster mixing. Bottausci et al. [4] reported a shear superposition mixer that employs actuating side channels that are perpendicular to the main channel (Fig. 4a). An oscillating pressure or velocity disturbance in these channels affects flow in the main channel and causes mixing. With the correct choice of driving frequencies and amplitudes in the side channels, it is possible to induce chaotic advection and rapid mixing. Another simple design is a modification of the T-mixer. Instead of a steady flow in the two input channels, the driving pressure or flow rates are oscillated so that the mixing channel receives alternating longitudinal bands of fluid from each input channel. The parabolic flow then stretches these bands, algebraically decreasing the striation length and enabling faster mixing.

Rotary Mixer Rotary mixers [6] are very useful in integrated microfluidics, pioneered by the group of Stephen Quake. This microfluidic architecture uses a control layer of fluidic channels that can squeeze an underlying layer of channels, just as stepping on a garden hose clamps it shut. The operation of such elements requires a flexible material such as PDMS for device fabrication. A single element can function as a valve, and three elements operating together can function as a pump. With this basic design of externally actuated valves and pumps, it is possible to perform complex multiplexed fluidic manipulation. The mixer works by driving fluid flow in a circular microchannel using a pump. Fluid volumes to be mixed are first metered into the circular channel, forming bands shaped like arcs in the circular microchannel. Driving fluid flow around the circular channel results in linear stretching of the fluid inside the channel and the striation length decreases algebraically with time. Complete mixing can be achieved within one second. Rotary mixers are useful in such architectures for mixing metered volumes of fluid in a serial fashion or for continuous stirring in confined volumes, and have found applications in chemical synthesis and combinatorial screening.

Induced Field Electroosmosis Mixers Induced field electroosmosis (sometimes known as AC electroosmosis) is electroosmotic flow generated under AC excitation in an electrolyte solution due to tangential migration of induced charges at the electrode-solution interface. This method is relatively simple for driving fluid flow because it does not involve any moving parts and planar electrodes can be easily fabricated using conventional lithographic techniques. Sasaki et al. [10] demonstrated one such mixer that involves asymmetric patterned electrodes inside a mixing microchannel. AC electroosmosis drives asymmetric circulating flow that results in rapid mixing. Mixing was observed to occur in 0.18 s, approximately independent of the flow velocity and 20 times faster than that in the absence of AC electroosmosis. While this mixer was not designed for chaotic advection, induced field electroosmosis offers a wide variety of design possibilities by changing the device geometry. The main drawback of induced field electroosmosis is that it is sensitive to the presence of buffers and biomolecules in the solution.

Other Types of Mixers Apart from the methods described above, there are several different ways in which microfluidic flows can be driven [5]. Several of these methods have been used for microfluidic mixing including



Microfluidic Mixing, Figure 4 (**a**) The shear superposition mixer employs side channels to drive oscillating flow and induce chaotic advection in the main channel. The micrograph depicts six side channels mixing a stream of water and dye solutions in the main microchannel. The grid shown is used for computing mixing using the mixing variance coefficient (MVC). (from [4]) (**b**) A mixer based on AC electroosmosis to mix by driving asymmetric circulating flows inside a microchannel. Cartoon depicts circulating flow; water and dye streams are shown in the absence and presence of AC electroosmosis. (from [10]) (**c**) A rotary mixer uses pumps to drive flow in a circular microchannel. Algebraic stretching of the fluid results in a rapid decrease in the striation length (h_{eff}) and thus enables mixing. (from [9])

dielectrophoresis (migration of polarizable particles under an electric field gradient), electrokinetics (fluid flow driven by migration of charges at microchannel surfaces under an electric field along the channel), acoustic actuation, thermally generated bubbles, magnetohydrodynamics (flow in a current-carrying fluid in a magnetic field induced by Lorentz forces) among others. Most of these mixers are highly specialized and do not find broad applications.

Future Directions for Research

Recent years have seen rapid progress in application of the theory of mixing as well as in the innovative design of new microfluidic mixers. The design space available for innovation in this field is vast, and new mixers are constantly being developed. The mathematical foundations of mixing are being used to optimize the design of mixers. Theorists have developed models and guidelines for mixer design that can be easily adapted by researchers who use microfluidic mixers, but are typically not involved in the theory of mixing. In the future, we may see innovative mixer designs that are effective yet easy to implement, and rest on the mathematical foundations of mixing.

Definition

Microfluidic optical devices are classified into two groups of devices: (1) devices using microscale on-chip optical methods/components for biochemical sensing or for manipulation of fluids or particles in Lab-on-a-Chip devices; and (2) devices using microfluidics to manipulate light at the microscale.

Overview

Microfluidic optical devices (MODs) represent an emerging technology that combines today's microfluidics technology with optics. Devices based on optofluidics – manipulating fluids and light at the microscale – are examples belonging to this class of microfluidic devices. (An excellent review on optofluidics can be found elsewhere [1].)

In many biological applications, microfluidics and optics technology are already being used in combination: microfluidics for control and manipulation of samples and optics for sensing. However, MODs can be classified as the integration of these two technologies rather than the combination of them. This integration results in integrated detection systems for microfluidic application (which increases the portability of the entire system) [2–4], a sensitivity increase for the existing detection system [5, 6], cell manipulation [7–9], tunable optical fibers [10] and variable-focus liquid lenses [11].

Chabinyc et al. [2] succeeded in the integration of a fluorescence detector based on a microavalanche photodiode into a polydimethylsiloxane (PDMS)-based microfluidic device. Their detection system was reusable, and the microfluidic device was disposable. The elimination of the index matching problem which occurs in some micromachined devices, the elimination of the need for collection optics and the inexpensiveness are the superiority of the design. Those authors also addressed some further improvements for the performance of the device.

Mazurczyk et al. [3] fabricated an integrated fluorescence detection system with a microfluidic Lab-on-a-Chip device. Various arrangements were tested for the fluorescence beam detection: free space optics, fiber optics and fully waveguiding optics. Free space optics was found to have the higher sensitivity, but it needed a bulk microscope-based detection system. Fiber and fully waveguiding optics seemed to be a possible option to overcome the need for a bulk microscope setup, but their sensitivity was not found to be sufficient especially for high-sensitivity applications. Anyhow, those authors showed the feasibility of their device for electrophoretic separations by performing some preliminary experiments. They proposed usage of soda lime glass for the fabrication of their device and envisaged fabrication of more sophisticated systems.

Heng et al. [4] developed a novel on-chip microscope system, which was called an optofluidic microscope (OFM). The feasibility of the OFM was demonstrated. Its images were comparable to those of a conventional microscope. Those authors suggested the possible use of multiple OFMs on a single microfluidic chip either for increasing imaging throughput in the case of parallel usage or sequential imaging of the same target in the case of serial usage.

Camou et al. [5] used two-dimensional optical PDMS lenses to improve the performance of fluorescence spectroscopy detection carried out on a portable chip using optical fibers. The fibers were directly inserted into chan-

nels ending with PDMS optical lenses. Compared to convention flat interfaces, these optical lenses increased the intensity of the fluorescent response close to the fiber which leads to a higher sensitivity of the on-chip detection method for fluorescence spectroscopy. Chen et al. [6] implemented a simple, on-chip arrayed waveguide excitation and detection scheme based on scattering. Detected signals were processed, and not only was sensitivity enhancement observed, but particles moving with different velocities were also detected accurately.

Kruger et al. [7] proposed a miniaturized flow cytometer using the latest photonics technology to perform detection, enumeration and sorting of fluorescent species. They successfully performed sample injection, single-file flow through the detection system and sorting of fluorescent microbeads. They could not achieve fully autonomous cell sorting, but they indicated that as a future direction. They also demonstrated the feasibility of high-gain avalanche photodiodes for more sensitive measurements of fluorescent signals compared to conventional detection techniques.

Optical tweezers are devices that use the force of strongly focused light to trap and move small objects whose dimensions are below tens of micrometers. The exerted force range and the resolution for optical tweezers are very suitable for biological and macromolecular systems. They have been used in many applications [8]. A detailed review on optical tweezers can be found elsewhere [8]. Besides optical tweezers, Mandal and Ericson [9] illustrated the optical transport of microparticles in a liquid core waveguiding structure over long lengths, which has great potential for much more precise particle separation and particle transport without flow field manipulations. The light–particle interaction length of their proposed technique was orders of magnitude larger than that of existing systems.

Mach et al. [10] presented microfluidics-based fiber optics. They demonstrated a multifunctional all-fiber filter. They achieved independent tuning over a broad range of both transmission wavelength and attenuation by locating and manipulating the locations of microfluidic plugs with adjustable position and optical properties.

Another interesting application of microfluidics and optics is the use of variable-focus liquid lenses, which was developed by Philips Research Eindhoven [11]. The lenses which are composed of two immiscible liquids of different refractive indices can be manipulated by electrowetting. By electrowetting, the meniscus curvature of the lenses can be changed, which also changes the effective focal length of the lenses.

Ruano-Lopez et al. [12] demonstrated a simple, inexpensive, new and reliable fabrication process for optical Lab-on-a-Chip devices. They used SU-8 waveguides as sensing elements, and fabricated their cladding by diluting SU-8-50 in a liquid aliphatic epoxy resin.

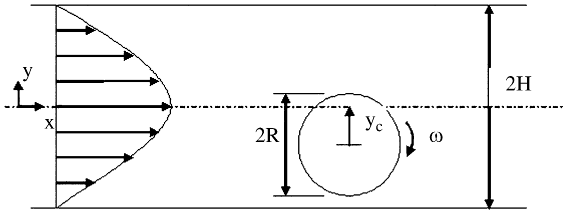
Definition

Conventional mechanical pumps based on centrifugal or axial turbomachinery are not suitable for micro and nano scales where the Reynolds numbers are usually small. Centrifugal and inertial forces are negligible, and viscous forces dominate the flow field in this length scale (an excellent review can be found on the physics of fluid flow at microscale in [1]). A microfluidic rotary pump, which is proposed by Sen et al. [2], is a device that is used for pumping fluids in microfluidic applications at extremely low Reynolds number. This miniature device consists of a rotating cylinder placed eccentrically inside a microchannel where the axis of the cylinder is perpendicular to the flow direction (see Fig. 1). Since it is placed asymmetrically, there exists a viscous resistance difference between the small and large gaps between the cylinder and the walls (i. e. unequally distributed shear force on the upper and lower surface of the rotating cylinder), which causes a net flow along the channel. They are capable of pumping very small flow rates which is desired for many medical and biological applications such as drug delivery.

Overview

The operation of the rotary pump depends on the viscous forces and can operate in any situation where viscous forces are dominant. Therefore, they are suitable for flow of low viscosity liquids in micro ducts as well as the flow of highly viscous liquids such as heavy polymers in macro ducts. Together with its simplicity from design point of view and this viscous nature makes rotary pumps suitable for scientific and industrial applications of MEMS (Micro-Electro-Mechanical-Systems), NEMS (Nano-Electro-Mechanical-Systems) and LOC (Lab-on-Chip) technologies.



Microfluidic Rotary Pump, Figure 1 Schematic drawing of microfluidic rotary pump. Eccentricity, $\varepsilon = y_c/(H - R)$. $\varepsilon = 0$ means the cylinder is at the center, $\varepsilon = 1$ means the cylinder touches the bottom wall

The channel height, eccentricity (i. e. degree of asymmetry, $\varepsilon = y_c/(H - R)$, see Fig. 1), Reynolds number, channel cross-section and the angular velocity of the rotating cylinder have the effect on the performance of the pump. These effects are extensively studied by many researches [2–8]. Sen et al. [2] first proposed the use of microfluidic rotary pump and conducted some experiments for circular, square and rectangular cross-section rotating rotors. 2D, steady [3] and transient [4, 5], and 3D, steady [6] numerical analysis of the rotary pump is studied for circular as well as the square and rectangular [5] cross-sectional rotors. Thermal effects due to viscous dissipation on pump performance are also analyzed by considering the temperature dependent fluid properties [7]. Closed form, analytical expressions are derived for the flow rate and pressure drop along the channel are derived by using lubrication approximation [8]. The effect of slip-flow boundary condition is also investigated [3]. Another challenging application of this eccentric cylinder inside a microchannel is proposed by DeCourtye et al. [6] as a microturbine which can be used as a microsensor for measuring exceedingly small flow rates in micro/nanofluidic applications.

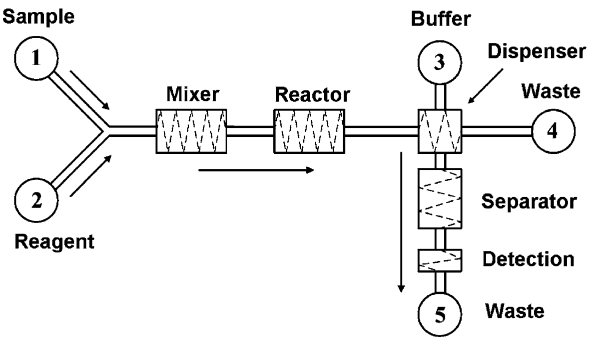
Definition

The term *microfluidic sample manipulation* refers to the processes involved in controlling the movement of small volumes of fluid or particles around a network of interconnected microchannels. These processes include sample introduction, injection, mixing, reaction, dispensing, separation, and detection, and are typically performed in a fully integrated micro total analysis system or a Lab-on-a-Chip device.

Overview

Recent advances in the field of microelectronics have made possible the miniaturization of microfluidic systems on a microchip to carry out analytical analytes. Such microfluidic systems are generally known as a Lab-on-a-Chip or a micro total analysis system (μTAS). These systems perform a complete, integrated, and automated analysis of the target analyze in a complex sample matrix. In general, μTAS devices are designed to carry out the following functions: sample introduction, injection, mixing, reaction, dispensing, separation, and detection. Figure 1 presents a schematic illustration of a typical Lab-on-a-Chip. The sample of interest is introduced via port 1 and subsequently interacts with a reagent injected via port 2. The sample is then mixed with the reagent to facilitate the subsequent chemical reaction process. Finally, the reacted product is dispensed into a separation channel for component separation and detection using optical instrumentation.



Microfluidic Sample Manipulation, Figure 1 Illustration of microfluidic components in typical Lab-on-a-Chip device

Basic Methodology

Sample Introduction/Storage/Injection

To support the requirements of typical biochemistry applications, current micro-analytical systems are generally designed to manipulate aqueous liquid samples. The sample introduction process includes both sample preparation and sample storage in a suitable reservoir. Four major categories of sample preparation can be identified: separation of the sample from the sample matrix, sample preconcentration, sample derivatization, and sample pretreatment. The original sample generally contains large organic or inorganic particles, which must be removed using some form of cell membrane rupture technique. If the sample analyte is only available in trace amounts, the sample is generally preconcentrated prior to analysis by squeezing the available analyte molecules into a smaller volume to enhance the detection sensitivity. Sample derivatization involves the chemical transformation of the analyte to render it detectable by the particular detection system employed in the microchip. In the biochemical domain, the biomolecules of interest are commonly pretreated by labeling them specifically or nonspecifically with fluorescent labels. In the genomic research field, the DNA sample is often amplified using either polymerase chain reaction (PCR) or cleavage by restriction enzymes. Following the sample preparation process, the sample is introduced into

the microfluidic chip via a reservoir. This reservoir is generally left open to enable the release of gas bubbles generated via electrolysis at the electrodes during electrokinetic manipulation.

The injection process introduces the prepared sample or reagent into the flowing carrier stream within the manifold. Ideally, the injector system should be designed so as to provide a high sample flow rate. Injection systems typically employ electrokinetic mobility or hydrodynamic pressure techniques. In the former systems, the sample flow into the microchannel is controlled by the application of an external electric field to the reservoir, while in the latter systems, a pressure difference is created in the reservoir using either a positive pressure (piston-type) technique or a suction pressure (vacuum) technique.

Mixing/Reaction

Mixing of two or more miscible fluids in microfluidic systems is important in a variety of applications, e. g., to achieve a homogenized solution of the reagents used in chemical reactions. Furthermore, biological processes such as cell activation, enzyme reaction, and protein folding commonly involve reactions which require the mixing of reactants for initiation. Achieving a rapid and efficient mixing effect is an essential but challenging task when developing microfluidic devices for chemical and biological analysis applications.

Since viscous forces dominate the flow in microfluidic devices and the flow is limited to the low Reynolds number regime, turbulence does not readily occur. In electrokinetically driven flow in microfluidic systems, the Reynolds number is typically less than unity (i. e., Stokes flow). In a conventional straight microchannel, the Stokes flow is generally unidirectional. Even in curved or twisted channels, the transverse flow component (i. e., the secondary flow) is very small compared to the streamwise component since the inertial effect is very weak. Therefore, mixing of two fluid streams within the microchannel takes place mainly as the result of molecular diffusion. The rate of diffusive mixing in microscale channels is very slow compared to the convection of the fluid along the channel since the Peclet number ($\mathrm{Pe} = Ul/D$, where U is the average flow velocity, l is the channel dimension, and D is the molecular diffusivity) of typical microchannel flows is very high. The diffusive mixing time is given by $\tau_D \sim l^2/D$ and the mixing length (L_m) along the downstream channel increases linearly with the Peclet number (i. e., $L_\mathrm{m} \sim \mathrm{Pe} \times l$). In practice, many biochemical applications, e. g., immunoassays and DNA hybridization, require the rapid mixing of macromolecules with relatively low molecular diffusivity (e. g., $40\,\mu\mathrm{m}^2/\mathrm{s}$ for small proteins). Typical values in conventional straight microchannel devices are that: an average electroosmotic flow (EOF) velocity is $500\,\mu\mathrm{m/s}$ and a channel dimension is $100\,\mu\mathrm{m}$, the mixing time and mixing length required to achieve a complete mixing are approximately 250 s and 125 mm, respectively. However, this mixing performance is unacceptable for rapid biochemical analysis in microfluidic systems. These values can be improved by increasing the interfacial contact area between the two species and reducing the diffusion length (l) between them. Adopting this approach, various micromixers have been developed to enhance the mixing effect in microfluidic systems. In general, these micromixers can be categorized as either passive or active in nature. Active mixers use either moving components or externally applied forcing functions to achieve mixing, whereas passive mixers induce a mixing effect simply by virtue of their particular geometry topologies or surface properties.

Mixing in micromixers relies primarily on molecular diffusion or chaotic advection (laminar chaos) mechanisms. As discussed above, the diffusive mixing effect can be improved by increasing the interfacial contact area between the different fluids and reducing the diffusion length between them. The use of unstable electrokinetic flow fields to achieve chaotic mixing effect can also be adopted.

Loading and Dispensing

In a microchip, the sample is transferred into the separation channel via pressure-driven or electrokinetically driven loading and dispensing processes. In microfluidic systems, the latter technique provides a particularly effective means of transporting reagents. The velocity of the EOF induced by electrokinetic driving schemes is governed by the Smoluchowski relation, i. e., $V_\mathrm{slip} = \varepsilon\varepsilon_0\zeta\nabla\phi/\mu$, where ε is the dielectric permittivity of the solvent, ε_0 is the vacuum permittivity, ϕ denotes the externally applied electrical potential, ζ is the surface zeta potential, and μ is the viscosity of the fluid. According to this relation, the EOF velocity is independent of the channel size and is governed primarily by the intensity of the applied electrical voltage.

Separation

Capillary electrophoresis (CE) is used to separate ionic species by exploiting their frictional forces and differences in the charges of the respective species. In traditional electrophoresis, electrically charged analytes move in a conductive liquid medium under the influence of an electric field. CE has proved to be highly successful in enabling the analysis of DNA fragments and other

biomolecules. Another commonly used method is the chromatographic technique which is performed in a chromatography column fabricated by immobilizing reversed-phase stationary-phase particles using sol–gel technology. In capillaries filled with a stationary phase the separation occurs on the basis of the different partition of the analytes between the stationary and the mobile phase. Applications include the separation of small neutral molecules, peptides, and proteins.

Key Research Findings

Sample Introduction/Storage/Injection

Before carrying out the analytical process, it is necessary to prepare the sample or reagent [1]. Since optical detection continues to be the method of choice, the compound of interest in the sample is generally labeled with fluorescent dye using a postcolumn reactor incorporated within the microfluidic system. Such a microfluidic system typically consists of a CE structure with an additional side channel intersecting the separation channel at right angles 6 mm downstream from the sample injection region. The labeling reagent is introduced through this channel and subsequently comes into contact with the separated analyte band. However, most species are not easily labeled. Hence, an alternative analytical method utilizing UV-visible absorbance detection and an electrochemical method has been proposed. Before a sample can be analyzed using this method, the species must be preconcentrated to ensure that trace amounts of the analytes can be reproduced quantitatively. The field amplification stacking (FAS) technique provides an effective approach for stacking analytes with a length of 400 μm, creating volume-defined sample plugs, and stacking a full column of the sample. In the FAS approach, preconcentration is achieved by generating a high electrical field within the injected sample plug in order to drive and stack sample ions at the end of the plug. Figure 2 shows a microchip structure for FAS [2], which allows the formation of comparatively long, volumetrically defined, sample plugs with a minimal electrophoretic bias.

Field-amplified injection (FAI) is an alterative preconcentration method. Although both methods are relatively straightforward in terms of their implementation, they are applicable only to the preconcentration of charged analytes. Accordingly, a number of recent studies have proposed methods for the stacking of neutral analytes for separation using micellar electrokinetic chromatography in fused silica capillaries. The polymerase chain reaction (PCR) is a fundamental technology in bioanalytical research. Microchips designed for the PCR (see Fig. 3) incorporate an etched reaction chamber with a volume of the order of several microliters [3].

Generally, the samples considered in microfluidic applications contain large organic or inorganic particles. Therefore, these particles must be removed prior to analysis to prevent fouling or blockage of the analytical system. Accordingly, various techniques have been proposed for separating the sample from the sample matrix, including physical filtering and retention of the particles using

M

integrated flow restrictors within the microchip, filtering by diffusion in laminar flow, microdialysis, liquid–liquid extraction, free-flow electrophoresis, cell lysis and purification.

Reservoirs are simply storage units designed to hold the reagents and samples used within the manifold. Reservoirs are commonly fabricated by drilling via holes into a flat glass plate using mechanical or (more commonly) ultrasonic methods and then bonding this plate onto a lower plate containing an etched or laser-ablated reservoir structure.

Electrokinetic injection schemes for microfluidic systems are generally designed to perform one of two different injection functions, namely time-based or discrete volume-based [4]. Time-based injection (also known as gated injection) allows for the introduction of the sample into the carrier stream over a controlled period of time. This technique has several key advantages, including a straightforward control and a variable injection volume, and allows for both continuous and sequential injection for on-line measurement applications.

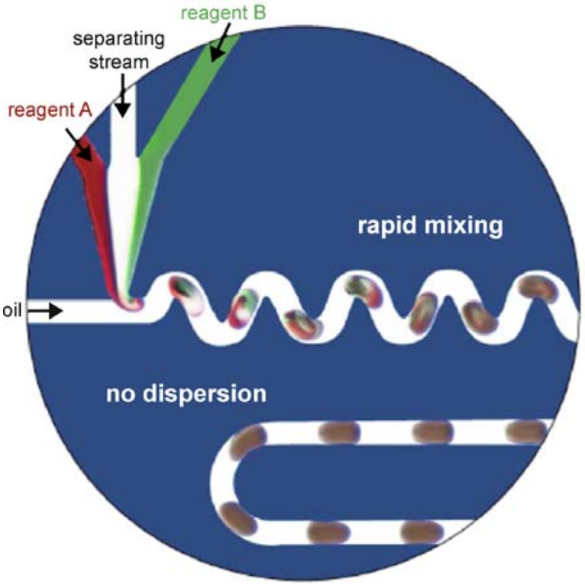
Mixing

Passive micromixers

Passive mixers can be categorized according to the arrangement of the mixed phases, i. e., parallel lamination mixers, serial lamination mixers, injection mixers, chaotic mixers, etc. [5].

Parallel lamination mixers split the inlet stream into two or more substreams, and then join them horizontally as individual laminae in a single stream. Such mixers commonly have the form of a long microchannel with two inlets arranged in either a T- or a Y-form configuration. Hydrodynamic focusing can also be used to reduce the diffusion length for parallel lamination mixers. In this technique, the microfluidic device is designed with three inlets. The sample (solute) flow is introduced through the middle inlet, while the solvent streams are fed through the side inlets and function as sheath flows to restrict the width of the sample flow and consequently to reduce the diffusion length. Knight et al. [6] have reported that the sample stream width can be focused to 50 nm, resulting in a mixing time of no more than a few microseconds. This rapid diffusion-based mixer has been successfully integrated with microfluidic platforms to enable the accurate description of fast reaction kinetics such as protein folding. Serial lamination mixers apply a similar approach to that of parallel lamination mixers. However, in this case, the inlet streams are joined horizontally in the first stage of the mixer and are then joined vertically in the following stage. Adopting a different approach, injection mixers split only the sample (solute) flow into many streams and then inject these streams into the solvent flow. Using an array of nozzles positioned over one of these streams, solute microplumes are produced which increase the contact area between the solute and the solvent and reduce the diffusion length between them.

In contrast to parallel lamination, serial lamination and injection mixers, chaotic mixers produce an effective increase in the interfacial contact area of the mixing species without splitting the inlet streams. Generally, chaotic advection is induced by manipulating laminar flow in microchannels via the use of specific topologies or surface properties. The resulting chaotic flow patterns cause the fluid elements to be repeatedly stretched and folded, resulting in a significantly increased interfacial contact area and a reduced diffusion length. Stroock et al. [7] have investigated the use of groove structures on the channel wall in pressure-driven chaotic advection mixing at very low Reynolds numbers. They considered two different groove patterns, namely a slanted groove structure and a staggered herringbone structure. The results showed that the latter structure provided a particularly significant improvement in the mixing performance at low Reynolds numbers. Various authors have successfully demonstrated electrokinetically driven mixers in which a chaotic mixing effect is induced by patterning the surface charge distribution on the microchannel walls [8, 9]. In addition, Song et al. [10] have proposed an efficient droplet-based reac-



Microfluidic Sample Manipulation, Figure 4 An example of chaotic mixing: mixing of discrete droplets moving in a twisted microchannel (reproduced from [4])

tor in which chaotic mixing occurs as discrete droplets move in a twisted microchannel at low Reynolds number, as shown in Fig. 4. The droplet-based reactors have been successfully demonstrated in the study of fast chemical kinetics.

Active micromixers

Active micromixers require an external disturbance energy source such as pressure, ultrasound, acoustic, electric, or magnetic fields [5]. These external disturbance functions generate chaotic flow patterns at low Reynolds numbers, resulting in a repeated stretching and folding of the fluid elements. Consequently, the interfacial contact area is increased and the diffusion length is reduced. Oddy et al. [11] have employed AC electric fields to induce an electrokinetic instability phenomenon in microscale channels. This instability phenomenon is similar to the electrohydrodynamic instability induced by AC or DC electric fields when an electrical conductivity gradient exists in the bulk flow. The instability effect causes the induced flow field to be more chaotic, and therefore enhances the mixing performance in electrokinetic-based microfluidic systems.

Loading/Dispensing

Advances in the microfluidics field have enabled many devices to be integrated into a single microfluidic chip, thus realizing the concept of a μTAS. However, this increased level of integration requires the assay performance to be optimized and the microchip architectures to be designed with improved sophistication and efficiency. Sample loading and dispensing are essential fluid manipulation tasks in microfabricated devices. The quality of the final results of many on-chip processes is critically dependent on the characteristics of the injected samples. In general, these characteristics tend to be application specific. Since the length of the channel required to separate two analytes via CE is directly proportional to the initial length of the sample, many researchers have developed on-chip dispensing schemes specifically designed to provide tightly focused samples. Typically, these schemes have been implemented in T-form, double-T form and conventional cross-form microchannels. The best sample loading and dispensing results are generally obtained by carefully controlling an eternally applied electric field in order to induce electroosmotic flow within the microchannel [12]. Using this approach, conventional cross-form microchips can function both as a constant-volume valve (i. e., pinched injection mode) and a variable-volume valve (i. e., a gated injection mode). The injected samples produced using these valving techniques enable high performance, electrokinetically driven separation to be performed in applications such as: CE, synchronized cyclic electrophoresis, capillary gel electrophoresis, open channel electro-chromatography, and micellar electrokinetic chromatography.

Separation

One of the biggest challenges for current μTAS devices is analyzing complex and heterogeneous samples such as whole blood or contaminated environmental specimens. Gel electrophoresis is a typical electrophoresis application in the field of molecular biology. This process is used to determine the different sizes of high density lipoproteins in order to establish an accurate representation of their effectiveness. A free-flow electrophoresis device was fabricated on a glass wafer. Separation of standard fluorescent markers was demonstrated by applying a focused free-flow zone electrophoresis technique and free-flow isoelectric focusing (IEF). Proteins focused by IEF were electrokinetically transferred into an array of orthogonal microchannels and then resolved by gel electrophoresis.

IEF is a zone electrophoresis technique, and is most commonly applied for the separation of proteins. IEF separates molecules according to their respective electric charges (assuming that they have a charge), exploiting the fact that the charge carried by a molecule changes as the pH of its surroundings changes. Cui et al. [13] have improved the resolving power of IEF by first focusing proteins in a straight channel using broad-range ampholytes and then refocusing segments of the first channel into secondary channels branching off the primary channel at T-junctions. DNA electrophoresis is an analytical technique used to separate DNA fragments in accordance with their size. In this technique, an electric field is applied to force the fragments to migrate through a gel. The DNA molecules normally migrate from a negative to a positive potential due to the net negative charge of the phosphate backbone of the DNA chain. Finally, chromatography is a collective term applied to a family of laboratory techniques designed to separate mixtures. Chromatography involves passing a mixture containing the analyte through a stationary phase, which separates the analyte from the other molecules in the mixture and allows it to be isolated. Reversed-phase capillary electrochromatography in a 5 mm C_{18} fully packed capillary was employed to optimize the separation of negatively charged nonsteroidal anti-inflammatory drugs [14]. In addition, researchers have shown that a μ-enzyme reactor can be coupled on-line with μ-membrane chromatography to realize an integrated micro-analytical tool enabling rapid protein digestion, high resolution peptide separation, and sensitive protein

M

identification using Electrospray Ionization Mass Spectrometry (ESI-MS).

Future Directions for Research

The task of integrating sample pretreatment processes into microfluidic chips is rendered complex by the enormous variation in the samples to be analyzed. Moreover, the pretreatment technique must be compatible with the analytical devices to which it is coupled in terms of time, reagent consumption, power supply requirements, and sample volume. Although electrokinetic injection has many advantages, it is necessary to address the limitations of this technique as regards applicable pH values, appropriate solvents, and so on. Furthermore, in pressure-driven techniques, problems remain to be resolved in providing samples of sufficiently small volume and making the miniaturized devices sufficiently robust to withstand the significant back-pressure created during the injection process.

Pressure- or electrokinetically driven flows in microfluidic devices are generally limited to the low Reynolds number regime and typically involve the transportation of biomolecules with low molecular diffusivity. Hence, micromixers are obliged to function under conditions of low Reynolds number and high Peclet number. However, current diffusion-based micromixers, e. g., parallel lamination and serial lamination mixers, only provide an acceptable mixing result at low Peclet numbers. By contrast, the performance of chaotic advection mixers is not largely dependent on the Peclet number. Accordingly, the development of future micromixers should focus particularly on passive or active chaotic mixing schemes.

Loading, dispensing, and separation are essential processes in many microfluidic systems. The feasibility of applying microfabrication techniques to manufacture biochips has been well established, and numerous applications have been demonstrated. For practical purposes, the loading and dispensing devices tend to manipulate the picovolumetric reagents. Electrokinetic manipulation makes possible the loading of small-volume sample plugs, the separation of charged species, and a high degree of control over the reaction processes in the microchip. However, the electrokinetic technique is limited to certain conditions, e. g., certain pH values, particular solvents, a limited set of compatible chip materials, etc.

Definition

A chemical reaction is said to have taken place when a detectable number of molecules have lost their identity and assumed a new form by a change in the kind or number of atoms in the compound and/or by a change in structure or configuration of the atoms. Microfluidic channels, which have critical length ranging from several microns to a millimeter, provide high heat and mass transfer rates, which can be used beneficially to carry out reactions selectively, for production or analytical purposes. A device containing such channels is termed a microreactor. Depending on how relevant a reaction is to living organisms, a reaction may be called a biochemical or a chemical reaction.

Overview

Introduction

Microfluidic reaction systems called *differential reactors* were reported before the 1960s and were used to measure the kinetics of catalytic reactions. The key early findings indicated that if the reactor volume was made small enough, the temperature and concentration gradients within the reactor would become negligible. This allowed more accurate measurement of reaction kinetics. Reactions involving microfluidic effects have been carried out in large-scale reactors with integrated packing and monolithic structures designed to give higher reaction yields. Such reaction systems have been studied and characterized mostly by empirically determined macroscale models. The advent of micromachining allows us to build low-volume reactors with a systematic channel design on a chip, and is helping us to study reaction kinetics on a scale at which they are much simpler.

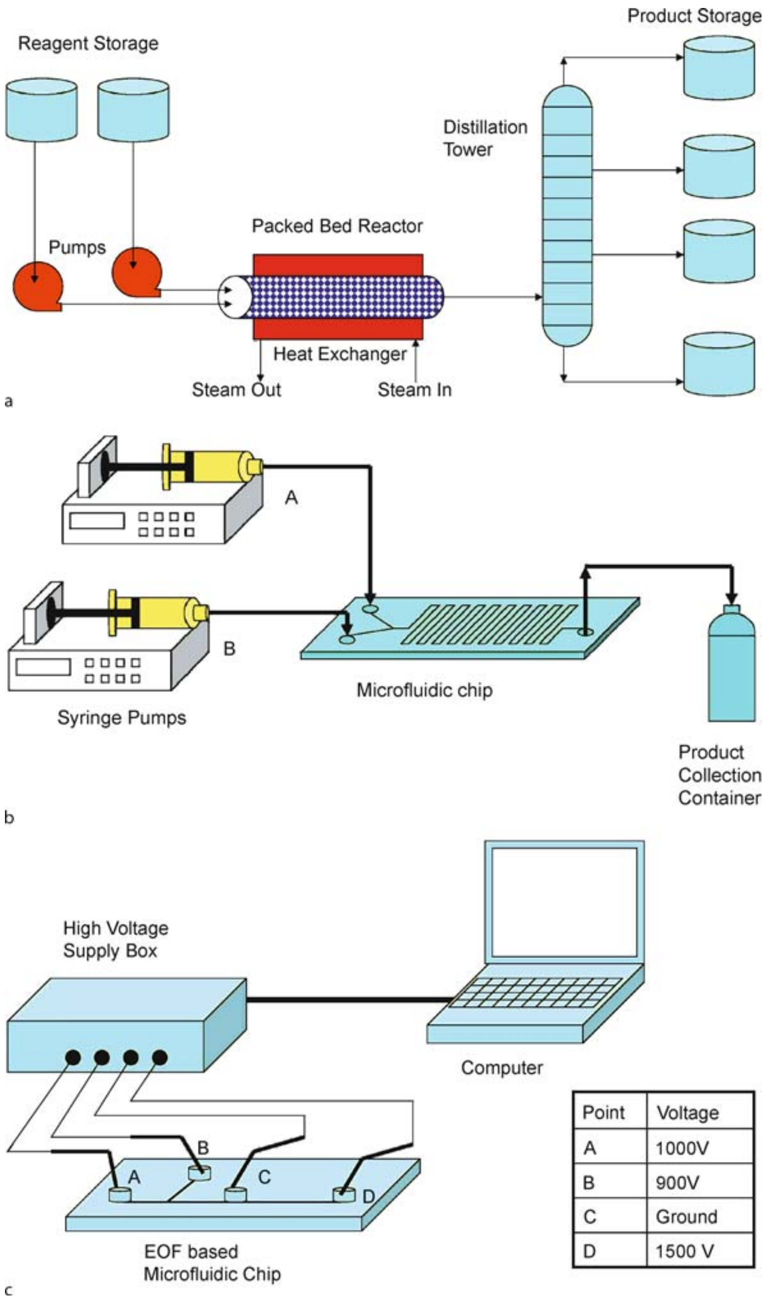
The reasons why small-volume microfluidic synthesis is preferred are:

- *Low reactant/product quantity* The pharmaceutical and biotechnology industries produce drugs, enzymes, and biomaterials in small quantities. The production of these materials is done industrially on a batch scale. Microfluidics enables the continuous production of chemicals in small quantities while maintaining consistency in quality, a common problem associated with batch production. Production on demand is more profitable, especially for chemicals with a limited lifetime. Some radiolabeled tracers need to be produced a short time before they are administered to a patient. Microfluidic systems also, owing to their small size, provide a portable platform for producing drugs on site and on demand. Microfluidics can be used to carry out rapid permutation and combination of reagents to create a library of synthetic chemicals. Such technology can be used to advantage to screen drugs and catalysts.
- *Safety* Some reactions involve hazardous chemicals as reactants or products. These unsafe chemicals need to be handled carefully. Microfluidics allows the safe handling of small amounts of hazardous chemicals. Hazardous reactions involving high exothermicity or damaging radiation exposure can be carried out safely.
- *Greater control over reactions* The diffusion paths for heat and mass transfer in microfluidic systems are very short, making such systems ideal candidates for heat- or mass-transfer-limited reactions. The surface-to-volume ratio of microscopic structures is very high. Thus, surface effects are likely to dominate over volumetric effects, increasing selectivity and yield.

An industrial batch reactor has neither an inflow nor an outflow of reactants or products while the reaction is being carried out. Batch reactions can be carried out in droplet microreactors, where nanoliters of fluid are individually manipulated using techniques such as electrowetting on dielectric (EWOD) and surface tension control. Semibatch reactors are used in cases where a by-product needs to be removed continuously and to carry out exothermic batch reactions where a reactant has to be added slowly. Microfluidics allows precise control of concentration and temperature, which allows batch and semibatch reactions to be carried out in a continuous manner. Figure 1 shows the general components of a simple industrial-reactor setup, compared with a laboratory-scale setup to carry out a reaction with microfluidic chips.

Modeling

The Reynolds number in microreaction systems usually ranges from 0.2 to 10. In contrast to the turbulent flow patterns that occur on the macroscale, viscous effects govern the behavior of fluids on the microscale and the flow is always laminar, resulting in a parabolic flow profile. In microfluidic reaction systems, where the characteristic length is usually greater than 10 μm, a continuum

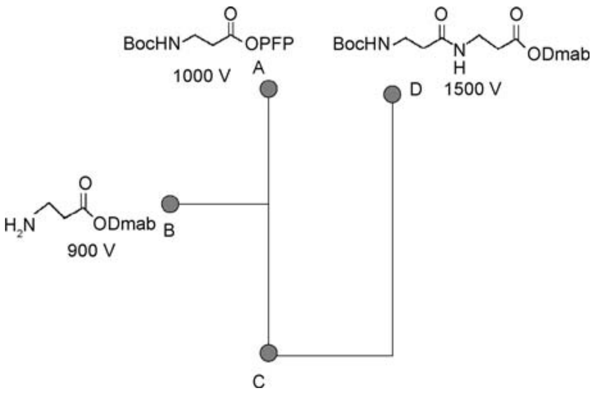


Microfluidics for Biochemical and Chemical Reactions, Figure 1 Schematics of a typical reaction setup (**a**) in industry; (**b**) in laboratory, using hydrodynamic force; and (**c**) in laboratory, using electroosmotic force

description can be used to predict the flow characteristics. This allows commercially written Navier–Stokes solvers such as FEMLAB and FLUENT to model liquid flows in microreaction channels. However, modeling gas flows may require one to take account of boundary slip conditions (if $10^{-2} < \mathrm{Kn} \leq 10^{-1}$, where Kn is the Knudsen number) and compressibility (if the Mach number Ma is greater than 0.3). Microfluidic reaction systems can be modeled on the basis of the Navier–Stokes equation, in conjunction with convection–diffusion equations for heat and mass transfer, and reaction-kinetic equations.

Examples of Microfluidic Reactions

What follows is not an exhaustive compilation of all known examples, but rather a sample of sufficient variety



Microfluidics for Biochemical and Chemical Reactions, Figure 2
Layout of microfluidic chip for simultaneous synthesis and separation of dipeptide

to illustrate the extent to which microfluidics has been used to perform biochemical and chemical reactions. Examples of the use of microfluidics for nanoparticle and polymer synthesis have been reported elsewhere.

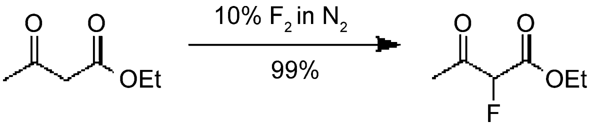
Ease of Manipulation

A newcomer to the field of microfluidics would find it easiest to operate a microreaction device with hydrodynamic control, using syringe pumps to move liquids within the microfluidic network. The disadvantage of using hydrodynamic forces is that this requires large external pumps. The pumping system becomes complex when one is manipulating more than three reagents in the device. An elegant way to manipulate solutions in a network of channels is the use of electroosmotic flow (EOF). One of the disadvantages of using EOF is the high voltages involved in moving fluids through microchannels.

Watts and Haswell have demonstrated dipeptide and tripeptide synthesis, as the first example of EOF-based multistep synthesis, in a borosilicate glass microfluidic channel, as shown in Fig. 2. A T-shaped microreactor with 200 μm × 50 μm channels was fabricated; the overall reactor dimensions were 20 mm × 20 mm × 25 mm. The channels were filled with microporous silica frit to reduce hydrodynamic effects. After deprotection with one equivalent of hydrazine, tripeptide synthesis was also demonstrated. An offline high-pressure liquid chromatograph (HPLC) was used to determine the results of the synthesis.

Increased Safety

Hazardous Product. The synthesis of hydrogen cyanide (HCN) is an example of a fast, high-temperature process that generates a hazardous gas. Researchers at the Institut für Microtechnik Mainz, Germany, aimed to develop a portable on-site, on-demand HCN-generating unit [2]. The Andrussov process was selected for generating HCN on the microscale. The reaction can be written as



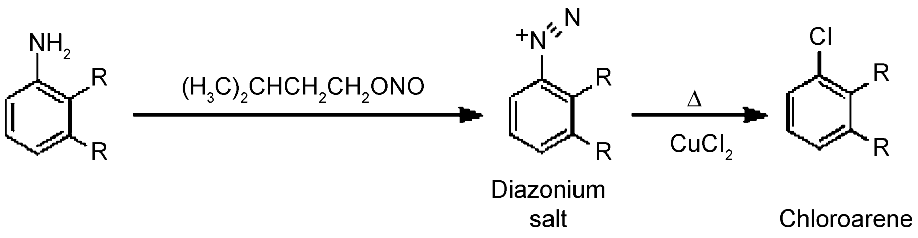
Microfluidics for Biochemical and Chemical Reactions, Figure 3
Fluorination of ethyl acetoacetate

$$CH_4 + NH_3 + 1.5O_2 \underset{Pt}{\rightarrow} HCN + 3H_2O\,.$$

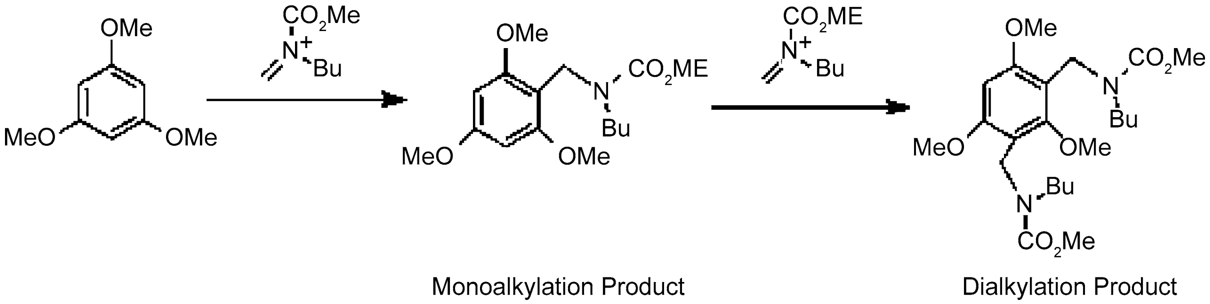
To carry out the above reaction, the reactant gases were heated to 600 °C before being mixed and exposed to a supported platinum catalyst structure in a 70 μm diameter channel. The reaction led to an increase in the gas temperature to 1000 °C; the gas was then cooled to 120 °C in a microscale heat exchanger.

Hazardous Reagent Elemental fluorination of organic compounds provides an example of the safe handling of hazardous gaseous reagents. Fluorination reactions are less selective than others and highly exothermic in nature. Chambers and Spink demonstrated the fluorination of β-dicarbonyl compounds in a microfluidic channel as per Fig. 3 [1]. The reactor consisted of a 500 μm wide, 500 μm deep channel machined into a nickel block and sealed with polychlorotrifluoroethene, which provided inertness and visual access to the reaction zone. 10% fluorine in nitrogen was introduced at 10 mL/min along with ethyl acetoacetate (a β-dicarbonyl compound) at 0.5 mL/h in formic acid into the 17 cm long reaction zone (reactor plus tubing length), which was maintained at 0 °C. The liquid was pumped with a syringe pump and the gas flow was controlled using a mass flow controller. The results were analyzed using an offline gas chromatograph.

Fast Operation with Unstable Intermediates Diazotization of aromatic amines poses hazards including light, heat, and shock sensitivity, which can all lead to uncontrolled decomposition of the diazonium salt, creating an explosion. Lower alkyl nitrites have been known to blow up the container even when refrigerated. The explosion hazard is related to the pressure increase caused by nitrogen generation and to the highly exothermic nature of the reaction. De Mello et al. minimized the transportation time between two sequential steps of a synthesis by incorporating reagent mixing, quench addition, and heated decomposition operations into a single device; transport distances and dead volumes were minimized, preventing precipita-



Microfluidics for Biochemical and Chemical Reactions, Figure 4 Chloro-dediazotization: the Sandmeyer reaction



Microfluidics for Biochemical and Chemical Reactions, Figure 5 Competitive consecutive reactions of trimethoxybenzene with *N*-acyliminium ions

tion [1]. The synthesis of chloroarenes was investigated in a pressure-driven glass microreactor with a 150 μm wide, 50 μm deep, 3.6 cm long channel.

The reaction (Fig. 4) was carried out by mixing aniline with isoamyl nitrite at room temperature in the first 80 mm of the channel length and heating the resulting solution with copper chloride at 65 °C in the remaining channel length. A moving stream of air cooled the first section to room temperature. The second section of the microreactor was contacted to a heated metal block to achieve a temperature of 65 °C. The results were analyzed using an offline gas chromatograph.

Increased Yields and Selectivity Control

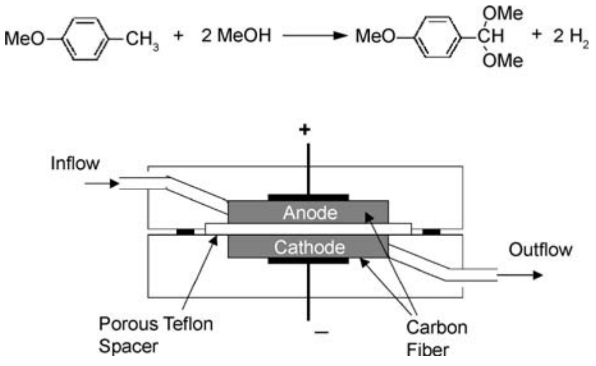
The Friedel–Crafts alkylation of aromatic and heteroaromatic compounds often suffers from a polyalkylation problem owing to competitive, consecutive alkylation reactions. Owing to the large exothermicity of the reaction, the product distribution has proved difficult to control on the macroscale, resulting in synthesis of a large proportion of dialkylated products (the monoalkylated : dialkylated ratio may be 1 : 1). Yoshida et al. carried out an alkylation reaction in a microchannel at −78 °C as per Fig. 5 [3].

Yoshida et al. also demonstrated the effect of mixing on alkylation yields and selectivity by using an efficient multilamination micromixer (supplied by IMM; channel width = 25 μm) and a T-mixer (500 μm).

Electrosynthesis Microfluidic fuel cells are a good example of microfluidic reaction systems where a reaction is performed catalytically to obtain electrical energy. Vice versa, electrical energy can also be used to form anion and cation radical intermediates and cleanly synthesize chemicals without the need for additional chemical reagents. Using microfluidics, microflow electrolysis reactions have been developed for carrying out electrosynthesis. Yoshida et al. have demonstrated the use of a microflow cell consisting of a porous carbon fiber anode and cathode separated by a porous Teflon spacer (3 μm pores, 75 μm thick) to carry out anodic methoxylation of several organic compounds, including *p*-methoxytoluene [1]. The reaction scheme and a schematic of the reactor are shown in Fig. 6. A *p*-methoxytoluene solution was fed through the anodic chamber and the spacer, and was collected as the solution left the cathode. The design of the reaction system allowed the process to be conducted in the absence of any intentionally added electrolyte.

Time and Temperature Reduction

The polymerase chain reaction (PCR) method is commonly used to create copies of specific DNA fragments. First, the individual strands of DNA are unwound and separated by heating (melting) to 90 – 96 °C. This is followed by cooling (annealing) to 50 – 60 °C, which allows primers to bind to the DNA strands. The primers allow the duplica-



Microfluidics for Biochemical and Chemical Reactions, Figure 6 Reaction scheme and reactor construction for electrosynthesis of dimethoxytoluene

tion process to start at a specific point on the DNA. Finally, the temperature is raised to 72 °C and *taq*-polymerase is used to grow two strands of DNA (extension) from the original single strand. Each cycle duplicates the DNA strand. Generally, the cycle is repeated perhaps 30 times to produce an increase in the DNA concentration by a factor of 2^{30} times.

In a conventional-scale device, each cycle takes 5 – 10 min, and the total time is 150 – 300 min. However, it is possible to do more rapid thermal cycling in a microfluidic channel owing to the high heat transfer rates possible, thus reducing the analysis time. Figure 7 shows a schematic of a PCR device reported by Kopp et al [4]. This utilizes a flow channel that repeatedly passes through three different temperature-controlled zones on the chip to perform the required thermal cycling; 20 cycles could be performed in a time ranging from 90 s to 18.7 min, depending on the flow rate through the microchannel. A more rigorous treatment of the above subject is given in the article ► PCR lab-on-chip devices.

Radiosynthetic Chemistry Positron emission tomography (PET) is a radiotracer imaging technique used to provide quantitative information on physiological and biochemical phenomena in animals and human subjects in vivo. PET uses carbon-11 ($t_{1/2} = 20.4$ min) or fluorine-18 ($t_{1/2} = 109.7$ min), which are usually obtained from [^{11}C]carbon dioxide and [^{18}F]fluoride, respectively. The challenge lies in the reliable and regular production of PET radiotracers, which requires to be performed in a lead-shielded hot cell with remotely controlled automated equipment. The radiotracers have to be synthesized with high yields, purified, and formulated for intravenous injection, all within only two to three half-lives of the radioisotope. Lu et al. demonstrated the feasibility of synthesizing a series of radiolabeled compounds with a T-shaped glass microfluidic reactor (with a 220 μm wide, 60 μm deep, 1.4 cm long channel) [1]. A premixed solution of 3-pyridin-3-yl-propionic acid (0.01 M) and tetra-*n*-butylammonium hydroxide (0.01 M in dimethylformamide (DMF)) was introduced from one inlet and a solution of $^{11}CH_3I$ (0.01 M in DMF) from a second inlet. The reaction products were quenched in methyl cyanide upon collection, and analyzed and purified by an offline HPLC.

Reduction of Chemoselective Reaction Time Panke et al. demonstrated enhanced reaction control in the crucial step of nitration of the pharmaceutically relevant intermediate 1-methyl-3-propyl-1*H*-pyrazole-5-carboxylic acid, a precursor to the lifestyle drug sildenafil citrate (Viagra) [5]. Control of the reaction temperature is absolutely necessary because the decay of the product above 100 °C creates excess CO_2 pressure and heat buildup. A standard 70 mL CYTOS microreactor was fed with reagents using external pumps. A flow rate of 1 mL/min was maintained within each channel, with the reaction temperature maintained at 90 °C.

Microchannel Enzyme Reactor Enzymatic conversion is receiving attention because it is an environmentally friendly approach to synthesizing chemicals. Reactions can be carried out enzymatically in the solution phase or by immobilizing enzymes on microfluidic walls. Use of the latter type of reaction has the same mass and heat transfer advantages as the use of a microfluidic synthetic reactor. More information can be found in a published review article [6] and in the article ► microfluidic bioreactors in this encyclopedia.

M

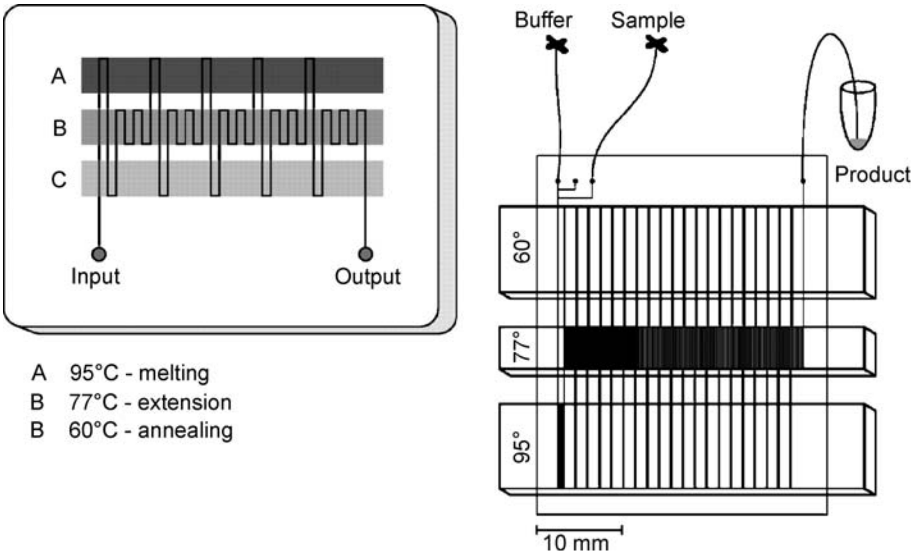
Improving Microfluidic Devices for Reactions

Microscale reactions have been studied mostly to demonstrate proofs of concept. There is a lack of reaction optimization studies on the microscale with respect to flow rates, stoichiometry, concentrations, mixing design, residence time distribution, and temperature. Conditions obtained from conventional-scale synthesis do not necessarily apply to microscale reactions. Only a few systematically studied reactions have been translated into real industrial technology. The mixing strategy, the parameters of the channel geometry, and the fabrication tolerance affect the microreaction conditions. The effects of the microscale on reactions are detailed in the following sections.

Basic Methodology

Figures of Merit

The percentage yield or percentage atom economy is a widely reported quantitative metric for evaluating



Microfluidics for Biochemical and Chemical Reactions, Figure 7 Layout of a PCR chip reported by [4]. (**a**) Schematic of a chip for flow-through PCR. (**b**) Layout of the device used in the PCR study

a microfluidic synthesis route and comparing it with conventional-scale synthesis. In the case of parallel reactions, the evaluation criterion with respect to obtaining the desired product is the percentage selectivity. The figures of merit are defined below:

$$\text{Reaction yield (\%)} = \frac{\text{(actual quantity of products achieved)}}{\text{(theoretical quantity of products achievable)}} \times 100 \tag{1}$$

$$\text{Reaction selectivity (\%)} = \frac{\text{(yield of desired products)}}{\text{(amount of reagent converted)}} \times 100 \tag{2}$$

$$\text{Atom economy (\%)} = \frac{\text{(Mole weight of desired product)}}{\text{(Mole weight of all products)}} \times 100 \tag{3}$$

Offline analytical techniques such as gas chromatography and high-pressure liquid chromatography are utilized to determine the minuscule amounts of reaction products produced. In cases where the products were not separated with these techniques, the percentage yields are sometimes reported in terms of the substrate used or remaining instead of the product produced. Measurement of the peak area or height is the most commonly utilized method for estimation of the substrate used before and after the reaction.

Control of Reaction Conditions

Chemical synthesis on chip involves dispensing and mixing reagents at a set temperature, pressure, and time, and purification of the products. Similarly, analysis on chip also usually starts with chemical reaction of a marker for the sample, followed by separation and detection. The purification and analysis of products on a chip is outside the scope of this discussion.

Fluid Manipulation

Reactions require accurate dosage of reactants to achieve the optimum stoichiometry. An array of components for fluid manipulation have been developed over the last decade for micrototal analysis systems (μTAS) and microreaction technology. Pumping of fluids is carried out using microfluidic components, which can be classified as either mechanical or nonmechanical. Mechanical pumps are distinguished from nonmechanical pumps by the presence of a moving physical part.

- *Mechanical pumping* Micromechanical pumps are usually based on the movement of a membrane, which results in periodic delivery of a fluid. The actuation schemes utilized for moving the membrane of a pump include piezoelectric, electrostatic, thermopneumatic, pneumatic, and electromagnetic devices, and shape memory alloys and electrowetting. The resulting fluid motion is pulsed, not continuous. The rotary displacement micropump is an example of a mechanical pump not based on membrane movement. External syringe

pumps have found widespread use at the research level. However, this results in challenges in obtaining leak-free connections and a low dead volume between the displacement pump and the device.

- *Nonmechanical pumping* Micropumps in this class are usually continuous and include the use of effects such as electrochemical displacement (bubble generation), thermal expansion, electrohydrodynamics, capillarity, and evaporation forces. The most commonly used nonmechanical pumping method is based on electrokinetic flow. In comparison with mechanical micropumps, field-induced flow is advantageous as it acts as both a valve and a pump, enabling both the direction and the magnitude of the flow to be controlled.

We recommend that readers consult other publications on microfluidic pumping for a comprehensive understanding of this topic.

Kinetic Regimes

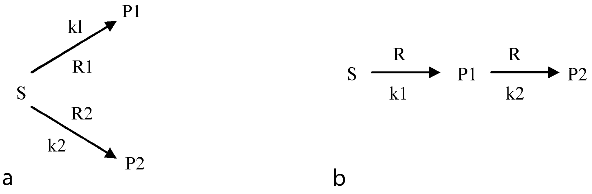
Competitive parallel reactions (Fig. 8a) and competitive consecutive reactions (Fig. 8b) are common in chemistry. Here R1 and R2 are two different reagents, S is the substrate, and k_1 and k_2 are reaction rate constants.

Selectivity is governed by kinetics and thermodynamics. The thermodynamic selectivity is not affected by the method of mixing. If, however, the reactions are kinetically controlled and there is no equilibrium between products, the product selectivity is determined by the ratio of the rate constants of the competing reactions. If $k_1 \gg k_2$, the reactions have to be ultrafast for mixing to play a role in the selectivity.

In reactions with rates that are fast compared with the rate of mixing, the reaction rate is independent of the rate constant (k) and is entirely dependent on the rate of mixing and the residence time distribution. The volume available for reaction is reduced from the volume of the entire reaction vessel to a plane between reacting streams. In this situation, designated the *diffusion regime*, the potential for the formation of secondary products is the greatest. In comparison, the mixing time in the *chemical regime* is fast compared with the reaction rate, and therefore mixing is complete before significant amounts of products are present. The entire reaction vessel is available for reaction, and only the smallest amounts of secondary products are formed.

Control of Mixing on the Microscale

On the macroscale, mixing is achieved using agitation provided by mechanical or magnetic stirrers, where large



Microfluidics for Biochemical and Chemical Reactions, Figure 8 Two competitive parallel reactions. (**b**) Two competitive consecutive reactions. k_1 and k_2 are rate constants

eddies are generated, allowing bulk diffusion to take place. On the microscale, viscous forces dominate and mixing is mainly governed by molecular diffusion, defined by Fick's first law,

$$J = D\frac{\partial c}{\partial x}\,, \qquad (4)$$

where J is the diffusive flux and D is the molecular diffusion coefficient. The molecular diffusion coefficients of complex biomolecules such as myosin, hemoglobin, and enzymes are two orders of magnitude lower than those of most liquids. From the molecular point of view, mixing is an unsteady-state mass transfer process described by a dimensionless diffusion time, or Fourier number, Fo_D, which is defined over a characteristic length l (usually the smallest of the cross-sectional dimensions) as

$$\mathrm{Fo}_D = \frac{D \times t}{l^2}\,. \qquad (5)$$

Typical values of the molecular diffusion coefficient are 1 to $10^{-2}\,\mathrm{cm^2/s}$ in gases and 10^{-4} to $10^{-6}\,\mathrm{cm^2/s}$ in liquids.

Microfluidic-based mixers allow ultrafast reactions to take place in the kinetically limited regime by achieving faster mixing, which is usually obtained by a complex coupling of increases in the advective flux and interfacial area. The micromixers that have been developed can be categorized into active and passive mixers.

- *Active mixers* Energy is input to control the reagent flow by the use of moving parts or varying pressure gradients. The energy for active mixing is obtained using a pressure disturbance, electrohydrodynamic forces, dielectrophoresis, electrokinetics, magnetohydrodynamics, or acoustic or thermal energy.
- *Passive mixers* No energy is input other than that used to mobilize the fluid within the device. The passive mixers that have been developed use serial or parallel lamination, injection, chaotic advection, or droplet formation. The most popular approaches to the mixing step for biochemical and chemical reactions involve increasing the contact area between two reagent streams. This

involves splitting the two reagent streams into thin laminae and subsequently bringing them back together to allow a greater degree of diffusive mixing at the point of confluence. The greater the number of laminae that are formed from the reagent streams, the faster the mixing occurs. With the ability to efficiently mix reagent streams, the reactions performed in miniaturized systems are limited simply by the inherent reaction kinetics.

Readers are referred to the article ▶ microfluidic mixing in this encyclopedia for a deeper understanding of this topic.

Residence Time and Residence Time Distribution

Flows through microfluidic reaction channels are typically characterized by their mean residence time τ_R, which is defined by

$$\tau_R = \frac{V}{Q} = \frac{L}{v}, \qquad (6)$$

where V is the reactor volume, Q is the volumetric flow rate, L is the reactor length, and v is the plug velocity. The residence time is optimized on the basis of the reaction rate, which is a function of the reaction rate constants and the chemical concentrations. Different atoms spend different amounts of time in the channel. This creates a residence time distribution (RTD). The RTD is indicative of the dispersion, back-mixing, and dead zones present in the microfluidic system. The presence of the latter zones leads to undesired by-products in the case of parallel reactions and consecutive competitive reactions. As a measure to be used for quality control, the RTD should be as narrow as possible if one wishes to run reactions in sequence within a short time. Neglecting axial dispersion, the peak width at half height of the RTD for a Dirac pulse at the inlet is given by

$$\mathrm{PW}_{1/2} = 0.241 \times \tau_R \times \mathrm{Fo}_D^{-0.515}. \qquad (7)$$

A quick estimate of the degree of conversion that can be achieved in a continuous-flow reactions is given by the Damkohler number Da, defined by

$$\mathrm{Da} = \frac{\text{rate of reagent consumption}}{\text{rate of transport of reagent by convection}}. \qquad (8)$$

The rule of thumb is that if Da > 10 then the conversion is greater than 90%, and if Da < 0.1 then the conversion is less than 10%.

Microfluidics for Biochemical and Chemical Reactions, Table 1 Surface-area-to-volume ratios for some common cross-sectional shapes

Cross-sectional shape		Surface area/volume
	Circle	$\frac{4}{d}$
	Rectangle	$\frac{2\,[1 + A.R.]}{A.R. \cdot w}$ where $A.R. = \frac{d}{w}$

Temperature Control on the Microscale

Because of the kinetics, temperature forms one of the important criteria for controlling the reaction rate, yield, and selectivity of product formation. Reactions can generally be classified thermodynamically into exothermic (heat-generating) and endothermic (heat-utilizing) reactions. In traditional large-scale reactors, reaction temperature fluctuations are difficult to correct, as any alterations made take time to have an effect on the system as a whole. Temperature control is needed in the case of exothermic reactions to prevent the reactor from going to a higher temperature, which may lead to undesirable by-products or, in severe cases, lead to an explosion.

From Table 1, the surface-area-to-volume ratio is inversely proportional to the critical cross-sectional dimension. Decreasing the channel width or depth results in an increase in the surface-area-to-volume ratio, which also reduces the heating and cooling times. The reaction rate is more uniform over the cross section owing to the minuscule thermal gradients across the walls in a microflow reactor. In systems such as PCR systems, thermal cycling of the fluid takes place by passing through different zones. Fick's law implies that the time needed for heat dissipation is directly proportional to the square of the channel depth (when $d < w$) for a flat rectangular channel, assuming that the chip and heating element have an infinite heat capacity relative to the heated fluid element.

The heat transfer characteristics on the microfluidic scale depend on the ability to heat the material of construction quickly, which is often characterized by the thermal diffusivity, defined as follows:

$$\alpha = \frac{\kappa}{\rho \times C_p}, \qquad (9)$$

Microfluidics for Biochemical and Chemical Reactions, Table 2 Thermal diffusivities of common construction materials for microreactors

Material	Thermal diffusivity ($cm^2 s$ at 300 K)
Air	0.24
Water	1.3×10^{-3}
Silicon	0.8
Pyrex 7740	0.7×10^{-2}
Aluminum	9
Copper	1.3
Gold	1.3
Nickel	0.24
Alumina	0.119
Teflon	0.34×10^{-2}
PMMA	0.124×10^{-2}

where κ is the thermal conductivity, ρ is the bulk density, and C_p is the heat capacity. Substances with a high thermal diffusivity adjust their temperature rapidly to that of their surroundings, because they conduct heat quickly in comparison with their thermal *bulk*. Table 2 lists the thermal-diffusivity properties of some materials used in constructing microreactors. Changes are observed almost immediately in a microscale reactor, which allows more precise control of reaction temperature.

The heating rate of a flowing fluid is usually reported as the Nusselt number instead of giving the solution to the temperature field across the channel cross section. The Nusselt number is a dimensionless quantity characterizing the efficiency of heat transfer and is defined by

$$\mathrm{Nu} = \frac{h \times D_h}{\kappa}, \tag{10}$$

where D_h is the hydraulic diameter and h is the heat transfer coefficient, measuring the transmitted thermal power per unit area divided by a characteristic temperature difference. The hydraulic diameter is given by $4A/P$, where A is the cross-sectional area of the channel and P is its perimeter.

Fabrication of Microreactors

Microstructured reactors have been fabricated from a variety of substrates, including silicon, quartz, metals, polymers, ceramics, and glass. The choice of substrate is largely dependent on the following parameters:

- chemical compatibility with reactants and solvents;
- thermal and pressure resistance;
- cost and ease of fabrication.

Fabrication methods such as DRIE (deep reactive ion etching) and laser ablation have been widely used owing to the exceptional surface quality and reproducibility that they provide. However, high-precision machining and serial processing increase the cost of mass production. Therefore rapid-prototyping processes, such as injection molding, microlamination, and hot embossing for polymeric, ceramic, and metal-based devices, and powder blasting and wet etching for glass, are finding more popularity for high-volume production. Researchers at IMM have demonstrated fabrication of a microreactor for portable HCN synthesis using conventional precision milling and electrode discharge machining [2].

The fabrication of a typical silicon microreactor starts with the reactor design, followed by the design of masks. The masks are printed on high-resolution transparencies or laser-written on chrome–soda-lime glass. The silicon etch pattern is transferred photolithographically to a photoresist-coated silicon wafer, and the latter is etched using DRIE. The silicon wafer is cleaned and anodically bonded to Pyrex 7740. Then, either the microreactor die is connected to a manifold or suitable connectors such as Nanoports® are epoxied to it for connection to the pumping device. A glass microreactor can be fabricated by a similar procedure, with wet etching replacing the DRIE. The etched glass channel is sealed to another glass surface using fusion bonding. In cases where injection molding and hot embossing are used, molds need to be prepared from masks. The resulting master/template is utilized to rapidly make multiple replicas of the microreactor. The main advantage of microfabrication is parallel fabrication, as compared with serial fabrication in the case of molding techniques. However, molding techniques are cheaper than microfabrication.

Surface Engineering and Functionalization of Reactor Walls

In the case of gas–solid and liquid–solid heterogeneous reactions, catalyst nanoparticles themselves or a catalyst supported on nanoparticles can be suspended in a liquid phase and passed through the reactor. Doing so, however, may lead to clogging of microchannels. A solution to the latter problem is to coat the catalyst layer onto the microfluidic walls. The formation of a catalyst layer on a reactor wall can be achieved using sol–gel layer formation. The sol–gel deposition method provides a high catalyst surface area owing to the high porosity of the resulting layer.

Catalyst impregnation can also be carried out by engineering the microfluidic walls to be porous enough to anchor catalyst nanoparticles. Ganley et al. have demonstrated that anodization of aluminum helps to create a porous surface that can anchor ruthenium catalyst particles for ammonia reforming [8]. Drott et al. have shown that anodizing a silicon channel creates

a high surface area for enzyme immobilization and hence higher enzyme activity [6]. A typical silicon anodization takes place at 0.25 A/cm^2 in a 1 : 1 hydrofluoric acid and ethanol electrolytic bath. Aluminum is optimally anodized at 30 V in a batch of 0.6 molar oxalic acid maintained at 18 °C. Anodization creates a semipermeable membrane with a high surface-area-to-volume ratio (10^8 m^{-1}). Borosilicate glasses can be rendered porous using treatment with concentrated hydrochloric acid at high temperature. This is a common practice in the manufacture of silica columns for gas chromatography to increase the surface-area-to-volume ratio of the stationary phase.

Oxide surfaces can be functionalized using a silane-based self-assembled monolayer. Amine functional groups are commonly utilized for functionalizing surfaces with biomaterials, by forming amide bonds. A common method is to expose the surface to 0.1 M aminopropyltrimethoxysilane (APTS) in toluene at 100 °C for 10 min to 1 h. This treatment renders the surface linkable with many biomaterials with a carboxylic group (–COOH). Various silanes can be utilized to decorate the surface with desired functional groups. Readers are referred to the article ▶ methods for surface modification for further understanding.

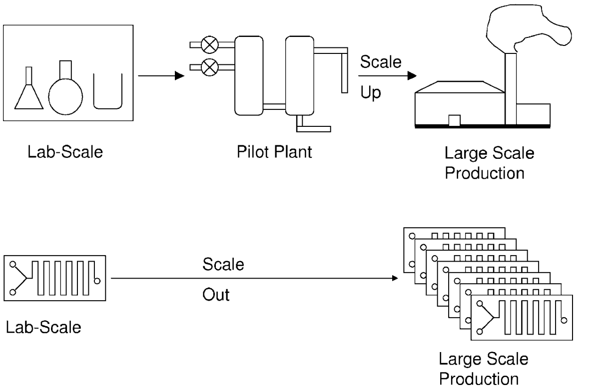
Process Intensification

A microreactor is advantageous for synthesizing small quantities of chemicals. Industry is always interested in large-scale production owing to the associated larger profit. In order to avoid changes in conditions due to scaling up, multiple microreactors can be put together to increase the production quantity as shown in Fig. 9. The surface-area-to-volume ratio remains the same, and hence so do the thermal and mass transport properties of the reaction.

This process is often referred to as *scale-out* or *numbering-up*. Replication of successful reaction units ensures that the product quality is consistent with that obtained with the laboratory-based optimizations. Currently, as cheaper mass production of microreaction units becomes a reality, the gap between research and industrial application is closing.

Key Research Findings

Three characteristic features of microreactors that have been found to be effective for the enhancement of chemical selectivity and yield are fast mixing, efficient heat exchange, and precise residence time control. However, it is rather difficult to completely separate the effects of these three factors on the outcome of chemical reactions.



Microfluidics for Biochemical and Chemical Reactions, Figure 9 Schematic comparison of scaling-up and scale-out processes towards large-scale production

Mass Transfer Rate Effects

The high mass transfer rates in microfluidic devices can be attributed to the high surface-to-volume ratio. Small volumes of reagents experience faster diffusive mixing. Watts and Haswell reported nearly 100% formation of dipeptide in 20 min, as compared with the 50% yield obtained by batch synthesis in 24 h [1]. This demonstrates the atomic efficiency of carrying out reactions inside microfluidic channels.

De Mello et al. found that the chloro-dediazotization reaction proceeded to 71% conversion, as compared with the 40 – 49% reported for traditional batch approaches [1]. This higher conversion was attributed to the high heat and mass transfer associated with microfluidics. Raman spectroscopy combined with a microreaction device was used to optimize the residence time for chloro-dediazotization on chip. The optimum time was found to be 600 s, which is significantly longer than the residence time required for complete mixing in a microfluidic reactor as defined by the Fourier number for the system (0.55 for a flow rate of 3.1 μL/min through each inlet). This indicates that the reaction was occurring in the kinetics-governed regime, rather than the diffusive domain. The halogen abstraction efficiency of the reaction with $CuCl_2$ was 100%.

The liquid–gas flow conditions used for fluorination by Chambers et al. gave rise to an annular flow of gas (in the center), with the liquid flowing at the walls [1]. This condition utilizes the high surface-area-to-volume ratio of microfluidic reactors, unlike the case of slug flow (alternate slugs of liquid and gas). Microfluidic fluorination of ethyl acetoacetate resulted in 98% conversion, with a 71% yield of monofluorinated product.

Interfacial areas per unit volume in falling-film microreactors have been reported to be as high as 25,000 m^2/m^3, as

Microfluidics for Biochemical and Chemical Reactions, Table 3 Effect of the method of mixing on the product selectivity of the alkylation reaction

Method of mixing	Product ratio (monoalkylated : dialkylated)
Batch reactor	37 : 32
T-shaped mixer	36 : 31
IMM single mixer	92 : 4

compared with the values of $1-200\ m^2/m^3$ typical in bubble columns. This effect is particularly important in gas–liquid reactions because the rate of mass transfer from the gas to the liquid limits the reaction rate. For the hydrogenation of cyclohexene to cyclohexane in this type of reactor, the mass transfer rate constant ($K_L a$) was found to be in the range $3-7\ s^{-1}$, which is two orders of magnitude higher than that for conventional reactors.

The mixing efficiency and complete mixing time play an important role in ultrafast reactions. Yoshida et al. compared two micromixers to see the effect of the mixing ability on reactions [3]. By use of a multilamination micromixer, a dramatic increase in product selectivity was obtained as compared with a T-mixer. Table 3 quantifies the effect of mixing on selectivity. The amount of monoalkylated products obtained depends highly on the mixing method. If a large amount of alkylation agent is available in relation to a small amount of reagent, dialkyl or trialkyl substitution can take place. Thus efficient mixing in less time also plays an important role.

Control over reagent diffusion is also an important microscale effect. Slow diffusive times can be used to advantage. Yoon et al. have shown that the effects of slow diffusive mixing can be used to advantage when laminar fuel cells are operated [7]. This is a case where a reaction is driven in the mass transfer domain to operate without an electrolyte membrane.

Heat Transfer Rate Effects

The presence of high heat transfer rates is another effect which is also attributed to the high surface-to-volume ratio. Heat transfer coefficients up to $41{,}000\ W/m^2K$ have been reported in silicon microreactors, as compared with $2500\ W/m^2K$ in conventional-scale reactors. In the case of low-thermal-mass microsystems, convective heat loss to the environment can be much more significant in microreactors than in conventional systems owing to their high surface-to-volume ratios. A consequence of this is that insulation generally enhances heat loss rather than mitigating it. The critical radius of a tube below which the use of an outer insulation layer will increase heat losses is given by the ratio of the thermal conductivity of the insulation layer (k) to the heat transfer coefficient at the interface between the insulation and the ambient (h_0), $r_{critical} = k/h_0$. For the most commonly used microfluidic materials and ambient air, this critical radius has been found to be on the order of 1 mm [9]. Localized hot spots occurring in conventional fluorination reactors can lead to undesired side reactions, including the formation of fluorine radicals and nonselected free-radical side reactions. Chamber et al. were able to carry out temperature control of a fluorination reactor at −78 °C, leading to unprecedented control over the reaction rate and process safety [1]. Yoshida et al. were able to run a Friedel–Crafts reaction at −78 °C, giving a selectivity of 96 : 4 (monoalkylated : dialkylated) [3]. During temperature optimization, an increase in temperature from −78 °C to −10 °C decreased the yield of monoalkylated products from 92% to 30%, and the selectivity also decreased.

At high temperatures, hydrogen cyanide can hydrolyze to ammonia. Hessel et al. were able to produce hydrogen cyanide isothermally in a microreactor via the Andrussov route and avoid this undesired reaction [2]. Air was used as the cooling medium, and cooling of the reaction products from 1000 °C to 120 °C was calculated to be achieved in 100 μs. Another example is the production of the antibiotic ciprofloxacin, which requires a complex 20–30 step synthesis to avoid explosions in conventional reactors [10]. CPC Systems has patented a synthesis route utilizing a microreactor to produce ciprofloxacin via a five-step synthesis, where the first step is a highly exothermic and potentially explosive cycloaddition.

Panke et al. carried out nitration at 90 °C, higher than the temperature of the usual laboratory-scale synthesis (50 °C) but below the product decomposition temperature (100 °C) [5]. The process was operated with a residence time 35 min, resulting in a throughput rate of 5.5 g/h. The high surface-to-volume-ratio (channel width $< 100\ \mu m$) inside the microreactor provided improved heat exchange compared with a batch vessel. A reaction yield of 73% was obtained. On the laboratory scale, the nitrating agent was added over 2 h, followed by 8 h of reaction time at 50 °C, to produce a 96% yield. No optimization was performed in order to increase the yield. The above exemplifies the reduction in time achieved by carrying out nitration in a microreactor at elevated temperatures with high control.

Other Small-Scale Effects

An ethyl acetoacetate fluorination reaction in a nickel reactor resulted in 98% conversion to give ethyl 2-fluoroacetoacetonate. A negligible amount of perfluorinated product was observed. This result suggested that the high surface

area of the nickel microreactor had a catalytic effect and promoted formation of the enol form, which reacts very rapidly with fluorine. Chambers et al. showed that selection of the solvent system matters [1]. The reagent and the product should be soluble, or else precipitation may cause the reactor to be blocked. Chambers et al. also demonstrated scale-out from one to three microchannels while maintaining the reaction yield.

Ganley et al. anodized alumina surfaces to create a high surface area for loading with a ruthenium catalyst in microchannels [8]. Their results show increased conversion and production rates for hydrogen synthesis via ammonia reforming in a small-scale microreactor.

Yoshida et al. have shown that electrosynthesis creates faster reactions, forming ions at a faster rate [1]. Here, the only rate-limiting step is the reaction step, where ions react with a molecule. Electrosynthesis also results in an environmentally clean process. Incorporating electrosynthesis into microfluidics enables an electrolyteless process and hence less use of chemicals. Yoshida et al. found that the oxidation of *p*-methoxytoluene in methanol resulted in a 70% yield of the dimethoxylated product. Scale-out of this kind of reaction system to cleanly produce oxidized organic products in large amounts with higher selectivity will be relatively easy.

Performing reactions on a small scale provides a high amount of safety along with portability. HCN synthesis in a microreactor resulted in a 31% yield of HCN, which is half the industrial value [2]. Although this is not a remarkable yield, the result exemplifies the ability to generate dangerous gaseous products portably. Lu et al. found that operating a microreactor at 1 μL/min could produced a radiolabeled ester with a radiochemical yield of 88.0%, and the total processing time amounted to 10 min [1]. As the preparation time was in the same range as that for the laboratory-scale reaction, microfluidics provided a safer alternative for PET tracer synthesis.

Process Optimization

Changes in the operation parameters of a microfluidic system are reflected in a very short time at the product end. An advantage of this is that optimization can be done rapidly. The ease of process optimization has been clearly demonstrated by Ehrfeld and Lowe [2]. These authors investigated a very fast, highly exothermic, homogeneously catalyzed reaction, which yields a vitamin precursor. During this reaction a side product is formed, causing a considerable decrease in yield. Optimization of the industrial procedure has already been accomplished by replacing a semibatch process (70% yield) with a process using a continuous mixer/heat exchanger reactor (80 – 85% yield). Yields of 85% were obtained with a residence time of 4 s at a reactor temperature of 50 °C. Because of the scale-out process associated with microreaction systems, optimization of the reactor conditions can be done on the laboratory scale and directly implemented on the industrial scale.

Future Directions for Research

The relatively low acceptance of microreaction in industry is due to the presence of an existing infrastructure and its inflexibility toward incorporating newer technology. The acceptance of microreactor technology will depend on its compatibility with the already existing infrastructure. Microfluidic tools will replace the conventional laboratory glassware used in biochemical and chemical research work when low-cost, well-characterized reaction systems are widely available. Some areas where microreactors may find faster adoption are in the drug discovery and biotechnology industries, where new drugs and assays need to synthesized and money is not a restriction in starting a new research setup. In such industries, the success rate is proportional to the rate at which permutations and combinations can be studied. Combinatorial research work will require microfluidics to integrate operational accessories of microreactors on chip, including valves and pumps, in a much simpler way than is current. External valves and pumps result in high dead volumes and a slower response to automatic control. PDMS has been used as a material on the laboratory scale for developing device layer microvalves for microreactor control. However, PDMS-based technology suffers from two big disadvantages:

- limited solvent compatibility and
- limited temperature range of operation.

Current state-of-the-art valve and pump microfabrication technology using rigid materials such as silicon, steel, and glass is difficult to use, and completely new development strategies are needed. On-chip analytical instrumentation will also allow microfluidics to be adopted faster in the drug-screening and biotechnology industries.

Microfluidics for Stem Cell Therapy

Michael R. King
University of Rochester, Rochester, NY, USA
mike_king@urmc.rochester.edu

Synonyms

Microfluidic stem cell culture; Stem cell tissue engineering; Stem cell isolation; Stem cell reprogramming

Definition

Stem cells are immature, undifferentiated biological cells that can multiply to create exact copies of themselves, and also differentiate into the various specific cells that comprise different tissues such as skin, muscle, blood, or brain. This encyclopedia entry refers to recent applications developed to measure, culture (i. e., grow for expansion), and control stem cell function using microfluidic systems. Microfluidic flow environments present several advantages for the manipulation and study of stem cell behavior, including therapeutic applications that are currently in development.

Overview

There is much hope that fundamental research into stem cell biology can eventually be translated into cell-based therapies to treat human disease. Stem cells possess the ability of self-replication, and can be expanded in culture. Stem cells can also be genetically modified, and differentiated into all of the cells comprising tissues that may one day be replaced or repaired via tissue-engineering applications. Rapid advances in materials chemistry, photolithography, microfabrication, and microfluidics have provided important new analytic approaches, and have led to new insights into the physical chemistry of biological behavior at the subcellular and molecular levels [1].

In the majority of stem cell research using microfluidics to date, standard fabrication of channels out of PDMS has been used, coupled with pressure-driven fluid flow of cell suspensions and cell media. The small volume of some of the successfully implemented stem cell culture microchannels allows biological experiments to be carried out for many days, while using only a single mililiter of media. It is often desirable to culture cells in *nonrecirculating* media, i. e., with cells continually contacting fresh media. This can be prohibitively expensive in a macroscale cell culture chamber, but is quite readably accomplished with microfluidics. For comparison, even using 384 well plates with a well volume of 20 µl, a 7 day experiment without recycling of media would use well over a liter of cell media.

Several in vitro strategies for controlled differentiation of embryonic stem cells have been attempted previously. Cell-based therapies are limited by the difficulty in precisely controlling the behavior of stem cells in culture. The precise control of stem cell proliferation and differentiation in culture remains an unsolved problem. In static culture, the chemical composition of the microenvironment cannot be controlled over space and time. Microfluidic technology can help address this, by providing much better control over the cell microenvironment. In addition,

the mechanical-stress environment can affect the state of adherent cell growth, and this is also easily regulated using microfluidics. Additionally, several research groups have pursued combined approaches to stem cell manipulation, using microfluidics combined with micropatterned matrix proteins and conducting large-scale parallel screening of optimal protein combinations. This approach builds on previous work to screen various extracellular matrix proteins for their effects in guiding embryonic stem cell differentiation, using robotic surface deposition. However, to motivate the study of cellular behavior and connect it to clinical outcomes, it is also necessary to concern oneself with the next higher length scale from single cells: that of cell aggregates and tissues [1]. The co-culture of stem cells with another cell type such as feeder cells is another active area of research that can benefit from microfluidic geometries.

Modern approaches to interventional medicine can generally be thought of as having three camps: chemical therapies (including drugs and biologics), devices, and more recently, cellular therapies. Stem cell therapies are among the best-known cell therapies, but a precedent in this area was set by bone marrow transplants, now a standard procedure. Numerous companies are developing stem cell lines for therapies ranging from neural regeneration in Parkinson's disease to prevention of scarring after myocardial infarction. The number of stem cell sources cited as starting materials is expanding steadily; they include adult marrow, blastocyst-derived fetal mass, embryos, and fusion products of adult nuclei and unfertilized eggs. Among all the promising news lie several problems associated with cell therapies:

- tissue compatibility;
- regulatory and ethical concerns;
- lack of control in situ.

Several approaches are being taken to tissue compatibility, ranging from engineered antigen silencing in stem cell lines to the harvesting of autologous adult cells from an individual's marrow or fat. Self-sourcing has become a popular idea for dealing with ethical and regulatory issues, too.

The technical challenges of in situ control are much more difficult to solve. Typically, stem cells are injected as a bolus into the artery feeding a target tissue area, such as a ventricle of the heart. Data from most stem cell companies show that just a few percent of the injected stem cells remain at the trauma site moments later. The majority of the cells pass through the target tissue capillaries and then enter the veins to be carried to other parts of the body. Stem cell markers and debris are typically traced to the lung and the liver. Tracking the migration of stem cells through microfabricated networks of channels could provide insight into the biophysical determinants which control the fate of implanted stem cells.

Basic Methodology

Single-Cell Assay

In a single-cell assay, cells can be confined inside a volume as small as 100 pl, formed by the compression of a flow channel by two adjacent control channels [2]. Actuation of two adjacent valves in the control layer defines the cell chamber volume, which may be as small as $100 \times 100 \times 100\ \mu$m. Fluorescent product molecules to be quantified accumulate in the small volume of the chamber. In miniature cell chambers, fast efflux rates and short mixing times ensure that the overall fluorescence signal in the cell surroundings accurately corresponds to the enzymatic activity within the stem cell. It is expected that 100 such single-cell chambers could be scanned in under 2 min, using a tightly focused laser beam that does not directly illuminate the cell to prevent photoinduced damage of the cell during measurement.

Stem Cell Culture

Lee et al. [3] have used a simple microfluidic device to manipulate transplanted embryonic stem cells while observing differentiation of the cell mass. The chambers were created with a fluid channel structure, constructed from PDMS and SU-8 photoresist. Others have used gradient-generating microfluidic systems to control and achieve proliferation and differentiation of neural stem cells [4]. Such a system exposes cells to a concentration gradient of growth factors under continuous flow, which acts to minimize autocrine (extracellular feedback from the same cell) or paracrine (chemical communication between nearby cells) signaling. Chung and coworkers have constructed gradient chambers out of PDMS using rapid prototyping and soft lithography as pioneered by George Whitesides. One such gradient-generating microchannel network, the "Christmas tree" configuration, uses laminar flow and diffusive mixing to create smoothly varying mixtures of two or more solutes. Neural stem cells retain the ability of self-renewal and can differentiate into the three main types of the central nervous system: neurons, astrocytes, and oligodendrocytes. It is hoped that one day cultured neural cells could be transplanted to alleviate degenerative diseases of the brain such as Alzheimer's and Parkinson's diseases, or be used to reconnect the spinal cord following injury.

Researchers have also built microfluidic devices for culturing adherent stem cells while simultaneously exposing those cells to a logarithmically varying range of flow rates

and to logarithmically varying concentration gradients [5]. One such implementation of this features four microscale culture chambers connected to a network of fluidic resistances, and perfused with a syringe pump (see Fig. 1). To create a 4×4 array of chambers with the flow rate varying along one axis and the concentration along the other axis, devices can be fabricated as four interconnected microfluidic layers:

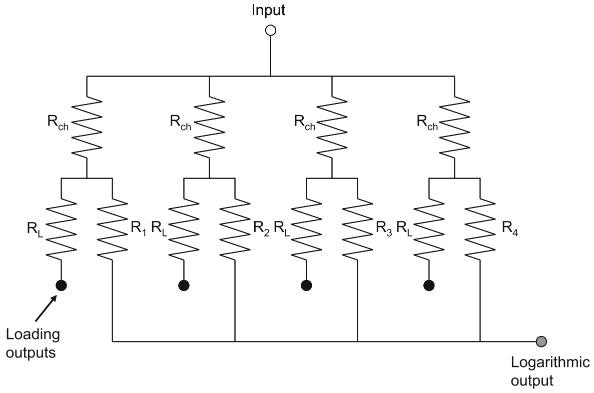
- a mixer layer of depth 30 μm,
- a delivery layer of depth 100 μm,
- a via layer of depth 100 μm, and
- a chamber layer of depth 100 μm.

This design is straightforward and does not require on-chip valves, and can be scaled up to feature additional culture chambers and wider ranges of flow rates. For rectangular microchannels with an $O(1)$ aspect ratio, the fluidic resistance of each component of the network can be designed using the following expression:

$$R = \frac{12\mu L}{wh^3}\left[1 - \frac{h}{w}\left(\frac{192}{\pi^5}\sum_{n=1,3,5}^{\infty}\frac{1}{n^5}\tanh\left(\frac{n\pi w}{2h}\right)\right)\right]^{-1},$$

where μ is the fluid viscosity, L is the channel length, and w and h are the channel width and height, respectively. In direct analogy with Kirchhoff's current and voltage laws, the individual flow rates through the four parallel branches are given by

$$Q_i = Q_{\text{total}}\left[(R_{\text{ch}} + R_i)\sum_j \frac{1}{R_{\text{ch}} + R_j}\right]^{-1}.$$



Microfluidics for Stem Cell Therapy, Figure 1 Resistance schematic for the logarithmic microfluidic device of Kim et al. [5]. A similar approach has been used to generate a logarithmically varying local shear rate and solute concentration gradient in a 2×2 array of culture chambers. R_{ch} denotes the flow resistance of each of the four culture chambers, R_{L} denotes the loading-mode flow resistances, and R_1–R_4 are the four logarithmically scaled flow resistors

The above combined device with varying flow rate and simultaneously varying solute concentration helps to control the transport of molecules toward and away from the cells of interest. Embryonic stem cells, for example, are particularly sensitive to their microenvironment. Logarithmically varying concentration gradients have also been used for pharmacological testing on patch-clamped cells.

Stem Cell Tissue Engineering

A long-term goal of tissue engineering is to construct a bioartificial organ containing a dense collection of living cells that can effectively replace the function of a diseased pancreas, liver, kidney, or heart muscle. Such a device, even with only short-term effectiveness, would be extremely valuable for providing temporary support for patients awaiting a matched donor organ. The main engineering challenge in developing a bioartificial liver replacement is that the organ is home to nearly 250 billion hepatocyte cells, each around 25 μm in diameter [6]. Other applications of tissue engineering aim to enhance, rather than fully replace, existing tissues. The three main approaches to tissue engineering have been described in a recent review [7]:

- the use of isolated cells or cell substitutes as cellular replacement components,
- the use of acellular biomaterials that can elicit a tissue regeneration response in the host organism, and
- a combination of cells and materials, i. e., a polymeric scaffold seeded with biological cells.

Two of the preferred biodegradable materials for use in microfabricated capillary networks are poly(DL-lactide-*co*-glycolide) (PLGA) and poly(glycerol sebacate) (PGS). Biodegradable PLGA microfluidic devices that serve as cell scaffolds have been created by stacking multiple layers after microfabrication steps. Functioning microvasculature can then be produced by coating the interior surfaces with fibronectin (an extracellular matrix protein) and then introducing endothelial cells, which grow to form confluent blood vessels within several days. In two dimensions, PLGA substrates can be micropatterned with ligand molecules, whereas 3D patterning has been less effective to date. Molecular micropatterning, when used to control the shape of adherent cells, can be used to control stem cell differentiation. For instance, when human mesenchymal stem cells are allowed to spread across a surface they are observed to differentiate into osteoblasts (cells which build bone), while cells confined so as to maintain a spherical shape mostly become adipocytes (fat cells). Biologists have determined that such a correlation between cell shape, mechanics, and stem cell differentiation is associated with the RhoA intracellular signaling pathway.

M

Multiphenotype cell arrays have been created by capturing cells in a connected network of reversibly sealed microfluidic channels [8]. Elastomeric PDMS molds can be reversibly sealed on a surface to sequentially deliver fluids or cell suspensions to specific locations on a substrate. Khademhosseini et al. [8] have used this technique to capture and immobilize embryonic stem cells in low-shear-stress microwells within microfluidic channels. Orthogonal alignment of a secondary array of channels was then used to perfuse the cell patterns with media.

Stem Cell Isolation

About 200,000 people currently live with leukemia in the US, with about 35,000 new cases and 23,000 deaths each year. Leukemia treatment typically involves high doses of chemotherapy, which kill both cancerous cells and blood-regenerating marrow progenitors. To restore bone marrow function after therapy, physicians perform bone marrow transplants of CD34+ hematopoietic stem cells (HSCs). Transplanted marrow can be sourced autologously (from the patient) or allogenically (from another person). Allogenic stem cells are usually sourced from a close relative, but only about one patient in three finds a donor whose tissue is compatible for a transplant. Autologous transplants have been rare in the past because of the danger of reintroduction of cancerous cells into the patient. However, stem cell isolation techniques are improving and autologous transplants are increasing in frequency.

The HSCs can be harvested by aspiration of marrow, or by isolation from peripheral blood. Studies have shown that peripheral blood stem cell transplants (PBSCTs) result in shorter hospital stays, and are safer and more cost-effective than bone marrow transplants. Donations for the purpose of PBSCTs are currently performed with the use of apheresis, where the white blood cells are separated out by centrifugation. The procedure typically takes 4 h each day over several days. Gambro and Baxter are the market leaders in apheresis instruments, sharing 70% of a market estimated at $145 million in 2002. Miltenyi Biotech markets anti-CD34 antibodies immobilized onto magnetic beads that can precipitate HSCs from the white cell fraction. Clinical applications including this isolation technique are in progress. A new medical device company, CellTraffix [9], is advancing commercial applications of adhesion technology by replicating an in vivo mechanism to build microfluidic devices and instruments capable of isolating HSCs from peripheral blood (see Fig. 2). This in vivo mechanism mediates leukocyte rolling on the vascular endothelium via the weak affinity between P- and E-selectin expressed by the vascular endothelium, and selectin-binding carbohydrate ligands expressed on circulating HSC and leukocytes. P-selectin in combination with specific antibodies is used as a coating on a solid support, over which blood flows at a rate that allows HSCs to roll slowly and all other cells to flow rapidly without rolling. This differential rolling is leveraged to isolate the HSCs in a manner akin to the chromatography of molecules.

Key Research Findings

Single-Cell Assay

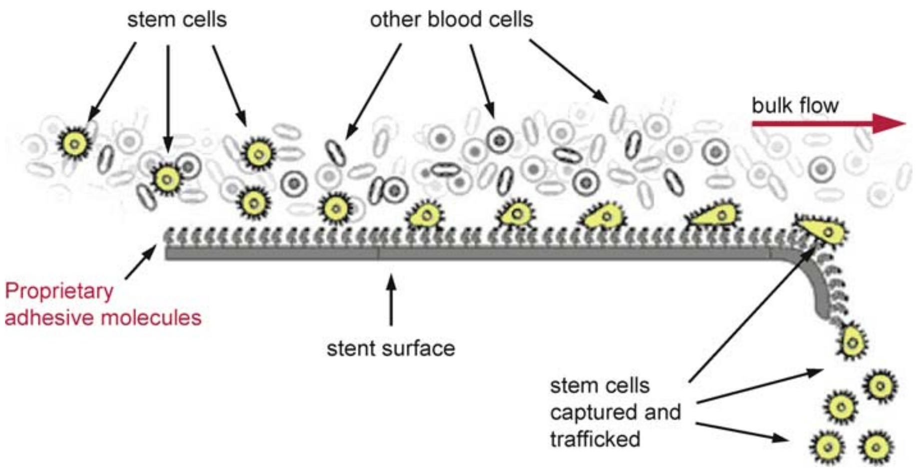
Cai et al. [2] have developed a microfluidic assay to perform real-time measurement of the expression of proteins in living stem cells with single-molecule sensitivity. They observed that protein production took place in bursts, with the number of molecules per burst (quantified as enzymatic rate) following a Poisson distribution. The single-cell, single-molecule microfluidic system that they developed was applied to study the mouse embryonic stem cell lines ES54A and ES17. The cells were cultured in a defined medium to prevent differentiation. Although stochastic gene expression had been demonstrated previously for higher expression levels using flow cytometry and fluorescence microscopy, the study of Cai et al. with a microfluidic system was the first to confirm such behavior with single-copy sensitivity.

Stem Cell Culture

Mouse P19 embryonic carcinoma stem cells have been xenotransplanted into an emptied chorion (the transparent envelope of a fertilized zebrafish egg) [3]. The chorion is a useful biological vessel for developing stem cells, owing to its relatively large size of 1 mm in diameter, and also to the presence of penetrating nanopores of dimensions 500 – 700 nm. In experiments by Lee et al. [3], a stem cell/chorion construct was transported using a microfluidic channel though one of ten rectangular culture wells. A thin microhole layer was used to perfuse nutrients to the chorion via microholes of diameter 300 μm, with cell media exchanges occurring every 48 hours. By day 15 of the experiment, Lee et al. determined that the outer layer of the cell mass had successfully differentiated into neural cells, while the inner layer of the large embryoid body had differentiated into beating cardiomyocytes (heart muscle cells). Cell types were verified using immunostaining.

In the growth factor gradients generated by Chung et al. [4], human neural stem cells from a developing cerebral cortex were cultured for over 1 week in a microfluidic chamber under continuous exposure to a smooth gradient of a growth factor mixture comprising

- epidermal growth factor,
- fibroblast growth factor 2, and
- platelet-derived growth factor.



Microfluidics for Stem Cell Therapy, Figure 2 Medical devices are being developed that use the adhesive properties of lectins, which are similar to antibodies in that their binding is highly selective [9]. Unlike antibodies, lectins bind rather weakly, allowing cells to roll over a surface without becoming permanently bound to it. Biomimetic adhesion technology harnesses this rolling behavior to control the movement of captured stem cells in the bloodstream. The advantages of lectins over antibodies include the fact that lectins are not consumed in the adhesion process, promising lower costs and simplicity in the isolation of rare stem cells from dilute solutions

The human neural stem cells were observed via time-lapse microscopy to proliferate and differentiate into astrocytes (star-shaped glial cells in the brain). The cell phenotype was verified by immunohistochemistry. The cells were found to be healthy during the entire week of culture, and the proliferation and differentiation of the cells followed directly from the local concentration of growth factor as expected. Chung et al. found a strong correlation between the total cell number and the local concentration of growth factor.

Logarithmically varying concentration gradients have been studied by Kim et al. [5], and verified with fluorescent measurement. In the presence of different solute concentrations and flow rates covering a range of a factor of 300, murine embryonic stem cells were cultured for up to 4 days. Kim et al. found that the stem cells did not proliferate at the slowest flow rate tested, whereas colonies grown at higher flow rates exhibited a healthy round morphology. The chambers operating at higher flow rates showed a smaller number of colonies, although the individual colonies were much larger in size.

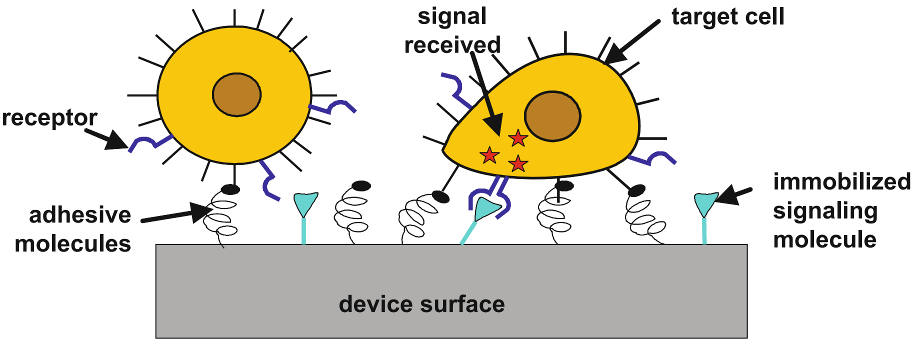
Stem Cell Tissue Engineering

Khademhosseini et al. [8] have successfully cultured murine embryonic stem cells in a microfluidic array of reversibly sealed channels. These authors have proposed to position microwells 100 μm apart using standard soft-lithography techniques, leaving sufficient room to overlay individual microchannels addressing each pattern. Thus, the total required area per microwell would be $200 \times 200\ \mu$m, with each well possibly operating under different culture conditions. Thus, 2500 unique tests could be performed in a 1 cm^2 area, far exceeding the capabilities of existing multiwell plates.

Stem Cell Isolation

The effects of immobilized P-selectin chimeras in the presence and absence of antibodies on the rolling velocities of normal cells (neutrophils and HSCs) and leukemic cell lines (Kg1a and HL60 cells) have been investigated [10]. This research aimed to compare the behavior of the leukemic cell lines with normal cells on P-selectin alone, and then to selectively reduce the rolling velocities of cells expressing the CD34 antigen on their surface (HSCs and Kg1a cells) using a combination of immobilized monoclonal antibodies against CD34 and P-selectin. A microfluidic channel assembly comprising polystyrene and acrylic layers was used, where a suspension of the cells in question was perfused at physiological shear rates over functionalized surfaces using methods developed for the study of neutrophil and platelet adhesion under flow. Movies of the rolling cells could be digitized and subsequently analyzed using a MATLAB program to determine the rolling velocity of each cell.

Cells of the similar sizes (HSCs and neutrophils; Kg1a and HL60 cells) rolled at similar rolling velocities on various concentrations of the immobilized P-selectin. The rolling velocities of cells expressing CD34 antigen (HSCs and Kg1a cells) were significantly reduced in the presence of the antibody and P-selectin, while the veloc-



Microfluidics for Stem Cell Therapy, Figure 3 Cell adhesion technology enables highly specific cellular signaling. If a signaling molecule is immobilized on the surface and only the targeted stem cells are rolling on the surface, then only the targeted stem cells will receive the signal

ities of cells that did not express CD34 were unaffected – the antibody alone did not support rolling. The success of these experiments suggests the use of a functionalized selectin/antibody surface to facilitate cell separation. Kg1a cells have been successfully isolated from a mixture of Kg1a and HL60 cells on the basis of their differential rolling velocities on immobilized P-selectin and anti-CD34, and this work has been extended to demonstrating effective separation protocols for a mixture of HSCs and mature blood components [11, 12]. Through the product development activities currently under way, this technology will have clinical and research applications as a low-stress method for purifying cells without significantly affecting their surface antigen profile, and will facilitate cell isolation for stem cell therapies [9].

Future Directions for Research

Single-stem-cell assays based on microfluidics can be scaled up to allow characterization of gene expression on the whole-genome scale, particularly in the limit of low expression levels [2]. Two-dimensional arrays of stem cells will, hopefully, lead to high-throughput screening of drugs and optimal conditions for tissue engineering. In the field of stem cell culture and tissue engineering, one new frontier of controlling the cell microenvironment is to expose an individual cell to multiple microenvironments by placing it at an interface between two adjacent flow streams [7]. While the discussion in this article has focused on the chemical microenvironment and local mechanical shear stress, temperature can also have a profound effect on the dynamics of embryonic development. Multiple research groups have explored the idea of using microfluidics to transport a growing embryonic body from one temperature environment to another as a simulation of in vivo conditions.

Stem Cell Reprogramming

Bone marrow was once thought unique among organs because of its regenerative ability. Since the discovery of stem cells, the marrow has been recognized as the largest of several stem cell sources. Stem cells routinely leave the marrow and circulate in the peripheral blood, trawling for signals that indicate a need for repair before homing back to the marrow. Biotechnology companies are currently developing applications around the concept of artificial marrow that collect and grow stem cells over time in the body [9]. Here, microfluidic capillary networks are placed in the peritoneal cavity, as a venous bypass, using laparoscopic procedures. This implant can be removed with minimally invasive techniques when an acute need for stem cells arises, for example after a heart attack. The idea of in situ stem cell storage overcomes a major obstacle associated with external storage: the cost of liquid nitrogen. The age-related decline in circulating stem cell numbers is well documented, suggesting a regenerative value to deliberately increasing circulating stem cell numbers as an antiaging therapy. Microfabricated flow channels could also enable the controlled release of stem cells from an artificial marrow device. A small number of stem cells circulate in our bodies at all times. Future work in this area will most likely be aimed at developing implants that capture these autologous cells and traffic or reprogram them to a site in need of regeneration (see Fig. 3). In combination with the technologies developed for artificial marrow, these implants could substantially accelerate healing. Likely indications include skin ulcers and peripheral vascular disease, which are chronic and likely to require continuous healing assistance.

Definition

► Microfluidic systems, ► Lab-on-a-Chip systems or micrototal analysis systems (μ-TAS) allow the miniaturization of various functional units, such as pumps, valves, and reactors, and make it possible to build novel integrated microsystems for various biological applications. These systems have been well recognized as a possible *enabling technology* that may play important roles in biology in the future. This observation is supported by the efforts that have been made to build functional microsystems for various studies of cells, including studies of apoptosis.

Apoptosis or programmed cell death, is the outcome of a metabolic cascade that results in cell death in a controlled manner. Apoptotic cells are characterized by a distinct set of morphological and biochemical characteristics, which are typically monitored in a multiwell culture plate, and, more recently, microfluidic devices have been employed.

In the early stages of apoptosis, mitochondria suffer specific damage that results in alteration of their integrity and function, for example release of cytochrome *c*, changes in electron transport, loss of the mitochondrial transmembrane potential, altered cellular oxidation and reduction, and participation of pro- and anti-apoptotic bcl-2 family proteins. A unique microfabricated device has been presented for the continuous separation of intact and compromised-membrane-potential mitochondria in apoptotic Hela cells by microscale isoelectric focusing, microIEF.

Phosphatidylserine is a membrane phospholipid, which is normally restricted to the inner leaflet of the plasma membrane. The translocation of phosphatidylserine from the inner to the outer leaflet of the plasma membrane is an early event in apoptosis. Annexin V, an endogenous human protein with a high affinity for membrane-bound phosphatidylserine, can be used in vitro to detect apoptosis. An annexin V assay in a microfluidic system has been developed for flow cytometric analysis of apoptosis using a minimal number of cells.

A shift in the cellular reduction/oxidation (redox) state has been found to be involved in the process of apoptosis.

M

Generally, the cellular redox state is a balance between the relative quantities of the intracellular oxidative substances (reactive oxygen species, ROS) and reductive substances (reduced glutathione, GSH). A microfluidic-device method with laser induced fluorescence, LIF detection for simultaneous, rapid determination of intracellular ROS and GSH in apoptotic leukemia cells has been described.

Internucleosomal DNA fragmentation is the result of activation of the endogenous endonuclease in apoptotic cells. The traditional gel electrophoresis method for the analysis of DNA fragmentation is labor-intensive. However, a microfluidic device has been developed which integrates the selection of individual cells, the lysis of cells, and separation of the released apoptotic DNA fragments.

Caspases are intracellular proteases and cleave their substrate proteins specifically behind an aspartate residue. Caspases are normally present as inactive proenzymes. However, during apoptosis, caspase activation is induced by cleavage at specific internal aspartate residues. Activation of the initiator caspases by pro-apoptotic signals leads to proteolytic activation of the execution caspases, which cleave a set of vital proteins and thus initiate and execute the apoptotic degradation phase. A self-contained on-chip cell culture and pretreatment microdevice system has been developed for the screening of caspase-3 expression in apoptotic cells.

Cytochrome *c* is a component of the mitochondrial electron transfer chain. The release of cytochrome *c* from mitochondria initiates caspase activation during apoptosis. A microchip-based system has been developed for direct monitoring of the cytochrome *c*distribution during the apoptosis process.

Alterations in the cytosolic Ca^{2+} concentration and/or intracellular Ca^{2+} compartmentalization are involved in the regulation of apoptosis. These apoptosis-associated Ca^{2+} fluxes are critical targets of evolutionarily conserved actions. A microfluidic device has been constructed for ionophore-mediated intracellular Ca^{2+} flux measurements and multistep receptor-mediated Ca^{2+} measurements at the single-cell level.

Overview

Apoptosis (programmed cell death) is a complex and tightly regulated process by which a cell orchestrates its own destruction in response to specific internal or external triggers. Apoptotic processes are crucially involved in the development of cells, maintenance of tissue homeostasis, regulation of the immune system, and elimination of damaged cells. Enhanced or inhibited apoptotic cell death can result in severe pathological alterations, including developmental defects, autoimmune diseases, neurodegeneration, and cancer. Owing to its importance in such biological processes, there has been explosive progress toward dissecting its molecular basis, with an exponential increase in PubMed citations. Recently, system-level understanding of biological systems has been pursued. Research into system-level characteristics by discovering the response of cells (die or live) to certain chemicals by studying cell death regulation, and efforts to model cell processes are of great interest in the emerging field of systems biology. These studies have become powerful drivers for new technologies designed to acquire ever more comprehensive information from single cells and cell populations.

Apoptotic cells are characterized by a distinct set of morphological and biochemical characteristics observed exclusively with this mode of cell death. These apoptotic features include loss of cell volume or cell shrinkage, chromatic condensation, internucleosomal DNA fragmentation, and the formation of *apoptotic bodies* that are then phagocytized by macrophages or neighboring cells to rid the body of the dying cells, thus preventing the induction of an inflammatory response. The existence of differential expression patterns or alternate mechanisms in apoptosis pathways among tissues and cell lines makes it necessary to perform two or even three parallel experiments to confirm and compare the kinetic events associated with cell death.

Basic Methodology

The techniques designed to identify, quantify, and characterize apoptosis are numerous. Some examples are fluorescence microscope, flow cytometry, and microplate analysis. Of these, flow cytometry remains the methodology of choice for studying the apoptotic cascade in relation to cell type, triggering, and timing. However, these methods still have some limitations:

- a large number of cells are required for each flow cytometric assay ($> 10^4$/mL);
- the cell preparation prior to analysis is time-consuming, requiring additional time for cell culture, cell staining, and washing steps, and thus real-time monitoring of cell death kinetics is problematic;
- cells are often fixed and destroyed so that intact single living cells cannot be analyzed. These restrictions make current assays of apoptosis cumbersome and impractical for clinical use.

Key Research Findings

The development of miniaturized (microfabricated, microfluidic-based) analytical devices and their integration to create micrototal analysis systems [1] is one of the directions that is being pursued to address future analytical

needs. Microfluidic technologies allow the miniaturization of various functional units, such as pumps, valves, and reactors, and make it possible to build novel integrated microsystems for various biological applications. Microfluidics has been well recognized as a foreseeable "enabling technology" that may play important roles in biology in the future. This observation is partly demonstrated by the efforts that have been made to build functional microsystems for various types of cellular analysis, including apoptosis analysis [2]. Some typical work in this field [3, 4] has shown that novel schemes could be applied on a microfluidic platform to investigate cellular behaviors, schemes which would not be possible with a conventional analytical system. It may be said that contemporary microfluidic technologies provide a bridge between biological materials and systems biology through large-scale multiparameter analysis, with applications ranging from molecular dissections of single cells and very small cell populations to multiparameter disease diagnostics from cells and blood.

Apoptosis is a complex biological process, which is regulated by several cell signal transduction pathways. The study of apoptosis involves the measurement of biological and morphological hallmarks at a variety of stages in the apoptotic cascade. Apoptotic assays in microfluidics can be classified into five themes:

1. alterations of the integrity and function of mitochondria;
2. changes in cell membranes (surface lipid translocation);
3. shifts in the cellular redox state;
4. caspase activation;
5. internucleosomal DNA fragmentation; and
6. intracellular Ca^{2+} concentration changes.

Alterations of Integrity and Function of Mitochondria

A variety of key events in apoptosis are related to mitochondria, such as the release of cytochrome *c*, changes in electron transport, loss of the mitochondrial transmembrane potential, altered cellular oxidation and reduction, and the participation of pro- and anti-apoptotic bcl-2 family proteins. Of these, the disruption of the mitochondrial transmembrane potential is one of the earliest intracellular events that occur following the induction of apoptosis.

Lu et al. [5] have presented a unique microfabricated device for the continuous separation of intact and compromised-membrane-potential mitochondria in apoptotic Hela cells by microIEF. A schematic of field-flow IEF and a photograph of the microfabricated device are shown in Figs. 1a–c. The device was fabricated using a combination of photolithography, thin-film metal deposition/patterning, and electroplating techniques. In a microIEF experiment using JC-1-stained whole-cell lysate, Hela cells were treated with TNF and cycloheximide to induce apoptosis. The different isoelectric points, *pI*s for intact and compromised-membrane-potential mitochondria could potentially be used to assay the fraction of mitochondria that lose their membrane potential when cells undergo apoptosis (Fig. 1d). This microdevice provides fast separation in very small samples while avoiding the large voltages and heating effects typically associated with conventional electrophoresis-based devices.

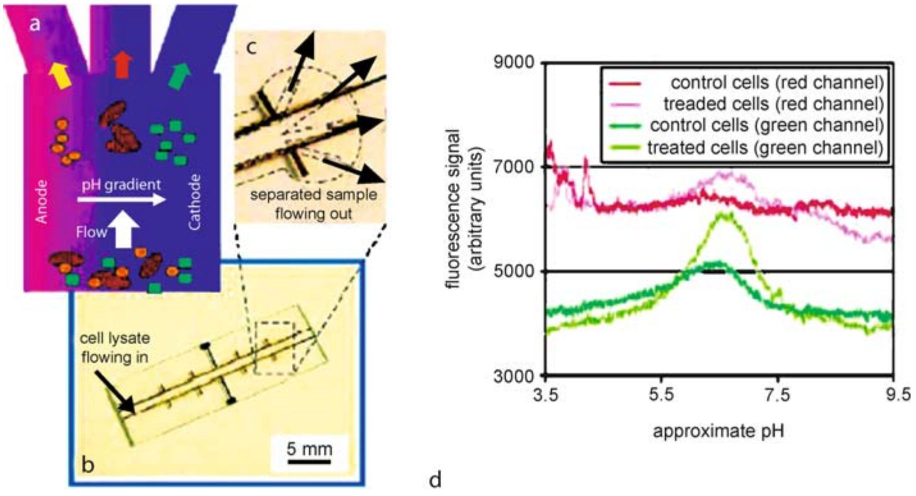
Cell Membrane Alterations (Surface Lipid Translocation)

One of the earliest events in programmed cell death is the externalization of phosphatidylserine, a membrane phospholipid normally restricted to the inner leaflet of the lipid bilayer. Annexin V, an endogenous human protein with a high affinity for membrane-bound phosphatidylserine, can be used in vitro to detect apoptosis before other well-described morphological or nuclear changes associated with programmed cell death.

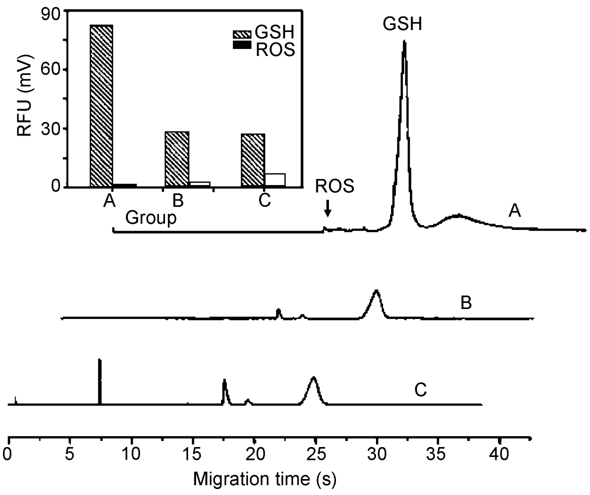
Calipter Technologies and Agilent have developed an annexin V assay in a microfluidic system, which allows flow cytometric analysis of apoptosis with a minimal number of cells [6, 7]. In this setup, the cells are moved by pressure-driven flow inside a network of microfluidic channels and are analyzed individually by two-channel fluorescence detection. As only a small number of cells (as few as 50 – 100) are consumed per assay, this setup is particularly suitable for working with cells of limited availability, for example primary cells. The system has been applied to evaluate staurosporine-induced apoptosis and annexin V binding in human umbilical vein endothelial cells (HUVECs) and normal human dermal fibroblasts (NHDFs). The results are in good correlation with results obtained using conventional flow cytometry but demonstrate new dimensions in low reagent and cell consumption.

Shift in Cellular Redox State

The cellular reduction/oxidation (redox) state has been found to be involved in the regulation of cell proliferation, differentiation, and apoptosis. Generally, the cellular redox state is a balance between the relative quantities of the intracellular oxidative substances (reactive oxygen species) and reductive substances (reduced glutathione). Conventionally, intracellular ROS and GSH can only be determined by flow cytometry, HPLC, or enzymatic methods. Qin et al. [8] have described a microfluidic device method with LIF detection for simultaneous, rapid determination of intracellular ROS and GSH in apoptotic



Microfluidics for Studies of Apoptosis, Figure 1 (**a**) Schematic of field-flow IEF of mitochondria. (**b**) Photograph of a microfabricated device before final assembly; (**c**) enlarged view of the fractionation end of the device. The device consists of electroplated gold electrodes and microfluidic channels formed in a photopatternable epoxy. (**d**) IEF of JC-1-labeled mitochondria from apoptotic Hela cells showing larger signals (in both the red and the green channel near neutral pH), which suggests that a number of mitochondria from the apoptotic cell population have lost their transmembrane potential. Reprinted from [5], with permission



Microfluidics for Studies of Apoptosis, Figure 2 Microchip electropherograms of ROS and GSH in apoptotic NB4 cells. (A) control; (B) 1.0 mM As_2O_3; (C) 1.5 mM As_2O_3. The cells were exposed to As_2O_3 for 72 h

leukemia cells on a glass chip. Both quantitative and qualitative information about the compounds investigated can be obtained, and the two analytes can be detected in just 27 s by using this method. Depletion of GSH and generation of ROS were observed in apoptotic NB4 cells after triggering with arsenic trioxide (As_2O_3) (Fig. 2), showing that the proposed microchip method can readily evaluate the production of ROS, which occurs simultaneously with the consumption of the inherent antioxidant.

DNA Fragmentation

The most familiar biochemical feature of apoptosis is endogenous endonuclease activation. This results in the production of domain-sized large (50 – 300 kb) DNA fragments and oligonucleosomal cleavage products commonly referred to as "DNA ladders". The traditional gel electrophoresis method is labor-intensive, requiring additional time for cell lysing and extraction of genomic DNA. Kleparnik and Horky [9] performed detection of doxorubicin-induced apoptosis in individual cardiomyocytes in a microfluidic device. Microstructures integrated on a CD-like plastic disk were adapted for selection of individual cells, lysis of cells in an alkaline environment, and separation of the released apoptotic DNA fragments. The fragments with the typical 180 bp ladder pattern were electrophoretically resolved in a 2% solution of linear polyacrylamide on a polycarbonate chip. The causal relation between the enhanced doxorubicin concentration and the extent of DNA fragmentation in a single cell was confirmed.

In addition to the use of electrophoresis for identification of the characteristic DNA ladders, DNA content analysis by flow cytometry is often employed to identify cells undergoing DNA fragmentation. This method is based on the fact that permeabilized apoptotic cells release fragmented DNA, resulting in a DNA content that is less than that in live diploid cells. Sohn et al. [10] developed a novel microfluidic technique – capacitance cytometry – that can be used to quantify the polarization response of

DNA within the nucleus of a single eukaryotic cell and to analyze the cell cycle kinetics of populations of cells. The fundamental basis of capacitance cytometry is an AC capacitance measurement. It has been found that there is a linear relationship between the DNA content of eukaryotic cells and the change in capacitance that is evoked by the passage of individual cells across a 1 kHz electric field. By monitoring the DNA content of populations of cells with this technique, one can produce a profile of their cell cycle kinetics. Thus, this might be advantageous in tumor cell detection and in real-time monitoring of the effects of a pharmacological agent on cell cycles and cell death.

Changes in Caspase Activity

A number of specific changes in enzyme activity occur during apoptotic programmed cell death. The protease caspase-3 increases in activity during apoptosis and participates in the degradation of several cellular proteins essential for DNA repair. Tabuchi and Baba [11] have developed a self-contained on-chip cell culture and pretreatment microdevice system, which was used for screening of caspase-3 expression in stress-shock-triggered apoptosis of Jurkat cells. The pretreatment microdevice included 96 hand-made wells and a 12-well inner cup, requiring no external pipetting or centrifugation steps for cell culture and washing. The cells were placed into the inner cup and inserted into wells that were filled with a culture medium. During exchange of the medium, the inserted cups containing cells were moved into the next row of wells, which were filled with new buffer or reagent. By connecting devices for all procedures to an electrophoretic separation chip, the cell culture, cell-washing, stimulation, protein extraction, and electrophoretic separation processes could be integrated. The microdevice could manipulate 12 samples simultaneously, and the total analysis time was around one-eighth of that of the conventional analytical method. Using this microdevice, an annexin V assay of cells treated with camptothecin or heat shock was also performed.

Protein Release from Cells

The release of cytochrome *c* from mitochondria to the cytosol is thought to be a key event for signal transduction in the apoptotic process. It has been suggested that it induces a series of biochemical reactions that result in caspase activation and subsequent cell death. Tamaki et al. [12] have developed a microchip-based system for direct monitoring of cytochrome *c* distribution during the apoptosis process. This system incorporated microscale cell culture, chemical stimulation, and a scanning-thermal-lens detection system under a microscope, which resulted in secure cell stimulation and coincident in vivo observation of the cell responses. Monitoring of the cytochrome *c*distribution in a neuroblastoma–glioma hybrid cell was performed in a microflask fabricated in a glass microchip. Cytochrome *c* was detected with an extremely high sensitivity ($\sim$ 10 zmol) without using any labeling substrate.

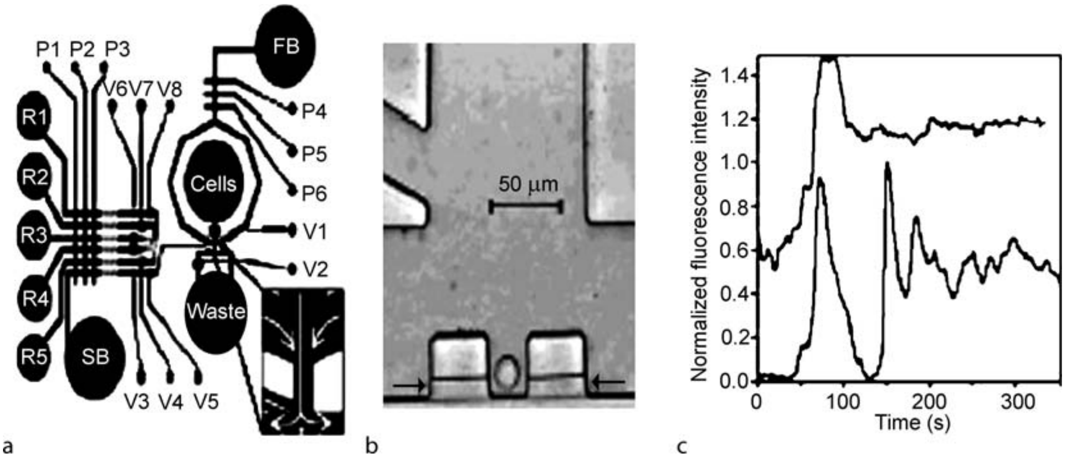
Intracellular Ca^{2+} Concentration Changes

Several lines of evidence indicate that alterations in the cytosolic Ca^{2+} concentration and/or intracellular Ca^{2+} compartmentalization are involved in the regulation of apoptosis. These apoptosis-associated Ca^{2+} fluxes are critical targets of evolutionarily conserved actions. Wheeler et al. [13] have developed a microfluidic device constructed from poly(dimethylsiloxane) (PDMS) for ionophore-mediated intracellular Ca^{2+} flux measurements and multistep receptor-mediated Ca^{2+} measurements at the single-cell level. A schematic diagram of the microfluidic device and results showing measurements of the ionomycin-mediated Ca^{2+} flux in Jurkat T-cells are presented in Fig. 3. The microfluidic network enabled passive, gentle separation of a single cell from the bulk cell suspension, and integrated valves and pumps enabled the precise delivery of nanoliter volumes of reagents to that cell. The method of cell trapping and perfusion with focusing and shield buffers provides an innate "washing", minimizing reagent consumption, analysis time, and stress on the cell. Thus, it might be useful for measuring intracellular Ca^{2+} concentrations in individual cells during apoptosis.

In addition, a microfluidic device for monitoring cellular Ca^{2+} uptake reactions has been developed by Yang et al. [14]. The device allows cell transport and immobilization, and dilution of an analyte solution to generate a concentration gradient. The ATP-dependent calcium uptake reaction of HL-60 cells was monitored, demonstrating the feasibility of using a microchip for real-time monitoring of cellular Ca^{2+} flux during apoptosis upon treatment with a concentration gradient of test solution.

Future Directions for Research

The central component of apoptosis is a genetically programmed network within cells, which is driving the development of new technology for system-level study. As already described above, microfluidic devices have been employed to characterize most of the key hallmarks of apoptotic processes. Also, there has been an attempt to integrate an ability to make multiple measurements on one microfluidic chip. However, in view of technical considerations, there is still enough space for this technology to be



Microfluidics for Studies of Apoptosis, Figure 3 (**a**) Schematic of single-cell analysis device. The fluidic channels are shown as dark, and the control channels as light. R1–R5 are reactant inlets, and SB and FB are the shield and focusing buffer inlets, respectively. Valves are actuated by applying pressure to the control inlets V1–V8. Pumps are activated by actuating P1–P3 or P4–P6 in series. Inset: close-up of cell-trapping region. Cells are pushed by hydrostatic pressure from the cell inlet to waste. They are focused to the center of the stream by the focusing buffer. (**b**) CCD image of an individual Jurkat T-cell trapped in a cell dock. (**c**) Measurements of ionomycin-mediated calcium flux in Jurkat T-cells. explored further in relation to the following aspects of the study of apoptosis.

Single-Cell-Analysis

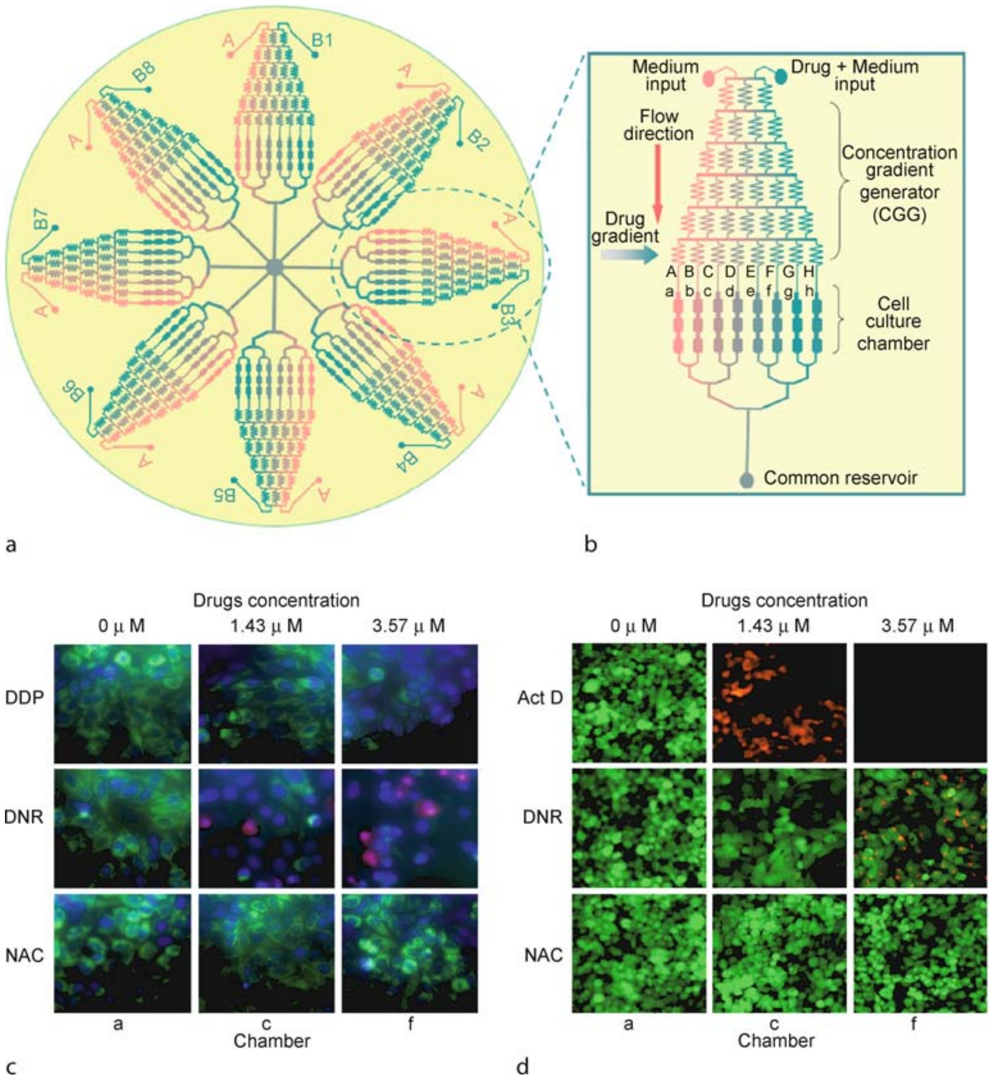
Apoptosis is found to proceed in different cells at different times after an initial stress is applied. However, the current experimental measurements on apoptotic processes in particular cells are typically performed on large cell populations. Such experiments necessarily lead to measurements of an inhomogeneous distribution of cell responses. Therefore, it is particularly attractive to be able to carry out external perturbations at the single-cell level.

Microfluidic technology appears to offer an effective platform for single-cell analysis [15], and many efforts are under way to mimic the properties of single cells and to design chips that are as efficient as cells. Various techniques, such as the use of hydrostatic pressure heads in device inlets, electrokinetic pumping with usage of multiple integrated off-chip pumps, and optical or dielectrophoretic traps, have been tried to control liquids or manipulate individual cells in a microdevice. The development of multilayer soft-lithography fabrication has greatly improved the control of fluids and cells in microfluidic devices, with the advantage of forming valves with near-zero dead volume. An integrated microfluidic process on a single chip using mechanical microvalves to achieve parallel, nanofluid processing in a highly integrated system has been demonstrated by Quake's group [16]. This system is capable of trapping mammalian cells, performing lysis, and purifying measurable amounts of mRNA from as little as a single cell. These studies are preparing the ground for the further study of cell death behavior using single cells whose behavior deviates from that of the bulk population, which otherwise would not be possible owing to the complexity of the system.

In Situ Dynamic Apoptosis Analysis

Apoptosis is a dynamic physiological process in the normal development and homeostasis of multicellular organisms. The ability to monitor cell death events over time provides a unique tool for the evaluation of the therapeutic efficacy of experimental therapeutic agents, and for studies on the role of apoptosis in various disease processes. Conventionally, apoptosis in a population is determined at a specific time by microscopic examination or flow cytometry. However, apoptotic cells exist in vitro for a limited time and occur only in a relatively narrow temporal window, after which they promptly disintegrate. Thus, an accurate determination of apoptosis in a population of cells requires either frequent determinations or continuous monitoring.

Microfluidic devices enable one to incorporate cell culture, manipulation of living cells, or cell lysing into a microchip-based platform, making it possible to investigate cell death events in the same cell or in a population of cells after stimuli over time. Recently, there has



Microfluidics for Studies of Apoptosis, Figure 4 (**a**) Schematic of the integrated microfluidic device, which consists of eight uniform structure units and each unit is connected by a common reservoir in the centre of device. (**b**) Magnified section of the single structure unit containing an upstream concentration gradient generator (CGG) and downstream parallel cell culture chambers. (**c**) Representative composite images from multiparametric apoptosis analysis in HepG2 cells by monitoring mitochondrial transmembrane potential (Rh-123, Green), membrane permeability (PI, Red) and nuclear morphology (Hoechst 33342, blue), respectively. been some work dealing with dynamic apoptosis analysis in real time with microfluidic devices. Muñoz-Pinedo et al. [17] have designed a microfluidic chip with a filter structure so that a certain number of cells could be retained in a microchamber, while the well-defined height of the chamber (25 mm) could confine the cells within the focal plane of a confocal microscope. This technology was used to monitor and image cell death events in human leukemic U937 cells over time. Multiple apoptosis events such as loss of mitochondrial transmembrane potential, exposure of phosphatidylserine, membrane blebbing, and permeabilization of the cell membrane have been observed, in real time, in individual cells.

High-Throughput Apoptosis Assays

Moving apoptosis and toxicity testing to an earlier stage in pharmacological screening for drug candidates has become a major focus in drug discovery. In the case of cancer cells, the goal is to develop chemotherapeutics that pro-

mote differential cell death. This search is often a quest to screen for triggers of apoptosis in a high-throughput assay. In addition, investigation of the comparative effectiveness of antiviral and antimicrobial compounds and examination of the general cytoxicity of new drugs are also important reasons to analyze cell death in high-throughput assays. Microfluidic technology enables the sorting of cells on the basis of dynamic functional responses to stimuli, and the manipulation of smaller volumes and cells while performing more complex biological experiments. Recently, Valero et al. [18] have presented the design and fabrication of a microfluidic cell-trapping device for potential high-throughput analysis of apoptosis. This microfluidic cell-trapping device consists of two channels, which join together in a crossway. The cross-flow devices introduced in this study offer tools to characterize single cells in a format that allows integration of high-throughput techniques with unique assay functionality. The microfluidic silicon–glass chip enables the immobilization of cells and real-time monitoring of apoptosis processes. The tumor necrosis factor TNF-a, in combination with the cycloheximide-induced cell death dynamics of HL-60 cells, was studied using this chip.

Recently, Ye et al. [19] developed a microfluidic device for high throughput and high content evaluation of anti-cancer drugs with apoptosis inducing capabilities in hepatocellular carcinoma (HepG2) cells. The device consists of multiple drug gradient generators and parallel cell culture chambers, in which the processes of liquid dilution and diffusion, micro-scale cell culture, cell stimulation and cell labeling can be integrated into a single device. The simple assay provides multi-parametric measurements of plasma membrane permeability, nuclear size, mitochondrial trans-membrane potential and intracellular redox states (GSH and ROS) in anti-cancer drug-induced apoptosis of HepG2 cells. The established platform is able to rapidly extract the maximum information in tumor cells in response to various drugs varying in concentrations with minimal sample and less time, which is very useful for basic biomedical research and cancer treatment.

Definition

Microfluidic systems manipulate or process tiny (10^{-9} to 10^{-18} l) volumes of fluids in channels with dimensions of tens to hundreds of micrometers. These systems, built using various *microfabrication techniques*, offer a number of advantages for chemical and biological analysis compared to standard laboratory instrumentation including low consumption of samples and reagents, low cost for mass production, short times for analysis, flexibility and dimensional precision, and separations and detections with high resolution and sensitivity. They can also probe physical phenomena and mechanisms that are not observable on the macroscopic scale. In addition, one key feature of these systems is the integration of different functional units for sampling, sample pre-treatment, sample transport, biochemical reactions, analyze separation, product isolation and detection in a microchannel network. *Microfluidic systems* enable serial processing and analysis, and furthermore, can accomplish massive parallelization through efficient miniaturization and multiplexing.

High-throughput chemical testing

Definition

Microfluidic systems for combinatorial chemistry are used to discover and optimise the chemical reactions used to produce novel materials, in particular catalysts and drugs. They may also be used to optimise the reaction conditions. The systems are designed to perform a large number of reactions in parallel, each differing – usually only a little – in some variable (or variables), like presence of reagents, their mixing ratio, composition of catalysts, etc., while other variables are kept invariant. The test results, such as properties of the reaction products, are evaluated and stored in the form of combinatorial libraries. Information extracted from the libraries is used to identify optimum reaction conditions.

Overview

The advantage of using microfluidics [1, 16] for combinatorial testing is the small size of the reactors [5] and other devices and the consequent possibility of high throughput by running a very large number of test reactions simultaneously. Most often, the evaluation of the results is made by composition analysis of reaction products. The essential part of a typical microfluidic system for this purpose

is a ▶sampling unit, taking one sample at a time and delivering it to the analyser. This task is complicated by strict requirements of sample purity. With the no-moving-part fluidic valves for sample flow control, a complete separation of the cavities containing different samples is impossible and maintaining sample purity requires a special design of the fluidic circuits, with generation of protective cleansing and ▶guard flows.

Combinatorial chemistry has been and is likely to remain for the foreseeable future an indispensable approach to the discovery of new materials and also the optimisation of their properties. It is particularly important in areas like the development of catalysts [3] and enzymes, where empirical testing is practically the only path to further progress. Essentially, the tests are done by performing similar chemical reactions under conditions identical in all other aspects, with the exception of a single variable (or a small number of variables). These variables may be qualitative (absence of some reagents or components) or quantitative, such as the mixing ratio of the input reagents, or the times at which the reaction is quenched. The quantitative changes are preferably made in small steps. Sometimes more refined steps are then used in subsequent test series. The result of the tests is a set of reaction products differing in the value of a pursued performance criterion or criteria.

The results are stored in combinatorial libraries. They may be in material form, consisting of stored actual reaction products themselves – usually in small wells on a tray or, if they are volatile or perishable, in small closed vials. More convenient is, of course, the library consisting of just stored resultant data as a table in a computer memory. The great advantage of the material library is the availability at a later time for repeated analysis or analysis by a different method, perhaps evaluating a different property of the compounds than was done in the original investigation. Considerable theoretical effort has been devoted to the procedures of using the information stored in the combinatorial libraries for identifying the desirable optimum – the compound with the best properties [2]. The approaches to the search for the optimum are based on combinatorial strategies which originated in pharmaceutical research. They often use advanced mathematical methods, such as genetic algorithms – function optimisation based on the genetic principle of natural selection and survival of the fittest [15]. These work well on mixed (qualitative *and* quantitative variables) optimisation problems and are robust against locking to local peaks. The search for he optimum is often complicated by requirements to meet several, sometimes contradictory optimality criteria. There are traditionally at least two criteria – yield and selectivity – in the case of catalysts, and five ones known as ADMET properties (adsorption, distribution, metabolism, elimination and toxicology) in the case of medicinal drug candidates.

Basic Methodology

Tests

The reliability, usefulness and general quality of the information that may be extracted from a ▶combinatorial library are critically dependent on the number of entries, i. e., the number of compounds produced by the reactions, and on the accuracy of maintaining identical conditions for the reaction. The safest way of securing uniformity of the conditions is to perform the tests at the same time in parallel, perhaps in the same thermostat. Obviously, the spatial requirements make it desirable to perform the large number of combinatorial tests in reactors of a minimum size and with the minimum amounts of reactants and reaction products.

The chemical reactions themselves as used in combinatorial chemistry do not differ substantially from standard reactions elsewhere. The design of the reactors is mainly influenced, as usual, by the reaction conditions. There is a difference between processing proteins at room temperature and testing catalysts at very high pressure and temperature levels. The desirability of minimum size very early led to the use of microreactors. They may be easily stowed in a thermostat and thus kept under the same temperature. Their large surface-to-volume ratio brings the additional advantage of making possible an extremely close temperature control. Many tests producing durable compounds as the reaction products are made in small wells on the surface of a solid support tray. The reaction product may remain on the support, subsequently stored as a combinatorial library in material form. A more progressive approach is, in general, performing the reactions in microchannel reactors. Typically, they are used in arrays made by etching in silicon substrates stacked on top of one another together with another system of channels used for flow of thermostatic fluid.

Also the tests and analyses used for evaluation of the reaction products (or, perhaps, by-products) do not differ significantly from standard test procedures. The testing may be done off-line, when the reactions are finished. With organic samples on the tray, the test may consist of laser irradiation of the whole tray and detection of individual sample properties using their luminiscence. The library then consists of a photograph of the tray with various light intensities in the well locations. For the microfluidic approach it is typical to perform the tests on-line using samples brought from the reactors while the reaction is in progress. Also, there is a trend to

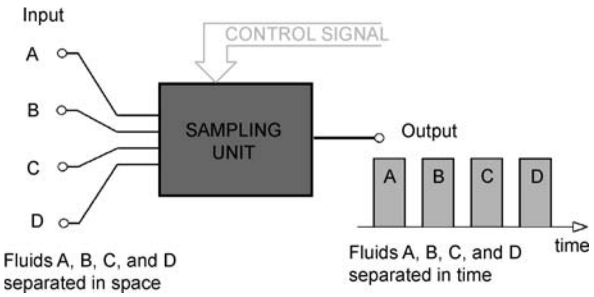
use very small instruments, commensurate with the small microreactors; some of the earliest gas chromatographs were developed in miniature size for this purpose. Another typically used method is mass spectrography. Due to the small analysed sample amounts, there is often a requirement of exceptional sensitivity of the test instruments. This makes them rather expensive. Because of the price there is almost always – provided the reaction is not too fast – just a single instrument performing the tests on all samples one after another even with a very large number of microreactors. After all, using a single analyser instrument brings the advantage of performing all tests under the same conditions and with the same instrument setting. If there are two or more instruments used, they more often than not are used to test different aspects of the samples. The ADMET properties of drugs traditionally required expensive and time-consuming tests on live animals. This is nowadays replaces by tests in microfluidic test devices using, for example, entrapped living human cells.

Sample Transfer

The use of a single test station places a particular emphasis on the transport of the sample to the analysis. There is still a strong tendency even in highly advanced systems to simply simulate the activity of a human operator. The characteristic feature of this approach is storing the reaction products in vials on a tray and transferring them to the analyser by a dedicated robot that opens the vials with its arm one by one by unscrewing their lids and then takes, perhaps by another arm, the sample from each vial, e. g. using a pipette, since the samples are usually liquid or dissolved solid, and carrying it to the analyser.

Even in tests performed in a more modern approach on-line, the traditional approach with mechanical motion, based on the idea of the robotic arm, still survives. Sample transfer to the analyser is still often made by a sampling unit with a moving probe [3]. In this case, the reactors are of the open exit type, with the reaction products issuing into the common space where there is the probe and its traversing gear. The probe is connected to the analyser by a flexible tube and moved from one reactor exit to another by a mechanical servomechanism positioner.

The approach typical for modern microfluidic systems, which is cheaper, faster and less prone to failure, is characterised by the reactor outputs directly connected to the analyser by means of a system of channels or cavities. Again, an essential part is the ►sampling unit between the reactors and the analyser. In its fluidic version, sometimes called a fluidic *selector or multiplexer*, it is an array of valves which open, one by one, the passage leading to the analyser. The sampling unit essentially performs spatiotemporal conversion according to Fig. 1.



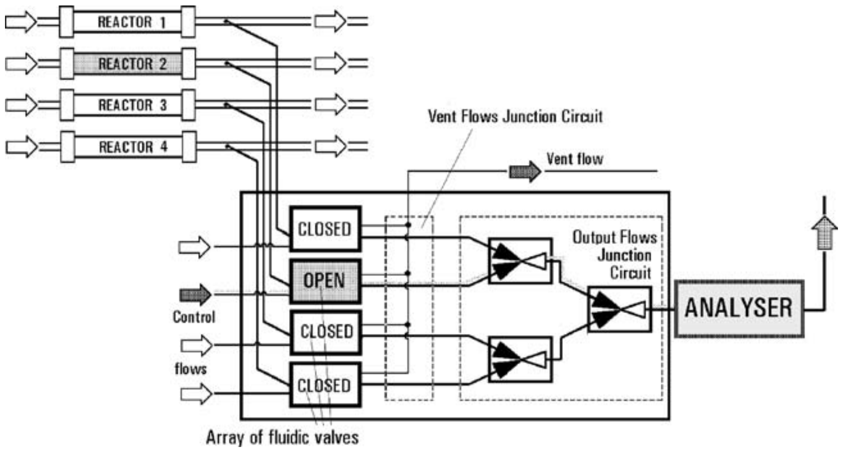
Microfluidic Systems for Combinatorial Chemistry, Figure 1 The task of the sampling unit in principle is a conversion of the spatial distribution of the samples (each available at a different location) into the temporal distribution admitted into the measurement device

There are a large number of possible variants. The fluid flows not selected at a particular instant of time may be halted (turning-down action), or dumped to a vent outlet (diverting action). The latter is preferable because it upsets less the basic requirement of sameness of all reactor conditions. The individual time steps need not be of the same duration, though they most often are. The sequence of the samples at the output is mostly of the simple repetitive periodic character, though the sequence may be varied according to some programme.

There are, nevertheless, features common to all sampling unit designs:

- The unit has several input terminals and a single output (an exception being aggregate designs with two or more outputs serving two or more analysers).
- The operation is controlled by an external signal (though the signal generator may be integrated into the unit – even to the degree of sharing some of its components).
- There is the essential requirement to eliminate any possibility of cross-contamination between the samples.

The sampling units consist of two essential constituent parts: the array of valves and the flow junction circuit. More conventional sampling units use mechanical valves – a single special multiposition scanning valve, or an array of common two-position on–off or diverting valves. In the mechanical on–off valves case, the junction circuits are rather trivial, because the mechanical closure ensures there is no communication between the cavities containing different samples. All valve outlets may be simply connected together. Nevertheless, the sections of the channels downstream from the valves should be as short as possible or eliminated altogether, because they contain different samples, and even though there is no flow in them, the escape



Microfluidic Systems for Combinatorial Chemistry, Figure 2 Schematic of the sampling unit consisting of an array of controlled valves and a junction circuit

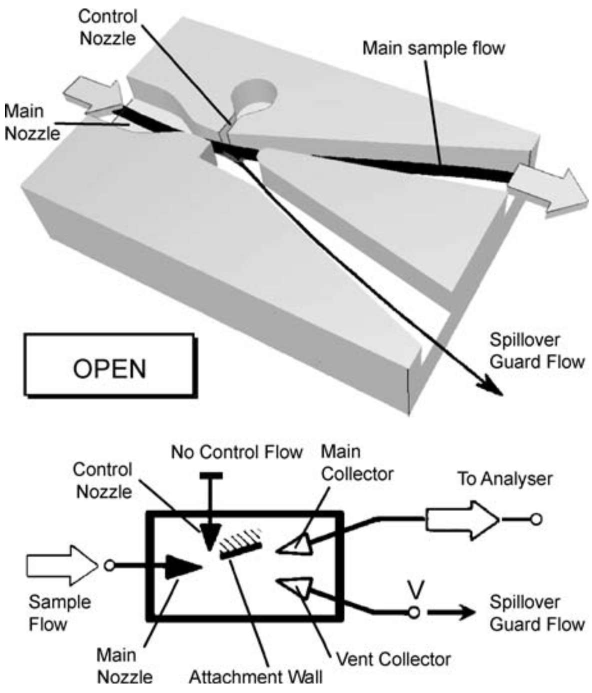
from the *dead* cavities by some convection or diffusive mechanisms cannot be altogether excluded.

Pure Fluidic Layouts

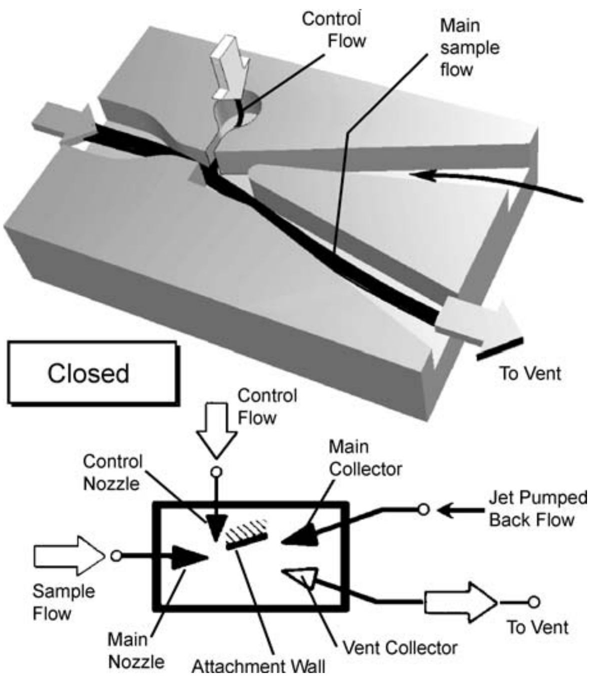
Chemical reactors not infrequently operate at high temperature and/or with aggressive fluids. This makes the conditions for the valves rather difficult. The small size of microreactors, calling for correspondingly small valves, makes the demands even more formidable. Although microvalves with moving parts are available, they are expensive, not easy to manufacture and prone to breakage. In direct contrast to mechanofluidic solutions, especially at the small size end of the spectrum of dimensions, are the advantages offered by purely fluidic valves [4]. These are suitable for easy manufacturing by the methods used in microengineering, may be made from heat- and corrosion-resistant material and have an almost unlimited operating life, even under extreme conditions, because there is nothing to stick, jam, or break.

There are many variants, mainly dependent on the driving mechanism and operating conditions. In principle, the flow in the valves may be driven by electrokinetic phenomena, such as electro-osmosis. This, however, limits the use to a rather narrow group of fluids – to polar liquids. More widely applicable are valves in which the fluid flow is pressure assisted or pressure driven [16]. They can operate with any liquid or gas. Designs of these valves depend mainly on the operating Reynolds number. Figures 3 and 4 present what may be a typical example of a no-moving-part pure fluidic valve suitable for operation at the high end of the Reynolds numbers range as used in present-day microfluidics. This valve is of the jet-deflection diverter type employing the Coanda effect. The sample flow is accelerated in the main nozzle and directed as a jet towards the two collectors placed opposite to the nozzle. One of them is connected to the analyser output. The jet is deflected into it in the *open* state of the valve if there is no acting control signal. This state is presented in Fig. 3. The other collector is connected with the vent, into which the sample flow is dumped in the *closed* state by the action of the control flow. This state is shown in Fig. 4. In the schematic representations, nozzles are drawn as black (filled) triangles. Their cross-section decreases in the direction of the flow and this means the pressure energy of fluid is converted into kinetic energy. The white triangles in the schematics are diffusers. Their cross-section increases in the direction of flow. They are usually used in the collectors for re-converting the kinetic energy of captured fluid to pressure energy.

While many fluidic valves are symmetric, the example in Figs. 3 and 4 is a monostable asymmetric valve with the attachment wall guiding the sample fluid to the main collector. Figure 5 shows an example of the use of these valves in the sampling unit. Only four valves are shown in this example – of course, modern sampling units for combinatorial chemistry sometimes contain hundreds of reactors and therefore also hundreds of the flow-control valves. These valves are basically just a shaped constant-depth cavity, easily made by standard microengineering manufacturing techniques, such as etching. There is no expensive assembly of moving components, nothing to break or seize. They may well operate without maintenance at extremely high temperature. It is easy to make them even from refractory materials with high corrosion and abrasion resistance. As shown in Fig. 5, a large number of these



Microfluidic Systems for Combinatorial Chemistry, Figure 3 An example of a monostable diverter valve based on the Coanda attachment and its schematic representation. In this *open* state the jet of sample fluid leaving the main nozzle attaches to the attachment wall and is led, via the main collector, to the analyser. Some sample fluid, spilled over into the vent, forms the *guard* flow



Microfluidic Systems for Combinatorial Chemistry, Figure 4 The valve from Fig. 3, the usual building block of the sampling unit, in the *closed* state with the jet of sample fluid diverted into the vent. The jet-pumping effect (entrainment into the jet) causes a return flow through the main collector

valves may be made in parallel on the same substrate plate. Since the shape of the valves is transferred optically, any shape, however complicated, can be manufactured with equal ease.

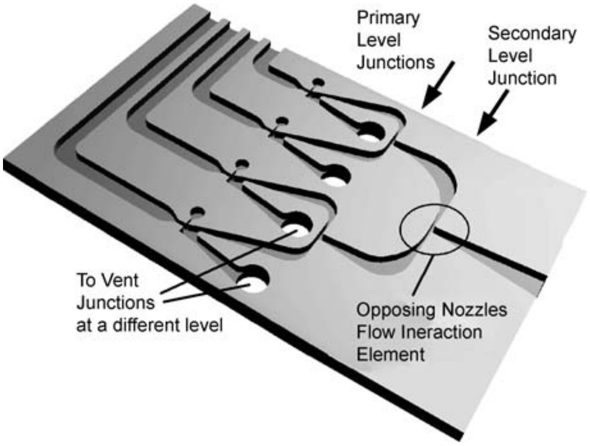
Guard Flows and Auxiliary Small Cleaning Flows

In mechanofluidic valves, flow is controlled by a mechanical component blocking the flow passage. In the absence of such components, fluidic valves do not secure directing all the sample fluid into just one of the two outlets. In principle, there is always a possibility of some of the supplied fluid overspilling into the other output terminal. On the other hand, some fluid may be sucked into the valve through the inactive terminal. This effect is caused by entrainment into the jet – the same phenomenon on which is based the operation of jet pumps.

The cavities through which the sample fluid passes in fluidic valves are open to the common vent outlets. All but one sample flows and all the control flows coming from the *closed* valves meet in the common vent cavities and freely mix there. This uncontrollable mixture must be prevented from coming into contact with the sample passing through the only *open* valve. The sample purity requirements call for another small auxiliary protective flow to be generated [13]. This *guard flow* is obtained by sacrificing a small amount from the sample flow and letting it to overspill into the vent, as shown in Fig. 3.

However, similar overspilling into the main or analyser collector in the *closed* state is unacceptable. The overspilled fluid would contaminate the tested sample coming through another, parallel valve. Here, however, it is the ►jet pumping effect (due to the entrainment into the jet) in the *closed* state, Fig. 4, which is useful. The channels and all other ►dead volumes downstream from the closed valves remain full of the earlier delivered samples, different from the sample which should come to the analyser at the particular instant of time. The small reverse flows back into all *closed* valves due to the jet-pumping effect remove the contaminating fluid from these volumes – and thus ensure high sample purity [13].

This capability to generate the *guard* flows and the cleaning reverse flows is another important advantage of purely fluidic sampling units. Of course, they mean a loss of a part of the sample flow. To keep the resultant total loss acceptable, these cleaning flows must be very small. To generate the *guard* flow in the *open* valve and the *cleaning reverse flow* in the *closed* state of the same valve is not easy – due



Microfluidic Systems for Combinatorial Chemistry, Figure 5 An example of a microfluidic integrated circuit using an array of the valves from Fig. 3, to define the sample flows into the analyser output

to the mutually opposite requirements. It requires a careful adjustment of the pressure conditions in the circuit.

Flow Junction Circuits: Flow-Enhancing and Flow-Inhibiting Elements

The task of getting the desired orientations of the small auxiliary flows may be made easier and less dependent on precise adjustments by proper shaping of the fluidic elements in the junctions of the valve exits [6]. This results in special flow junction circuits (Figs. 5 and 6). The fluidic elements there are also no-moving-part devices (sharing the advantages of easy manufacture and extreme reliability under adverse conditions). Their task is to generate a specified mutual interaction of the flows that meet in them. The effects are dependent upon dynamic effects in flowing fluids, which – similarly as in the valves – limits the use of these elements to higher Reynolds numbers, of the order of at least 10^2.

There are two basic arrangements of these flow interaction elements. Both consist of two nozzles and one collector and differ only in the angle at which the nozzle exits meet. If the angle is small, the jet generated in one nozzle induces flow in the other inlet by jet pumping action.

The very opposite effect is achieved if the angle at which in the nozzles meet is large, near and preferably equal to π. This is shown in Fig. 5 and schematically in Fig. 6. The flow admitted into one of the nozzles tends to generate a flow of opposite sign in the other inlet. This element is usefully connected to the output terminals of two adjacent diverter valves. The sample flow from the valve in its *open* state generates the desired backward flow through the output collector of the other valve, which is in the *closed* state. Of course, specific requirements of pressure and flow balancing in the junction circuit may call for devices in between, with intermediate values of the angle.

Complete Sampling Unit

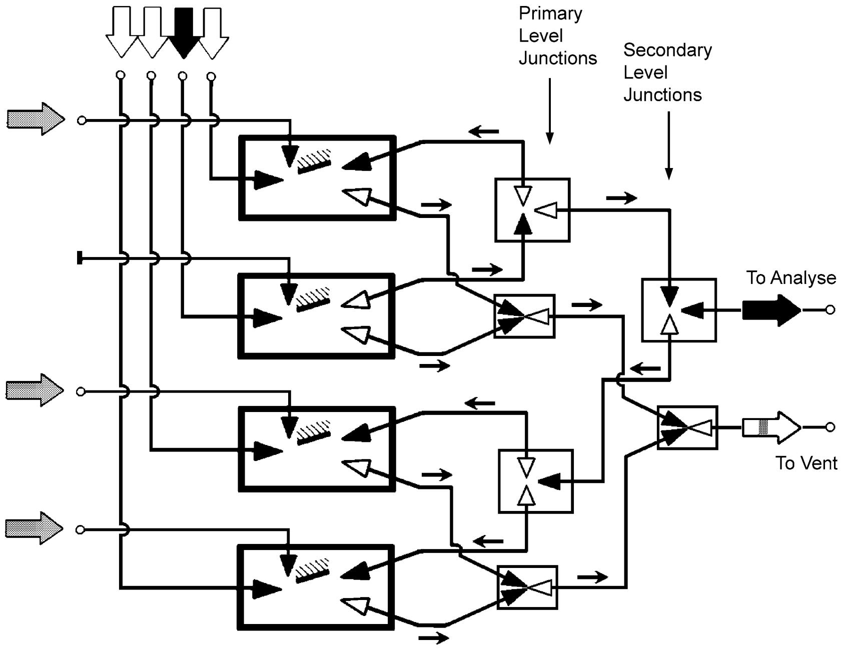
A simple, four-valve design of a unit built from the elements described above is shown in the circuit diagram Fig. 6. There are flow reversing interaction elements connected to the main output terminals, leading to the analyser. Also flow-enhancing junction elements are used. They are connected to the vent outlets of the valves.

The outlets from each pair of interaction elements of the neighbouring valves are seen in Fig. 6 connected to the interaction elements of the secondary level junctions. A similar tree-like connection principle [6] at higher levels is applied to build sampling units for a larger number of sample flows. The disadvantage of this layout is the inevitable crossing of the valve outlet channels, requiring multi-layer design of the unit.

Such complete junction circuits – with both kinds of flow interaction elements – are, however, rare. At least one of the desirable small protective flows (and sometimes both) may be generated just by proper adjustment of the pressure levels making these elements superfluous. The example in Fig. 5 has the vents simply open to the common space below the substrate plate. This makes possible building the whole sampling unit on a single plate.

Low Re Microfluidic Sampling Units

A characteristic trend of present-day microfluidics [1], associated with the progress in micromachining, is decreasing size of devices. Together with the often high viscosity (due to the use of viscous biological fluids as used when working with enzymes, or due to high temperature of the gas in ►catalyst testing) and the small flow rates (demanded by the requirements of residence time in the reactor) this means that devices have to be designed for operation at low Reynolds number Re. This dimensionless characterisation quantity is the product of flow velocity and a characteristic length dimension (usually the main nozzle width) divided by viscosity. Reynolds number may be interpreted as the ratio of inertial forces to viscous forces acting on the fluid. If it is low, the dynamic effects even in the accelerated fluid downstream from a nozzle are weak and the flow is dominated by viscous damping. Inertial effects, however, are the very phenomena upon which the operation of fluidic valves and other elements as described above is based. Below about $Re = 40$, the flow issuing from a nozzle forms no jets at all. The fluid simply spreads equally in all available directions. In this ►subdynamic regime [4], the operation of the above described



Microfluidic Systems for Combinatorial Chemistry, Figure 6 Schematic representation of the microfluidic circuit using an array of the valves from Fig. 3, to control the sample flows and the junction circuits. Basically similar to the layout from Fig. 5, this circuit has a more complicated way of leading the fluids into the vent. Arrows indicate the protective flows

M

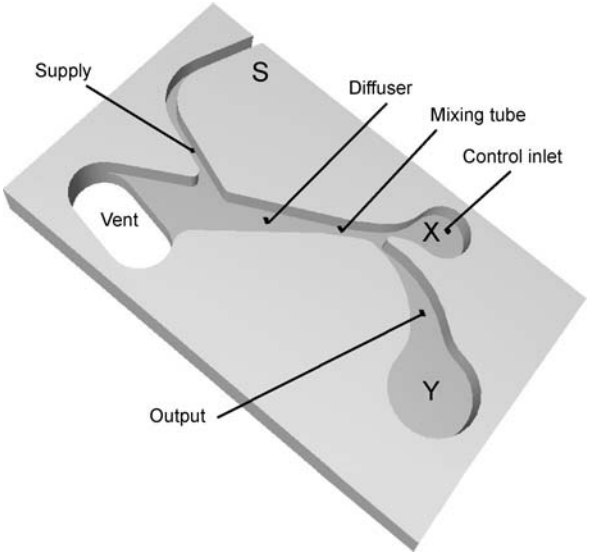
jet-type fluidic elements ceases to be possible. In fact, the Coanda effect attachment to a wall employed in the valves from Figs. 3 and 4 is usually almost absent already below about $Re = 800$.

This means that with the present tendency towards smaller size, new operating principles are needed. *Pressure-driven* valves [16], instead of relying on the inertia of fluid accelerated in a nozzle, force the sample flow by pressure difference maintained between vent V and output terminal Y. Generating and maintaining this pressure difference may require addition of a pressure regulator to the chip. This is not a problem in the context of MEMS, of which microfluidic sampling units form a part, often made by etching directly on a silicon chip together with the electronic control circuits, which are thus readily available.

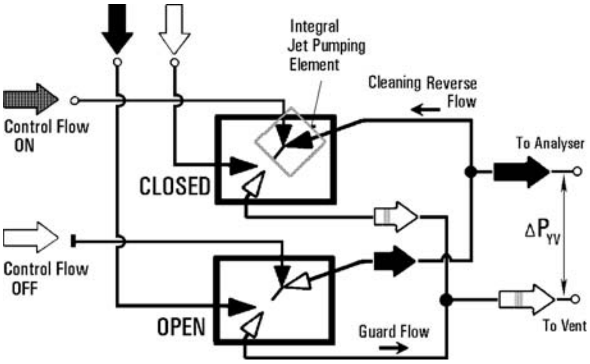
At low Re there is no point in using flow interaction elements. Instead, all the vent terminals V on the one hand and all the output terminals Y in the unit on the other hand are usually simply mutually connected. The driving pressure difference ΔP_{YV} is acting simultaneously in all the valves. It acts also in those valves which are in the *closed* state. To obtain in the *open* state the small desirable spillover *guard flow* into the vent terminal V requires just a careful adjustment of the driving pressure. In contrast, in the *closed* state, it is difficult to generate the desirable cleaning back flow, since it must overcome the pressure difference ΔP_{YV} acting in the opposing direction. Moreover, there is no hope of producing this reverse flow by the jet pumping effect of the sample flow, which at low Re is too slow and lacks the developed turbulent eddies on its outer boundary, which otherwise in the entrainment play an important role.

Jet Pumping by a Powerful Control Flow

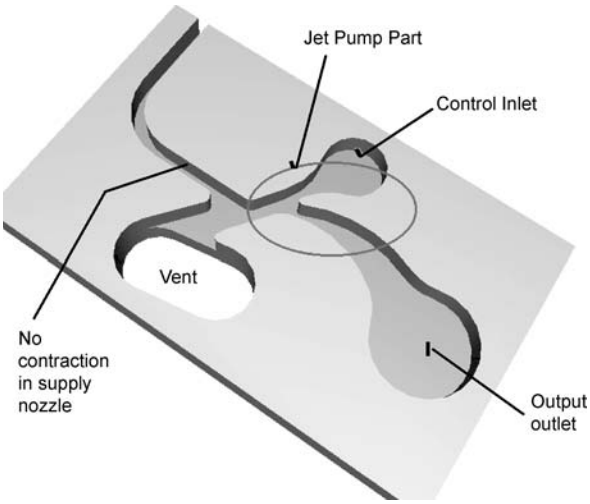
One solution of this problem with the cleaning back flow circumvents the weak entrainment effect of the sample flow by using another available fluid flow [11, 12]. The only one present with the proper timing is the control flow. Standard valves for larger Re are fluidic amplifiers – the control flow, because of the amplification property, may be much less powerful than the controlled main sample flow. The ratio of the supply flow rate to the control flow rate is called the *flow gain*. As Re decreases, so does the values of the gain. In low Re microfluidics it is often necessary to use relatively powerful control flows. Fractional gain values of less than 1.00 are no exception. This does not cause difficulties because the absolute magnitudes of the handled fluid are almost negligibly small anyway. The valves do not operate as fluidic amplifiers, but this property is not used.



Microfluidic Systems for Combinatorial Chemistry, Figure 7 An example of a microfluidic valve for pressure-driven operation at very low Reynolds numbers. The flow deflection principle is combined with an integral jet pump used to generate the protective back flow in the absence of a significant entrainment into the low-Re sample flow



Microfluidic Systems for Combinatorial Chemistry, Figure 8 Schematic representation of a part of a sampling unit with two neighbour valves with the integral jet pumps. One of them is in the *closed* state and the other is in the *open* state. Flows are driven by the pressure difference ΔP_{YV}

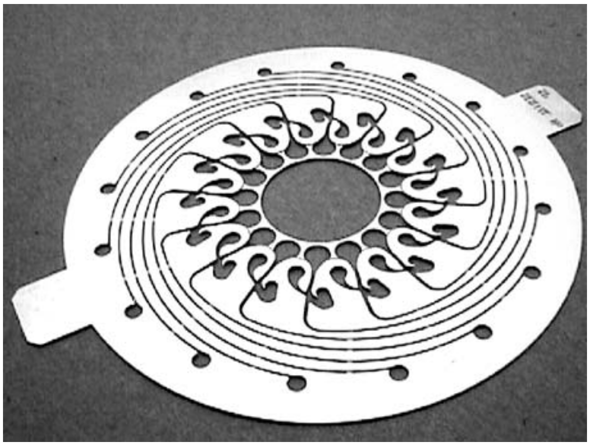


Microfluidic Systems for Combinatorial Chemistry, Figure 9 A valve with rudimental integral jet pump and more straight main flow into the output than in the version from Fig. 7

An example of a valve designed for these regimes is presented in Fig. 7. It operates with very low Re of the main, sample flow, but incorporates a classic, large Re fluidic element: a jet pump driven by the powerful control flow. This generates the desired cleaning return flow in the *closed* state. The exit from the jet pump is directed towards the vent. At the same time, the powerful jet pump exit flow sweeps the sample into the vent as well. The axes of the jet pump and vent collector are inclined with respect to the main (sample supply) nozzle axis. This is a useful feature, since jet momentum interaction studies indicate that optimum jet deflection is achieved with the control jet inclined to have a velocity component opposed to the supply flow velocity. The inclination is even more useful in the *open* valve state as well. The sample flow has to pass through the valve into the output terminal Y, and it is advantageous to have the path towards this terminal as straight as possible in order to operate with a lower value of the driving pressure drop ΔP_{YV}.

Application Example of a Low Re Sampling Unit

Designing a microfluidic valve based on this principle is a question of finding the best compromise between the conflicting requirements of the *closed* and the *open* states. An efficient layout of the jet pump part is shown in Fig. 7. This improves the achievable clearing backflow in the *closed* state, but because of the ensuing complexity of the sample path, this means a higher necessary driving pressure loss ΔP_{YV} in the *open* state to be maintained by the pressure regulator – and to be overcome by stronger *closed* state jet pumping. In the compromise example shown in Fig. 9, no attempt is made to have a really efficient geometry of the integral jet pump. Instead, there is no diffuser of the jet pump, which is reduced to only a very short collector. The idea is to make the flow path through the *open* state valve shorter and easier, with lower pressure loss ΔP_{YV} to be overcome in the *closed* state by the jet pumping. Typical for low-Re microfluidic devices is the missing cross-sectional area contraction in the supply (*main*) nozzle, as there is no point in trying to accelerate the sample flow there.



Microfluidic Systems for Combinatorial Chemistry, Figure 10 A sampling unit with 16 valves in the version from Fig. 9. This example of a microfluidic integrated circuit was made by etching in stainless steel [12]

The operation of the sampling unit using these valves may be followed in the circuit diagram of the basic valve pair shown in Fig. 8. To recognise the degenerated character of the jet pump the collector symbols in this schematic diagram are replaced by just a symbol of a short channel. There are no flow interaction fluidic elements in the valve exit junctions. As a consequence, maintaining the driving pressure difference ΔP_{YV} is easier – it has to be kept just between the final exit terminals of the complete sampling unit circuit. An early example of a sampling unit, with a mere 16 valves [12], is shown in Fig. 10. It was built for a research facility and used in combinatorial development of catalysts for the Fischer–Tropsch reaction (hydrogenation of carbon monoxide to ethanol). The reaction conditions are characterised by high temperature (400 °C) and high pressure (4 MPa). The valves are switched by essentially cold nitrogen control flows. The unit was made by etching in a 0.25 mm thin stainless steel foil, together with flow-equalising restrictors. To achieve a higher aspect ratio of the cavities, two-sided etching was used. This would unduly free the central parts of the foil held on long flexible strips. Structural integrity was obtained by braces (seen in Fig. 10) located downstream from the valves. The braces are etched only from one side so that there is a space above them allowing sample flow into the central cavity, which is connected to the analyser. The valves are not very small – the supply nozzle channel width is 340 μm – but they operate at very low Re of about 32 because of the small velocity and high gas viscosity. The sample fluid is *syngas* – fuel synthetisation gas, a mixture of hydrogen and carbon monoxide. Its pressure before reaching the valves drops to 0.5 MPa. Despite cooling of the valve plate by the nitrogen control flows, the kinematic viscosity of the sample gas – also due to its large contents of H_2 – is as high as 40×10^{-6} m^2/s. The nozzle exit bulk velocity is only about 3.8 m/s – in spite of the favourable fact of full reaction product flow being available for composition analysis. The ▶ guard flow magnitude is adjusted by the choice of driving pressure, kept by an external pressure regulator, so that 6% of the sample flow in the *open* state is spilled over into the vent. Only 3% return flow in the *closed* state is chosen (which still means sacrificing in total more than half of the available sample, from which the return flow is taken). The control flow rate needed to generate the jet-pumping effect is about 40 times the sample mass flow rate supplied into the valve (flow gain of 0.025, an absurdly small number from point of view of large-scale fluidics). With lower viscosity of the control nitrogen gas and a narrower, 0.27 mm wide, control nozzle to get higher control jet velocity (around 55 m/s), the Reynolds number of the control jet is around Re = 1000, just high enough to get some vortex entrainment effect.

Key Research Findings

In some areas, often as intellectual property of a particular manufacturer, extensive combinatorial libraries have already been accumulated. However, considering the huge, theoretically infinite number of possible combinations, there is still a vast space for continuing research. Substantial research activity has been directed to the development of the procedures for processing the library data so as to identify the optimum outcome. The mathematics of the search for the optimum is complicated by there being usually a number of optimality criteria. These results, however, are in principle more widely applicable and not particularly specific to the application of microfluidics.

The microscale aspect of combinatorial chemistry has already been proven to be the main road to follow. Earlier rather crude designs with the tested substances typically positioned in wells on a tray, with moving probes sequentially positioned into the wells, have generally been replaced by the approach using no-moving-part microfluidic circuits controlling the flow into an analyser. Successful designs of sampling units, consisting of these circuits, have been already developed [12] and are in everyday use, especially for developments in inorganic chemistry and non-biomedical areas of organic chemistry. Special fluid flow control valves have been developed for operation ensuring minimum cross-contamination between various samples.

Future Directions for Research

Continuing the already extensive past effort, more effective methods have to be developed for processing the

obtained combinatorial data so as to minimise the necessary extent of expensive tests to be performed. The continuing development of microfluidic devices for performing combinatorial testing has to meet more demanding requirements usually associated with processing biological material, such as proteins, and especially when handling living cells. The current microfluidic circuits, often pressure driven and using operating principles based on the inertial effects in flowing fluids, will become more difficult to develop as the smaller size and higher viscosity of biological samples will lead to lower values of flow Reynolds number. This may lead to the development of valves based on different, new flow control principles.

Definition

► High-throughput screening (HTS) is a method of scientific experimentation widely used in drug discovery and relevant to the fields of biology and chemistry. A screen

is a large experiment designed to test for the presence or absence of particular chemical compounds or biological markers. ►Microfluidic systems are well suited for HTS due to their small size, which allows massively parallel experimentation.

Overview

►Microfluidic systems manipulate or process tiny (10^{-9} to 10^{-18} liters) volumes of fluids in channels with dimensions of tens to hundreds of micrometers. These systems, built using various microfabrication techniques, offer a number of advantages for chemical and biological analysis compared to standard laboratory instrumentation including low consumption of samples and reagents, low cost for mass production, short times for analysis, flexibility and dimensional precision, and separations and detections with high resolution and sensitivity. They can also probe physical phenomena and mechanisms that are not observable on the macroscopic scale. In addition, one key feature of these systems is the integration of different functional units for sampling, sample pre-treatment, sample transport, biochemical reactions, analyte separation, product isolation and detection in a microchannel network. ►Microfluidic systems enable serial processing and analysis, and furthermore, can accomplish massive parallelization through efficient miniaturization and multiplexing.

During the past decade there has been tremendous development in microfluidic systems and related applications. Recent advances in genomics, proteomics and combinatorial chemistry have provided an opportunity for the pharmaceutical industry to accelerate the pace of drug discovery using high throughput techniques. The sequencing of the human genome has generated a number of new molecular targets with unknown function (*new targets*) as well as those with known function (*established targets*). Rapid progress in protein biochemistry and combinatorial chemistry has enabled the arrangement of chemical building blocks into all possible combinations, generating a library of millions of compounds. This increase in experimental complexity demands the organization, interpretation and utilization of experimental data in a methodical and rational manner. *High throughput screening (HTS)* technologies have emerged to meet this demand, and the need for reliability has motivated advances in throughput, accuracy and ease of use.

High throughput screening (HTS) is a method for scientific experimentation widely used in drug discovery and relevant to the fields of biology and chemistry. Modern *HTS* consists of robotics, data processing and control software, liquid handling devices and sensitive detectors to perform millions of biochemical, genetic or pharmacological tests on samples in parallel, allowing screening at significantly higher rates than convential serial screening methods. It facilitates the understanding of human biological pathways that require large experimental data sets to study genes, proteins and metabolites. The primary ways to save time and minimize usage of chemical compounds involve miniaturization of existing technologies like high-density wells on assay plates and nanoliter dispensing systems. However, current robotic systems have limitations in dispensing very small liquid volumes quickly and accurately. Rapid evaporation of the dispensed liquid and high cost are other challenges in modern *HTS* systems. Microfluidic systems are capable of resolving many of these issues and offer the possibility of technological breakthroughs in *HTS*. Herein, novel microfluidic technologies for developing *HTS* are reviewed.

Basic Methodology

Microfluidic Physics

Microfluidics is a large field involving numerous disciplines such as microfabrication, chemistry, biology, and physics. Reviewed below are basic concepts from microfluidic physics relevant to *HTS*. A fluid is a substance that deforms continuously when acted on by a shear stress of any magnitude.

In general, fluid velocity is given by the Navier-Stokes and continuity equations. For fluids that are Newtonian (shear stress linearly related to fluid shear rate) and incompressible, the Navier-Stokes equation is written as

$$\frac{\partial \boldsymbol{V}}{\partial t} + \boldsymbol{V} \cdot \nabla \boldsymbol{V} = \boldsymbol{B} - \frac{1}{\rho}\nabla p + \frac{\mu}{\rho}\nabla^2 \boldsymbol{V}\,, \tag{1}$$

and the continuity equation is written as

$$\nabla \cdot \boldsymbol{V} = 0\,, \tag{2}$$

where $\boldsymbol{V}$ is the velocity of the fluid flow, $\boldsymbol{B}$ is the body force per unit mass, p is pressure, ρ is the density of the fluid, and μ is the viscosity of the fluid. The small characteristic dimensions of microfluidic systems lead to high surface-to-volume ratios, small diffusion distances, and significant surface and interfacial tension effects. Nondimensionalization of Eq. (1) using the characteristic fluid velocity V_c and characteristic microfluidic channel dimension L leads to a dimensionless parameter called the Reynolds number:

$$\mathrm{Re} = \frac{\rho V_c L}{\mu}\,. \tag{3}$$

The Reynolds number represents the ratio of inertia forces to viscous forces acting on a fluid. For water as a working

M

fluid, assuming typical velocities and channel dimensions in the ranges $1\,\mu\text{m/s} - 1\,\text{cm/s}$ and $1 - 100\,\mu\text{m}$, respectively, the Reynolds numbers range between 10^{-6} and 1. These low values indicate that viscous forces overwhelm inertia forces in microfluidic systems, and that the fluid flow is laminar. For these low Reynolds numbers the nonlinear term of the Navier-Stokes equation can be neglected:

$$\frac{\partial \boldsymbol{V}}{\partial t} = \boldsymbol{B} - \frac{1}{\rho}\nabla p + \frac{\mu}{\rho}\nabla^2 \boldsymbol{V}. \quad (4)$$

For certain microfluidic applications, the characteristic time and body force scales may be such that the time derivative and/or body force terms in Eq. (4) are also negligible.

One of the consequences of laminar flow is that mixing in the fluid occurs primarily by diffusion. This is illustrated by the low values of the Péclet number

$$\text{Pe} = \frac{V_\text{c} L}{D}, \quad (5)$$

which is the important dimensionless parameter governing mixing and which represents the ratio of convective mass transport to diffusive mass transport. In Eq. (5), D represents the diffusion coefficient of a molecule in liquid. The characteristic time t for a molecule to diffuse a distance x is proportional to x^2/D. As an example, a protein with a molecular weight of 20 kDa ($1\,\text{Da} = 1.66 \times 10^{-27}\,\text{kg}$) and one hydration layer has a diffusion constant $D \sim 10^{-10}\,\text{m}^2/\text{s}$ at ambient temperature, and will diffuse a distance of $1\,\mu\text{m}$ in approximately 10 ms. To control mixing, a microfluidic system should be designed with these diffusion times in mind. For instance, fast mixing is required for chemical reactions, so the characteristic dimensions of the microchannels should be made small to enable diffusion to occur quickly. In separation processes, mixing should be suppressed, so the dimensions should be made large enough to prevent significant diffusion on the time scale of the experiment.

Thus far, the key dimensionless parameters useful in the design of microfluidic systems for *miscible* fluids have been discussed. For *immiscible* fluids, surface tension σ also becomes important; this parameter affects the dynamics of the free surface. This gives rise to two additional dimensionless quantities: the capillary number and the Weber number. The capillary number represents the ratio of viscous forces to the surface tension forces acting across an interface between a liquid and a gas or between two immiscible liquids. It is defined as

$$\text{Ca} = \frac{\mu V_\text{c}}{\sigma}. \quad (6)$$

The Weber number, which is the ratio of inertial to surface tension forces, is also useful for analyzing fluid flows where there is an interface between two different fluids. It is defined as

$$\text{We} = \frac{\rho V_\text{c}^2 L}{\sigma}. \quad (7)$$

In multiphase microfluidic systems, the complicated interplay between interfacial, viscous and inertial forces corresponds to phase distributions and flow patterns. At low velocities and small channel sizes, interfacial forces dominate over inertial and viscous forces. However, at very high flow rates or in the presence of very large accelerations, inertial forces can affect the dynamic behavior of multiphase flows. Thus, both the capillary and Weber numbers are useful for predicting multiphase flow behavior in microchannel networks and designing multiphase microsystems. Most multiphase microfluidic systems take advantage of flow regimes in which the two phases are segregated (called segmented flows). The flow regime depends on geometry, flow rates and instabilities that occur at the interface between two immiscible liquids. Segmented flows in microfluidic networks enable us to overcome transport limitations in single-phase microflows with high throughput rates. Further details of microfluidic physics are reviewed in [1].

The control of fluids in microfluidic systems can be accomplished using active pumping, passive forces or electrical forces. Active control of fluid flow is often achieved simply by direct connection to external pressure and/or vacuum sources, for example programmable syringe pumps or peristaltic pumps. Micropumps due to thermopneumatic, electrostatic and piezoelectric actuation have also been used for manipulating and transporting fluids within a microfluidic network. In addition, compact disc-type systems based on centrifuge platforms can provide a wide range of flow rates depending on disc geometry, rotational rate and fluid properties. Alternatively, passive forces such as capillary forces provide a means to create a pressure difference in small conduits. If the microchannel has a rectangular cross section of height d and width w, then the resulting capillary pressure P_c of a liquid-air meniscus is expressed as

$$P_\text{c} = -\gamma \left(\frac{\cos\theta_b + \cos\theta_t}{d} + \frac{\cos\theta_l + \cos\theta_r}{w} \right), \quad (8)$$

where γ is the surface tension of the liquid, $\theta_{b,t,l,r}$ are the contact angles of the liquid on bottom, top, left and right sides of the microchannel, respectively. The wettable ($\theta < 90°$) wall induces a negative pressure in front of the liquid and then draws the liquid into the channel. Thus,

tailoring interfacial energies can enable capillary-driven pumping and may remove the need for other peripherals to transport fluids. Recently, capillary forces have been used for processing surfaces and miniaturizing assays.

Electrokinetic techniques are another popular method for manipulating fluids non-mechanically in microfluidic systems. When exposed to electrolyte, the channel wall tends to develop surface charge, which attracts oppositely charged counter-ions and repels similarly charged co-ions. The resulting electric double layer (EDL) screens the surface charge over a characteristic length called the Debye length λ_D. When an external electric field E is applied, the fluid in this charged layer acquires a momentum which is then transmitted to adjacent layers of fluid through the effect of viscosity. In microfluidic systems, this momentum is enough to cause bulk fluid flow in a phenomenon known as electroosmotic flow (EOF). The bulk EOF velocity is proportional to the applied electric field and the electro-osmotic mobility μ_{EOF}.

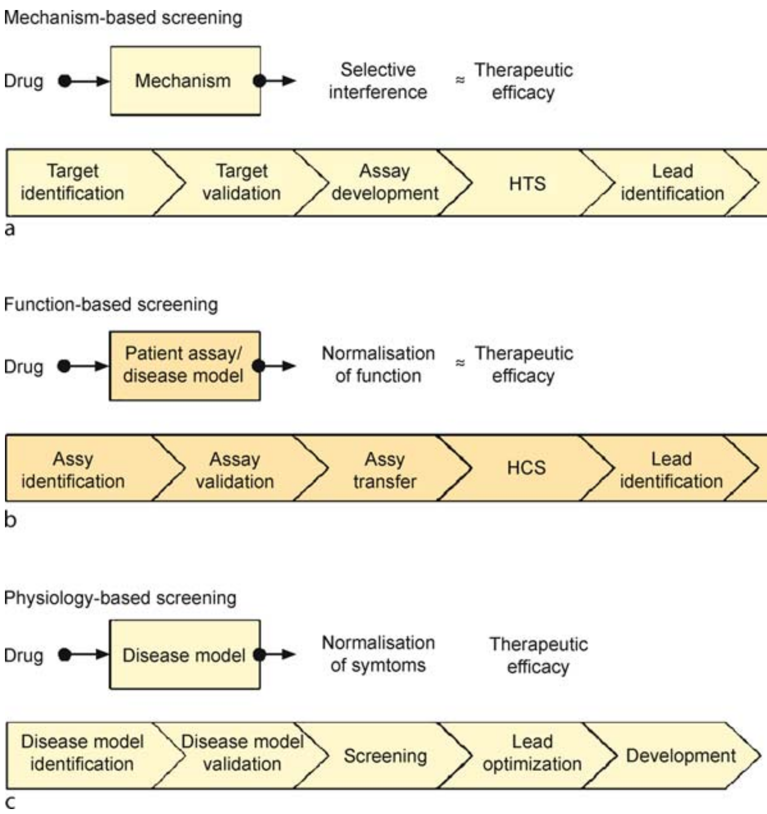
$$u_{\mathrm{EOF}} = \mu_{\mathrm{EOF}} E \tag{9}$$

The electro-osmotic mobility and bulk EOF velocity are sensitive to the physicochemical properties of the solution and channel walls. Because electroosmosis is a surface-driven phenomenon, EOF fluid transport is characterized by *plug flow*. Except in the thin EDL, there is no shear in the fluid flow and so the velocity profile is flat. At the same time, the individual species charged permanently or spontaneously in the bulk fluid also undergo electric forces. These effects are classified as either electrophoresis (EP) or dielectrophoresis (DEP). Whereas EP arises from the interaction of a fixed charge and an electric field, DEP results from the interaction of an induced charge and the spatial or temporal gradient of the electric field. In EP, direct current (DC) or low-frequency fields, usually homogeneous, are applied. On the other hand, in DEP, alternating current (AC) fields over a wide range of frequencies are used.

Drug Discovery and Current Novel HTS

Drug discovery entails a series of serial and/or parallel processes including candidate identification, synthesis, characterization, screening and assays for therapeutic efficacy. These processes are shown in Fig. 1. First, both natural products and chemical libraries are screened to determine which compounds bind to a particular target protein or inhibit a particular enzymatic reaction. The successful compounds (called *hits*) that exceed a certain threshold value in a given assay are progressed into *leads* by more complicated assessments of chemical integrity, accessibility, functional behavior, structure-activity-relationships (SAR) as well as bio-physicochemcal and absorption, distribution, metabolism and excretion (ADME) properties. The lead series that demonstrate activity and selectivity in the secondary screens are tested in progressively more complex systems from cells to whole animals before reaching clinical trials. Therefore, robust and fast methods are needed to vet an extremely large number of candidates and to minimize the attrition of chemical entities in the costly clinical phases of drug discovery. Based on these demands, *HTS* technologies including small-molecule library design and assembly, robotics, assay development and data handling have developed since the 1980s. Presently, libraries of millions of compounds are screened routinely with single compounds of high purity in 384- and 1536-well formats. Fully automated robotic systems improve screening data quality. Figure 2 shows the configuration of the integrated Ultra-High Throughput Screening System (UHTSS™ platform. This platform integrates several microfluidic dispensing devices into appropriate wells of the 3456-well NanoWell™ assay plates (Aurora BioSciences, San Diego, CA, USA). One primary purpose of this system is the automated screening of over 100,000 compounds and 2400 re-tests per day in a miniaturized assay format. However, robotic *HTS* has been faced with several challenges, including high cost of the technology, poor reliability of data, standardization of data types, rapid and accurate dispensing of very small volumes, and quick evaporation of the dispensed liquid.

Alternatively, microchip technologies offer other platforms for *HTS* such as microarrays and microfluidic devices. Microarrays allow the simultaneous analysis of thousands of parameters within a single experiment and for this reason have become crucial tools in drug discovery and life sciences research. They consist of immobilized biomolecules spatially addressed on planar surfaces, microchannels or microwells, or an array of beads immobilized with different biomolecules. Biomolecules commonly immobilized on microarrays include oligonucleotides, polymerase chain reaction (PCR) products, proteins, lipids, peptides and carbohydrates. Currently, in situ synthesized microarrays can be purchased or they can be custom fabricated in the laboratory. During the past few years, chemical compound microarrays with different surface chemistries and activation strategies have emerged in drug screening and discovery. By contrast, microfluidic devices can perform screening assays in a continuous flow that allows serial processing and analysis on a single chip. They require a series of generic components for introducing reagents and samples, moving the fluids within a microchannel network, combining and mixing them, and various other functional units such as valves, pumps, detectors, sorters and purifiers. So far this field



Microfluidic Systems for High-Throughput Screening, Figure 1 Drug discovery approaches: (**a**) mechanism-based drug discovery seeking to produce a therapeutic effect by targeting a specific mechanism, (**b**) function-based drug discovery seeking to induce a therapeutic effect by normalizing a disease-specific functional abnormality, and (**c**) physiology-based drug discovery seeking to induce a therapeutic effect by reducing disease-specific symptoms or physiological changes [11]

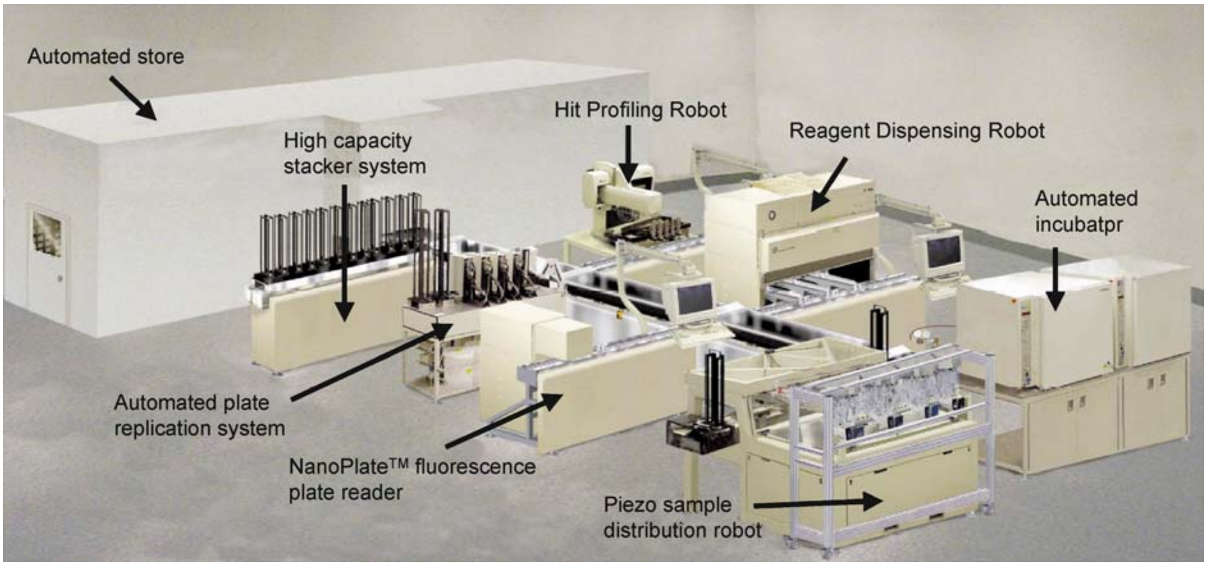
has focused on demonstrating concepts for these components and integrating them into a single chip. The majority of microfluidic devices are simple planar microfluidic chips fabricated on substrates such as glass, silicon or polymers using microfabrication techniques. Custom-made planar microfluidic chips and entire measuring systems have been launched commercially (Agilent Technologies, Evotec Technologies, Caliper Life Sciences, Fluidigm, Gyros). Recently, because of the several advantages of microfluidic technology mentioned above, the pharmaceutical industry has begun investing substantially in this technology as a way to expand screening capacity at several stages in drug discovery. The unique physical behavior of fluids within a microfluidic network can give insight into new ways to resolve the current challenges of HTS and to revolutionize all stages of drug discovery.

The testing of analyte on living cells is also an important part of high throughput drug discovery. Microfluidic devices enable manipulation of cells, maintentance of cellular environments close to the physiological conditions typically found in biological systems, simultaneous characterization of cells under comparable conditions, and subsequent analysis. A fundamental paradigm shift in drug discovery, coined *high-content screening* by Cellomics, has motivated the development of cell-based high throughput assays for simultaneous analysis of individual cells and subcellular processes under complex physiological parameters. Below, recent progress in novel microfluidic devices for cell treatment, especially with high throughput rates, is discussed. Additionally, recent progress in microarraying strategies based on microfluidics will be discussed, but the current status and challenges are beyond the scope of this entry. Further information in this area can be found in [2].

Key Research Findings

Novel Surface Patterning

Inkjet and other non-contact droplet formation technologies are able to dispense nanoliter-sized drops onto surfaces, but they offer no control once the liquid has left the confinement of the ejection nozzle and, consequently, suffer from problematic drying and spreading of the ink on



Microfluidic Systems for High-Throughput Screening, Figure 2 A schematic visualization of the UHTSS™ configuration (Aurora Biosciences, San Diego, CA, USA): a working compound solution store, an automated plate replication system, microfluidic dispensing systems, high density 3456-well NanoWell™ assay plates, automated incubators and a high-performance fluorescence plate-reader [12]

the surface. Patterns can also be formed using pins or pen-like devices loaded with the appropriate solute and solvent to draw individual spots or lines. However, the friction and resulting mechanical wear between the pen and the substrate during drawing have limited the resolution of writing techniques to a few hundreds of micrometers. The extension of the pen concept to the micro- and nano-scale using cantilevers is dip-pen nanolithography (DPN) based on atomic force microscope (AFM) technologies. In the DPN process, molecular inks coated on an AFM tip are transferred to a substrate while the tip is held or laterally moved along a surface as programmed. Feature sizes less than 15 nm can be routinely patterned by molecular self-assembly of the ink on the substrate. However, the necessity of molecular-ink replenishment in the DPN technique leads to limited throughput and inevitable realignment during the patterning process.

In the viewpoint of dispensing technologies, Espinosa and co-workers [3] have demonstrated a novel microfluidic AFM probe called the *Nanofountain Probe (NFP)* with a sub-100 nm patterning capability. It consists of a hollow tip, integrated microchannels and on-chip reservoir (Fig. 3a). When an ink solution is fed into the reservoir, it is driven by capillary action through the microchannel to the tip to form a liquid-air interface around the tip core. Molecules are transferred by diffusion from the interface to a substrate and a water meniscus is formed by capillary condensation. Although the NFP is the state-of-the-art patterning technology, massively parallel probe arrays and integration of multiple reservoirs over large areas with multiple inks still are key challenges for high throughput screening applications. Henderson and co-workers (Bioforce Nanoscience Inc., Ames, IA, USA) have commercialized multiple microcantilevers with open microfluidic channels constantly delivering a supply of liquid to be transferred onto the surface for multiplexed biomolecular arrays. As illustrated in Fig. 3b, fluids from the reservoir, down the channel, to the end of the cantilever where the channel narrows to a tiny gap. Upon contact with the surface, a small volume of liquid held in the gap by surface tension is directly transferred to the surface in an event typically requiring less than 1 ms. Capillary fluid flow down the channel instantly replenishes the volume at the gap, and the device is then ready to write the next feature. Recently, they launched the Nano eNabler™ system, which prints proteins and other biological and non-biological materials onto silicon and other surfaces with spot sizes from 20 μm to 1 μm.

Delamarche and co-workers [4] proposed a new format for surface patterning and biological assays using capillary forces. Fluids fill the microstructure of microfluidic networks (μFNs) due to the capillary pressures generated by the small dimensions of the channels and the hydrophilicity of their walls. One example for immunoassays using a μFN is shown in Fig. 4a. A μFN patterns a series of antigens as narrow stripes onto a planar substrate. After a blocking step with bovine serum albumin (BSA), the antigens in each line may be recognized

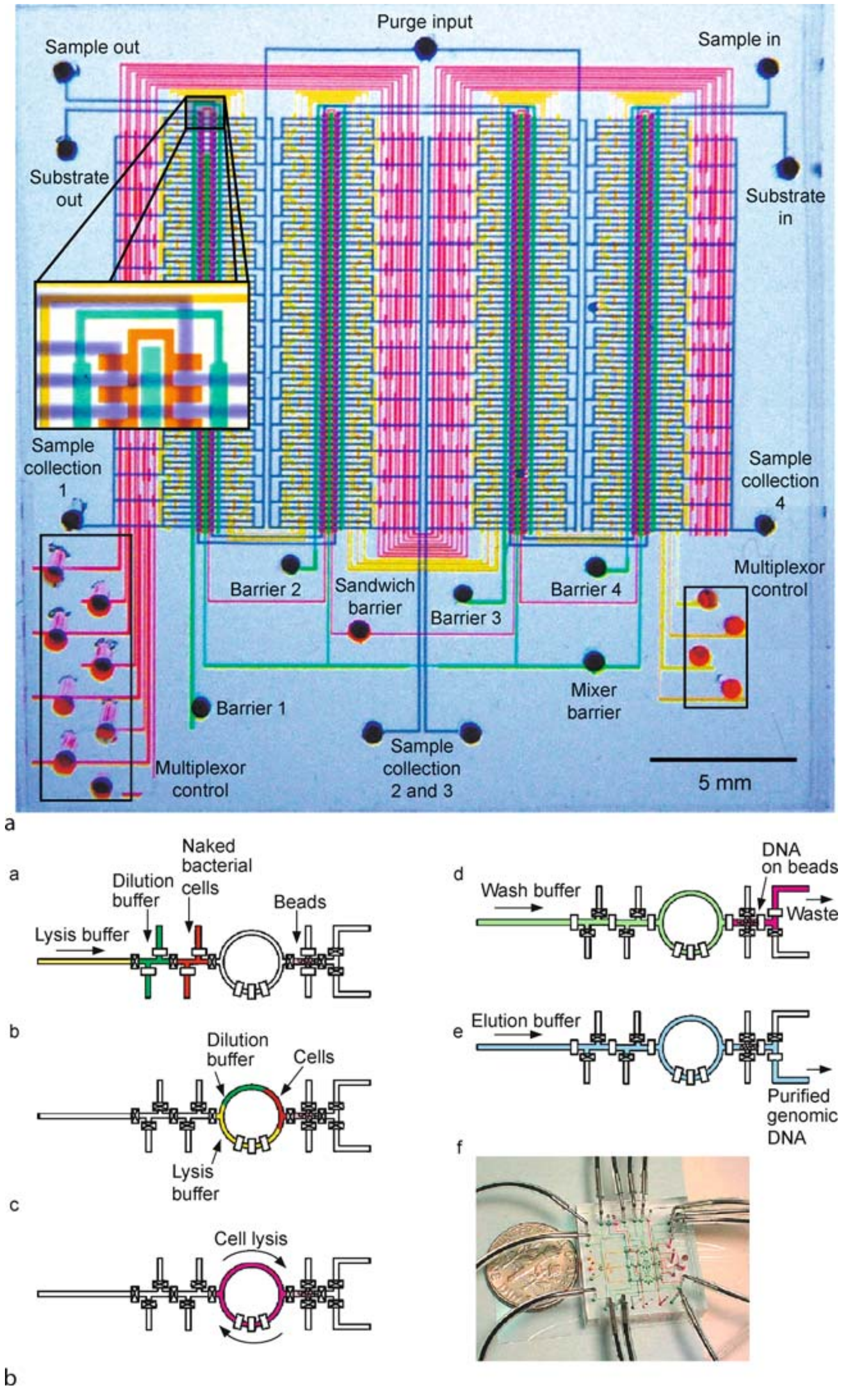
wide intersecting lines, thus providing a mosaic of signals from cross-reacted zones. Figure 4b shows the feasibility of µMIAs for high throughput screening. Using n and m microchannels for a µMIA yields $n \times m$ binding sites but only requires $n + m$ pipetting steps. Delamarche et al. [4] claim that the µMIA would necessitate ~10 times less time, ~100 times less volume of samples and reagents, and ~1000 times less area per site than an assay done using a 1536-well microtiter plate. Recently, µMIAs and similar approaches have been developed to screen for biological analytes in combinatorial fashion with various detection schemes. In addition, thermoplastic microtiter plates with high-density wells, which are commonly used for conventional high-throughput screening systems, can be replaced with a novel approach based on nanoliter through-hole arrays [BioTrove Inc., Woburn, MA, USA] (Fig. 4c). A series of vapor and liquid deposition steps covalently attaches a polyethylene glycol (PEG) hydrophilic layer amine-coupled to the interior surface of each through-hole, and a hydrophobic fluoroalkyl layer to the exterior surface of the platen. Capillary pressure draws fluids into microchannels and surface tension holds the liquids in place, isolated from neighboring channels. The differential hydrophilic-hydrophobic coating facilitates precise loading and isolated retention of fluid in each channel. This platform can reduce capital cost of a thermal cycler and a plate reader, technician labor and expense, reagent consumption and time compared to those of microwell-based *HTS* systems.

Novel Microfluidic Devices

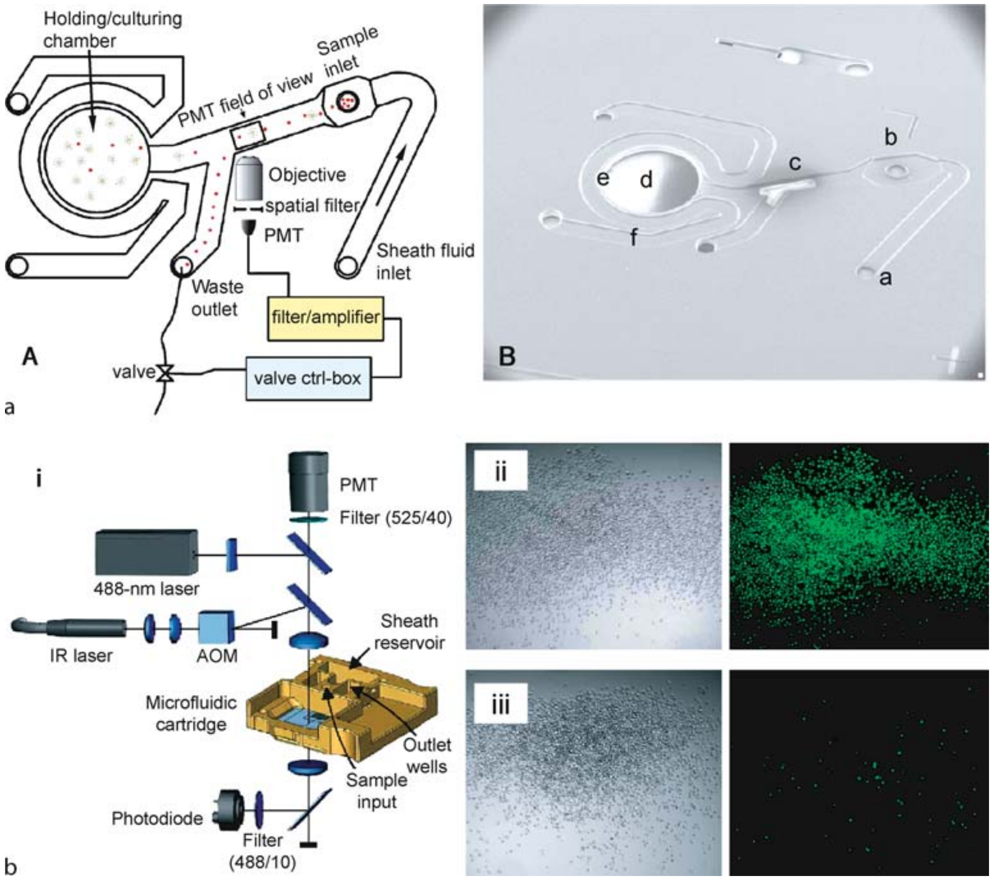
One key feature of microfluidic systems is the integration of different functional units for sampling, sample pre-treatment, sample transport, biochemical reactions, analyte separation, product isolation and analysis in a continuous-flow manner. The technology has centered on proof-of-concept studies for these components and it is still maturing. Two particular contributions have accelerated the development of an integrated microfluidic system. One is soft lithography in poly(dimethysiloxane) (PDMS) as a method for fabricating prototype devices [5]. This allows quicker, less expensive fabrication of prototype devices that test new ideas as compared to devices made using silicon technology. The other is a simple method for fabricating pneumatically actuated valves, mixers and pumps by multilayer soft lithography [6]. Monolithic elastomer actuators restrict fluid flow in a channel by pressurization of an adjacent channel under pressure. Figure 5 shows schematic operation mechanisms of monolithic elastomer valves and pumps. When pressure is introduced into the control channels, the elastic membranes expand into the fluidic channel. In a regular valve having a round-profiled fluidic channel, the fluidic channel is completely sealed because of the perfect fit between the expanded membrane and the fluidic channel. In a sieve valve having a square-profiled fluidic channel, the fluidic channel is partially closed and so fluid flow is allowed along the edges. A peristaltic pump with three elastomer valves works by applying air pressure sequentially in each air channel. These elastomer actuators have enabled the design and realization of integrated microfluidic systems for high throughput processing of increasingly smaller volumes with higher degrees of parallelization.

Quake and co-workers [7] have developed high-density microfluidic chips that contain plumbing networks with thousands of micromechanical valves and hundreds of individually addressable chambers. They demonstrated



Microfluidic Systems for High-Throughput Screening, Figure 6 Integrated nanoliter systems: (**a**) optical micrograph of a chip for parallelized high-throughput screening of fluorescence-based single-cell assays and (**b**) an integrated processor for DNA purification from cell culture to DNA recovery scheme [7]

a microfluidic system for highly parallel high-throughput screening which integrated 2056 valves with 256 compartments containing bacterial cells expressing an enzyme of interest that could be combined on a pairwise basis with 256 other compartments containing a fluorogenic substrate used to assay for a desired activity (Fig. 6a). In following



Microfluidic Systems for High-Throughput Screening, Figure 7 High throughput cell sorters: (**a**) an optically switched microfluidic fluorescence-activated cell sorter [15] and (**b**) a micro cell sorter chip with integrated holding/culturing chamber [16] ►Flow Cytometer Lab-on-Chip Devices

work, they developed mechanical valve-based systems for automation of serial and parallel bioprocesses including cell isolation, cell lysis, DNA purification and DNA recovery without any pre- or post-sample treatment on a single microfluidic chip (Fig. 6b). Meanwhile, much effort has been made to develop miniaturized fluorescence-activated cell-sorting devices (μFACS) with high throughput rates. Wolff et al. designed and developed a novel pressure-driven μFACS device with advanced functional components including a chamber for holding and culturing the sorted cells and monolithically integrated waveguides for cell analysis (Fig. 7a). They achieved a 100-fold enrichment of fluorescent beads at a throughput of 12,000 cells per second while sorting a mixture of fluorescent latex beads and chicken red blood cells. Wang et al. demonstrated a high throughput cell sorter with all-optical control switch for living cells (Fig. 7b). The optical forces, which depend on the optical power and relative optical properties of the particle and its surrounding medium, were used to deviate the cell from the flow stream to a sufficient degree to that it was directed toward the target output channel. They showed that sorting runs of cell populations ranging from as few as 1000 cells up to 280,000 cells can be completed in less than an hour. More detailed information on novel flow cytometer based on microfluidic technologies can be found in the entry ►Flow cytometer Lab-on-a-Chip devices in this volume.

The manipulation of multiphase flows is another application for high throughput rate microfluidic systems. These systems enable the generation and manipulation of monodisperse bubbles or droplets of a dispersed gas or liquid phase in a continuous stream. These techniques have been applied to many different types of biochemical reactions that are performed in parallel as well as in series. For instance, single-cell enzymatic assays have been achieved by encapsulating single cells inside droplets (Fig. 8a). A single droplet of controlled femtoliter volume was generated by specially designed *T* channels. Before

the formation of the droplet, a single cell was selected from the aqueous solution and moved by optical trapping to the interface between the aqueous phase and the carrier fluid. These techniques make it possible to investigate each cell under controlled, physiologically relevant environments. Droplet-based microfluidics is also a useful tool for molecular evolution that is particularly interesting for the optimization of drug candidates. Aqueous droplets form cell-sized compartments that keep together the genes, the RNAs and proteins that they encode, and the products of their activity. In vitro expression of green fluorescent protein (GFP) to directly analyze the contents of individual droplets has been achieved on a microfluidic system (Fig. 8b). More detailed information on droplet-based microfluidics can be found in [8].

In addition, laminar flow within microchannels can be exploited to deliver compounds to a local area of one cell, potentially allowing the evaluation of the stochastic nature of cellular responses or the effect of chemical gradients or drug interactions within a single cell. Recently, Lee and co-workers [10] have developed a microfluidic cell-culture array with an integrated concentration gradient generator for long-term cellular monitoring (Fig. 9a). The gradient generation permits many growth conditions to be analyzed in a combinatorial fashion and is thus well suited for high-throughput experimentation, where a large number of con-

ditions need to be screened in parallel with minimal consumption of analytes and reagents. Lee et al. also demonstrated high-density regular arrays of single cells isolated in a purely hydrodynamic fashion within a microfluidic device (Fig. 9b). Cells were held by obstacles incorporated into the channel while the fluid passed above and around both sides of the cells in the microchannel. Using obstacles of appropriate shape and size, just one cell per obstacle was trapped. The trapped cells were used for studies of enzyme kinetics on a single-cell level.

Future Directions for Research

The field of microfluidic systems for high throughput screening continues to mature. Before microfluidic devices replace existing assays and systems, several challenges still remain: standardization, interfacing between micro- and macro-worlds, ease of handling and robustness of systems, massive parallelization and cost. With these problems surmounted, future microfluidic systems will be capable of performing extensive processing and analysis for biological and drug discovery applications, on components ranging from DNA fragments to entire cells. The processing and analysis functions will be performed on a single chip, with high throughput rates in a continuous-flow manner, and in near-physiological environments as close to in vivo conditions as possible. Furthermore, microfluidic systems combined with computational tools and nanobiotechnologies will make technological breakthroughs in the near future. For instance, personalized medicine could be realized to treat an individual patient with the exact drug with optimal efficacy and safety.

Definition

Microfluidics is the science of designing, manufacturing, and formulating devices and processes that deal with volumes of fluid of the order of nanoliters. The devices themselves have dimensions ranging from millimeters down to

micrometers. The microfluidic systems are initially developed at a larger scale and then miniaturized for technological applications such as in space science. They have diverse and widespread potential applications. Some examples of particular systems and processes that might use this technology include inkjet printers, blood cell separation equipment, etc.

Overview

During the past 10 years, the concepts of miniaturization have been successfully applied to chemical and biological problems. The development and application of microfluidic or 'Lab-on-a-Chip' technology has been of particular interest. A few studies are developed on earth for future use in space considering the mass reduction benefit of the microscale [1, 2]. But at this stage, the main difficulty is to understand fluid behavior inside the Lab-on-Chip when biological or chemical reactions occur. On earth microfluidic systems have been used in a wide variety of applications including nucleic acid separations, protein analysis, process control, and small-molecule organic synthesis; from a fundamental point of view, chip-based analytical systems have many advantages over their macroscale analogues. These advantages *for space use* concern an improved efficiency in respect to the sample size, response times, cost, analytical performance, process control, integration, throughput, and automation. The idea that microfabricated analysis systems could be used in extraterrestrial environments is not new. The small size and low power requirements of the first silicon 6sgas chromatograph fabricated at Stanford University in 1975 were seen at the time as ideal characteristics for better utilizing spacecraft resources. Chip-based analysis systems possess many distinct advantages in comparison to their conventional counterparts for spaceflight purposes.

Miniature heat pipes

Definition

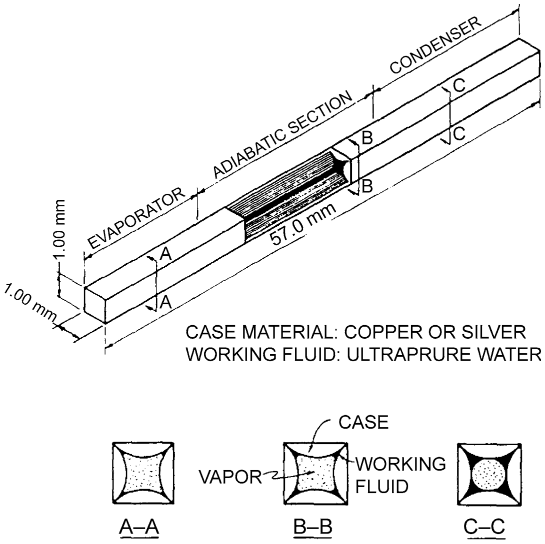
The heat pipe is a device that utilizes evaporation heat transfer in the evaporator and condensation heat transfer in the condenser, in which the vapor flow from the evaporator to the condenser is caused by the vapor pressure difference and the liquid flow from the condenser to the evaporator is produced by capillary force, gravitational force, electrostatic force, or other forces directly acting on it. A *micro heat pipe* is so small that the mean curvature of the liquid–vapor interface is comparable in magnitude to the reciprocal of the hydraulic radius of the total flow channel. Mathematically, the definition of micro heat pipe can be expressed as

$$\frac{r_c}{r_h} \geqslant 1 \tag{1}$$

where r_c is the meniscus radius of the mean curvature of liquid–vapor interface, and r_h is the hydraulic radius of the flow channel. A typical micro heat pipe consists of a small noncircular channel that utilizes the sharp angled corner regions or micro grooves as liquid arteries.

Overview

The first heat pipe concept utilizing a wicking structure as part of a two-phase heat transfer device capable of transferring large quantities of heat with a minimal temperature difference was first introduced by Gaugler [1] in 1942. The heat pipe concept received relatively little attention, however, until Grover et al. [2] first applied the term *heat pipe* to describe a *synergistic engineering structure which is equivalent to a material having a thermal conductivity greatly exceeding that of any known metal*. In 1984, Cotter [3] initialized the concept of micro heat pipes. Since that time, micro heat pipes have been extensively investigated resulting in numerous applications ranging from temperature control of the human body to the thermal management of microelectronic systems and components.



Micro Heat Pipes, Figure 1 Schematic of a micro heat pipe [4]

Figure 1 illustrates a typical micro heat pipe consisting of three sections: an evaporator or heat addition section, an adiabatic section, and a condenser or heat rejection section. A micro heat pipe, which is similar to a conventional heat pipe, consists of three major components: the container, which can be constructed from plastics, ceramics, or metals; a wicking structure constructed from sharp angled corner regions or micro grooves; and a working fluid, which remains at saturation conditions as long as the operating temperature is between the triple point and the critical state. Heat pipes operate on a closed two-phase cycle and only pure liquid and vapor are present in the cycle. Each of these three components is equally important with careful consideration given to the material type, thermophysical properties, and compatibility. For example, the container material must be compatible with the working fluid, and strong enough to withstand pressures associated with the saturation temperature encountered during storage and normal operation. In addition, the container material must be resistant to corrosion resulting from interaction with the environment and must be malleable enough to be formed into the appropriate size and shape. The sharp angled corner region directly formed from the container wall, as shown in Fig. 1, has two functions in heat pipe operation: it is the vehicle through which the working fluid is returned from the condenser to the evaporator. It also ensures that the working fluid is evenly distributed over

the evaporator surface. Because the basis for operation of a heat pipe is the vaporization and condensation of the working fluid, selection of a suitable fluid is an important factor in the design and manufacturing of the micro heat pipes. Care must be taken in selecting the working fluid to ensure that the operating temperature range is adequate for the application.

The fundamental operating principles of micro heat pipes are essentially the same as those occurring in larger more conventional heat pipes. Heat applied to one end of the heat pipe vaporizes the liquid in that region and forces it to move to the cooler end where it condenses and gives up the latent heat of vaporization. This vaporization and condensation process causes the liquid–vapor interface in the liquid arteries to change continually along the pipe, as illustrated in Fig. 1 and results in a capillary pressure difference between the evaporator and condenser regions. This capillary pressure difference promotes the flow of the working fluid from the condenser back to the evaporator through the sharp angled corner regions or micro grooves. These corner regions or micro grooves serve as liquid arteries. Because the conventional wick structures such as meshes and sintered particles do not exist in the micro heat pipe, the vapor flow will significantly affect the liquid flow in the cornered region due to the frictional shear stress, which directly influences the capillary limitation. In addition, the thin film evaporation, wetting characteristics, and condensation heat transfer significantly affect the heat transport capability in a micro heat pipe.

Basic Methodology

Capillary Limitation

For a micro heat pipe to function, the capillary pressure difference occurring in the heat pipe must always be greater than the summation of all the pressure losses occurring throughout the liquid and vapor flow paths. When the heat transfer rate increases, the pressure losses increase, which will be overcome by the increase of the capillary pressure difference. The continuous increase of the heat transfer rate in a heat pipe will significantly increase the pressure losses, and at one heat transfer rate the total capillary pressure difference is no longer equal or greater than the total pressure losses. This relationship, referred to as the capillary limit, can be expressed mathematically as [4]

$$\Delta p_{c,\max} \geqslant \Delta p_l + \Delta p_v + \Delta p_g \tag{2}$$

where

$\Delta p_{c,\max}$ = maximum capillary pressure difference generated within sharp angled corner region

Δp_l = sum of inertial and viscous pressure drops occurring in liquid phase

Δp_v = sum of inertial and viscous pressure drops occurring in vapor phase

Δp_g = hydrostatic pressure drop

When the maximum capillary pressure difference is equal to or greater than the summation of these pressure drops, the capillary structure is capable of returning an adequate amount of working fluid to prevent dry-out of the evaporating section. This condition varies according to the micro channel shape, working fluid, heat flux in the evaporator, vapor flow channel, and operating temperature.

Capillary Pressure

When a meniscus radius exists at a liquid–vapor interface, there is a pressure difference across the interface, which can be determined by the Laplace-Young equation, i. e.,

$$p_{\mathrm{I}} - p_{\mathrm{II}} = \sigma\left(\frac{1}{r_1} + \frac{1}{r_2}\right) \tag{3}$$

where r_1 is the meniscus radius along the x-direction and r_2 is the meniscus radius along the y-direction. In order to generalize the application, the maximum capillary pressure occurring in a micro heat pipe can be expressed as

$$\Delta p_{c,\max} = \sigma\left(\frac{1}{r_{e,\min}} - \frac{1}{r_{c,\max}}\right) \tag{4}$$

where $r_{e,\min}$ and $r_{c,\max}$ are the minimum meniscus radius occurring in the evaporator and the maximum meniscus radius in the condenser, respectively. Both values depend on the shape of the corner region and the amount of liquid charged to the heat pipe.

Liquid Pressure Drop

The liquid pressure drop is the result of the combined effect of both viscous and inertial forces. If the flow rate in the corner regions of the micro heat pipe is very small, the effect of inertial force can be neglected, and the pressure difference in the liquid phase is caused only by the frictional forces at the liquid–solid interface and the liquid–vapor interface due to the vapor flow effect. The total liquid pressure drop can be determined by integrating the pressure gradient over the length of the flow passage, or,

$$\Delta p_l(x) = -\int_0^x \frac{\mathrm{d}p_l}{\mathrm{d}x}\mathrm{d}x \tag{5}$$

where the limits of integration are from the evaporator end ($x = 0$) to the condenser end ($x = L$), and $\mathrm{d}p_l/\mathrm{d}x$ is the liquid pressure gradient resulting from the frictional forces

from the solid wall and vapor flow at the liquid–vapor interface, which can be written as

$$\frac{dp_l}{dx} = -\left(\frac{\mu_l}{KA_l\rho_l}\right)\dot{m}_l \tag{6}$$

where $\dot{m}_l$ is the local mass flow rate in the corner region, and K, the permeability, can be expressed as

$$K = \frac{2r_{h,l}^2}{c_{f,l} \cdot \mathrm{Re}_l} \tag{7}$$

The hydraulic radius, $r_{h,l}$, in Eq. (7) is defined as twice the cross-sectional area divided by the wetted perimeter, or, $r_{h,l} = 2A_l/P$. It should be noted that Eq. (7) is valid for both the circular and non-circular channels/grooves. If the Reynolds number of the working fluid flowing through the corner region is less than the critical value, then laminar flow is assumed. The product of the friction coefficient and Reynolds number, $c_{f,l} \cdot \mathrm{Re}_l$, for laminar flow is constant and depends only on the passage shape. It should be noticed that when the liquid–vapor interface is affected by the vapor flow, the friction coefficient Reynolds number product, $c_{f,l} \cdot \mathrm{Re}_l$, depends on the vapor flow in addition to the contact angle and channel angle [5]. For uniform heat addition and rejection, Eq. (5) can be expressed as

$$\Delta p_l = \left(\frac{\mu_l}{KA_l h_{fg}\rho_l}\right) L_{eff} q \tag{8}$$

where the effective heat pipe length, L_{eff}, can be found as

$$L_{eff} = 0.5L_e + L_a + 0.5L_c \tag{9}$$

Vapor Pressure Drop

If the heat pipe is charged with an appropriate amount of working fluid and the wetting point occurs at the cap end of condenser, the vapor pressure drop can be calculated by the approach recommended by Peterson [4]. Based on the one-dimensional vapor flow approximation, the vapor pressure drop can be determined by

$$\Delta p_v = \left(\frac{C(c_{f,v} \cdot \mathrm{Re}_v)\mu_v}{2r_{h,v}^2 A_v \rho_v h_{fg}}\right) L_{eff} q \tag{10}$$

where C is the constant that depends on the Mach number defined by

$$\mathrm{Ma}_v = \frac{q}{A_v \rho_v h_{fg}(R_v T_v \gamma_v)^{1/2}} \tag{11}$$

The ratio of specific heats, γ_v, in Eq. (11) depends on the molecule types, which is equal to 1.67, 1.4, and 1.33 for monatomic, diatomic, and polyatomic molecules, respectively. Previous investigations summarized by Peterson [4] have demonstrated that the friction coefficient Reynolds number product, $c_{f,v} \cdot \mathrm{Re}_v$, and the constant, C, shown in Eq. (10) can be determined by

$$\begin{aligned} &\mathrm{Re}_v < 2300 \quad \text{and} \quad \mathrm{Ma}_v < 0.2 \\ &c_{f,v} \cdot \mathrm{Re}_v = \text{constant}, \quad C = 1.0 \end{aligned} \tag{12}$$

$$\begin{aligned} &\mathrm{Re}_v < 2300 \quad \text{and} \quad \mathrm{Ma}_v > 0.2 \\ &c_{f,v} \cdot \mathrm{Re}_v = \text{constant}, \quad C = \left[1 + \left(\frac{\gamma_v - 1}{2}\right)\mathrm{Ma}_v^2\right]^{-1/2} \end{aligned} \tag{13}$$

$$\begin{aligned} &\mathrm{Re}_v > 2300 \quad \text{and} \quad \mathrm{Ma}_v < 0.2 \\ &c_{f,v} \cdot \mathrm{Re}_v = 0.038\left(\frac{2r_{h,v}q}{A_v \mu_v h_{fg}}\right)^{3/4}, \quad C = 1.0 \end{aligned} \tag{14}$$

It should be noted that Eq. (14) was determined based on a round cross section. Because the equations used to evaluate both the Reynolds number and the Mach number are functions of the heat transport capacity, it is first necessary to assume the conditions of the vapor flow, and an iterative procedure must be used to determine the vapor pressure drop.

Although the capillary limitation governs the heat transport capability in a micro/miniature heat pipe, several other important mechanisms might limit the maximum heat transport capability. Among these are the viscous limit, sonic limit, entrainment limit, boiling limit, and thermal resistance limit. The viscous limits deal with the pressure drop occurring in the vapor phase. The sonic limit results from the occurrence of choked flow in the vapor passage, while the entrainment limit is due to the high liquid vapor shear forces developed as the vapor passes in a counterflow direction over the liquid flow. The boiling limit is reached when the heat flux applied in the evaporator portion is so high that nucleate boiling occurs in the evaporator liquid channels. This creates vapor bubbles that partially block the return of fluid and may ultimately lead to premature dry-out of the evaporator. The thermal resistance limit is related to the thermal resistance occurring in the condenser section.

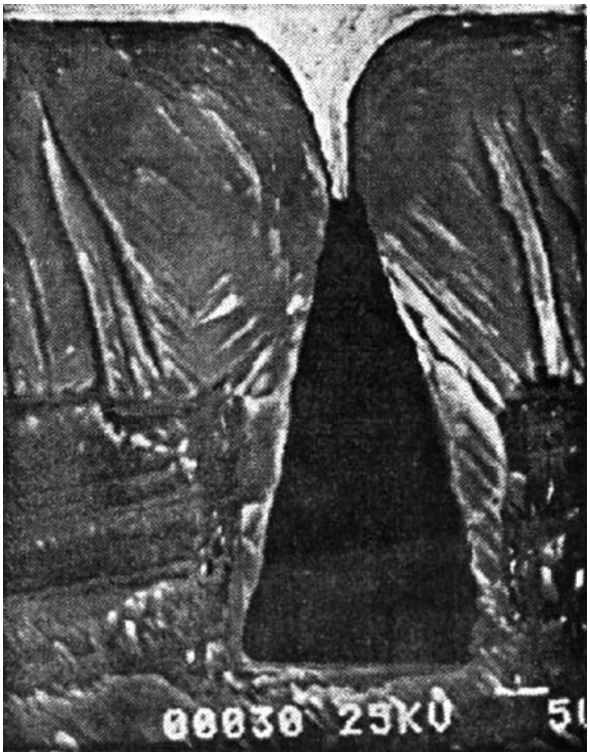
Heat Pipe Fabrication Methods

Conventional wick structures such as meshes, sintered particles do not exist in the micro heat pipe. The sharp angled corner regions or channels formed by the heat pipe wall are used to pump the condensate from the condenser

to the evaporator. Because of the vapor flow effect and thermal resistance, the heat transport capability shown in Fig. 1 is limited. Micro heat pipe arrays or miniature heat pipes have been extensively investigated and developed. As a result, a number of fabrication techniques have been advanced. The typical fabrication processes include the formation of a series of parallel triangular grooves using directionally dependent etching [6], a multisource vapor deposition process [7], and low-cost fabrication techniques which utilize the grooved tubes with a thermally-shaping method.

In the first method, anisotropic or orientation dependent etching is used to produce a series of parallel micro channels in a silicon wafer. While wet chemical etching processes have been used extensively in semiconductor processing, Peterson [4] utilized an orientation dependent etching processes which allowed etching of silicon wafers in one particular direction at a higher rate as compared to the other directions. This orientation dependent etching occurs because the crystal structure of silicon is in the diamond cubic group, which causes the crystallographic directions, indicated by the notation ⟨hkl⟩, to be perpendicular to the crystal planes, indicated by the notation (hkl). As a result, the packing density is considerably higher in the ⟨111⟩ direction which is perpendicular to the (111) plane as compared with the ⟨100⟩ direction. This results in an etching rate that is faster in the ⟨100⟩ direction than in the ⟨111⟩ direction. If an orientation dependent etchant is used on a (100) oriented slice covered by an oxide mask, it will create V-shaped grooves limited by the (111) planes. The etching process will stop at the point where the (111) planes intersect and the (100) surface reduces to a line. Once the micro channels are etched into the silicon wafer, a clear glass cover plate is bonded to the surface to form the closed triangular channels using either an ionic bonding process (for bonding silicon to silicon) or an ultraviolet bonding process (for bonding silicon and glass).

The second fabrication technique utilizes a dual source vapor deposition process. The process begins with the fabrication of a series of square or rectangular grooves either machined or etched in a silicon wafer. Then, using a dual E-Beam vapor deposition process, the grooves are closed creating an array of long narrow channels of triangular cross-section and open on both ends. Figure 2 shows a photo micrograph of the end view of a vapor deposited micro heat pipe which has not quite been completely closed at the top. As shown, the micro heat pipes are lined with a thin layer of copper, significantly reducing problems associated with the migration of the working fluid (methanol) throughout the semiconductor material. Using copper as the material for the vapor deposited heat pipes on silicon substrate, ensured less than 2.0% differential expansion during the deposition process.



Micro Heat Pipes, Figure 2 A vapor deposited micro heat pipes [4]

The third typical fabrication technique, which is currently and widely used for the mass production of micro/miniature heat pipes, utilizes the commercially available grooved tubes or channels. Using the extrusion or forging processes, the micro grooves are formed on the inside surface of the tubes. Based on the required dimensions for a given application, the grooved tube is cut into the appropriate length. Using the tubing shrinking machine, both ends of cut tubes can be shrunk. One end is directly sealed and another end is reduced to a diameter ranging from 0.5 mm to 1.5 mm for charging. After cleaning, the heat pipe is charged with a working fluid. Once the heat pipe is fabricated, the heat pipe will be thermally shaped into a flat micro/miniature heat pipe.

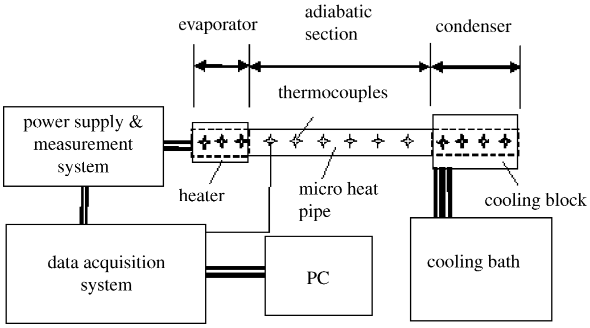
Cleaning and Charging All of the materials used in a micro heat pipe must be clean. Cleanliness achieves two important objectives: it ensures that the working fluid will wet the materials and that no foreign matter is present which could hinder capillary action or create incompatibilities. The presence of contaminants either in solid, liquid, or gaseous state may be detrimental to heat pipe performance. If the interior of a heat pipe is not clean, degra-

dation of the performance can result over time. Solid particles can physically block the liquid flow in the corner region due to the very small flow channel, decreasing the capillary limit. Oils from machining or from the human hand can decrease the wettability in the heat pipe. Oxides formed on the inside surface of wall can also decrease the ability for the liquid to wet the surface. Therefore, proper cleaning of all of the parts in contact with the interior of the heat pipe is necessary for maximum reliability and performance. Several steps are needed in order to properly clean the heat pipe container and sharp corner regions, such as solvent cleaning, vapor degreasing, alkaline cleaning, acid cleaning, passivation, pickling, ultrasonic cleaning, and vacuum baking. Many of these steps are used in a single cleaning operation [4].

It is necessary to treat the working fluid used in a heat pipe with the same care as that given to the heat pipe container. The working fluid should be the most highly pure available, and further purification may be necessary following purchase. This may be carried out by distillation. The case of low temperature working fluids, such as acetone, methanol, and ammonia in the presence of water, can lead to incompatibilities, and a minimum possible water content should be achieved. The amount of working fluid required for a heat pipe can be approximately calculated by estimating the volume occupied by the working fluid in the sharp corner regions. The amount of working fluid charged to a heat pipe significantly affects the heat transfer performance of the heat pipe. For example, the heat transfer performance of a grooved micro/miniature heat pipe currently being used in the laptop computer is very sensitive to the charging amount of the working fluid.

Once the amount of working fluid required is determined, the working fluid can be introduced into the heat pipe by an evacuation and back-filling technique, a liquid fill and vapor generation technique, a solid fill and sublimation technique, or a supercritical vapor technique [4]. The most common among those for the low or moderate temperature working fluids currently being used for the electronics cooling is the evacuation and back-fill techniques. All these charging methods are to prevent noncondensable gases from entering the heat pipe during the charging process. In order to charge the working fluid in, a suitable evacuation/filling apparatus must be applied. The apparatus must be able to evacuate the container to 10^{-4} torr or less. The filling device is used to evacuate the pipe and charge it with the proper amount of working fluid. Details of the charging process depend on the state of the working fluid at the ambient temperature. The material of construction is generally glass, copper, or plastic materials. Glass has advantages when handling liquids in that the presence of liquid droplets within the ductwork can be observed and their vaporization under vacuum noted. Copper has obvious strength benefits. If plastic materials are chosen, the working fluid used in the charging process would have to not react with the plastic materials. Because the micro heat pipe is so small, several special charging methods have been developed. The most reliable of these is to place the micro heat pipe array in a high pressure chamber. After evacuating the chamber, a predetermined amount of working fluid is added and the chamber is heated to a point above the critical temperature of the working fluid. In this state all of the working fluid exists as a vapor and is uniformly distributed throughout the chamber and micro heat pipe array. The heat pipes are then sealed using an ionic or ultraviolet bonding process. When the chamber is then opened and the temperature reduced, a portion of the working fluid condenses. By controlling the volume of the pressure vessel and the quantity of the working fluid added after initial evacuation, the final amount of fluid in each heat pipe can be precisely controlled. An alternative method, which is simpler but somewhat less accurate has been developed by Peterson [4] and consists of sealing one end of the micro heat pipe array and positioning the wafer in a vacuum chamber vertically with the open end of the micro heat pipes approximately 1 mm above a small charging trough. After evacuating the vacuum chamber, a small amount of working fluid is slowly injected into the charging trough using a micro syringe. As the chamber pressure increases and approaches the saturation pressure corresponding to the temperature of the chamber, the working fluid forms a pool in the charging trough and wicks up into the heat pipe channels effectively sealing off the channel and trapping vapor in the upper portion of the heat pipe. The micro heat pipes can then be removed from the vacuum chamber and the open ends sealed. The final amount of liquid and vapor present in the microgrooves after sealing can be controlled by varying the temperature of the wafer, the height of the wafer above the bottom of the charging trough, and the rate at which the working fluid is injected into the vacuum chamber.

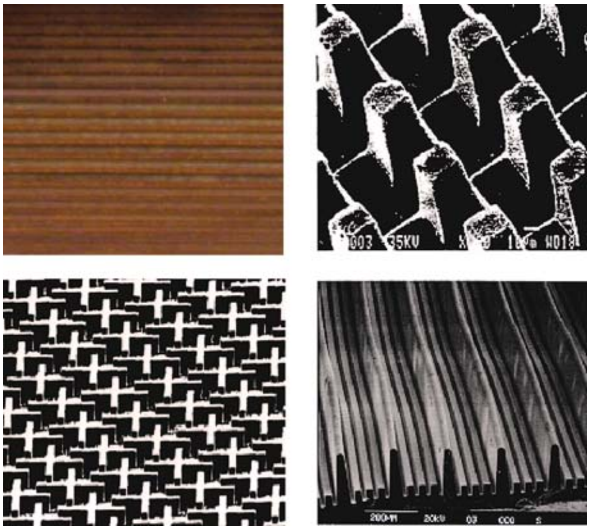
Working Fluid Selections Because a micro heat pipe cannot function below the freezing point or above the critical temperature of its working fluid, the selected working fluid must be within this temperature range. Peterson [4] has listed some working fluids which can be used in the heat pipe for a given operating temperature. In addition, the vapor pressure, surface tension, contact angle, and viscosity in the heat pipe must be considered in the selection of working fluid. For example, the vapor pressure in the heat pipe should not be less than 0.1 atm or higher than 10 atm. Typical working fluids for cryogenic heat pipes include helium, argon, oxygen, and krypton. For



Micro Heat Pipes, Figure 3 Schematic of a heat pipe test setup

most common low-temperature heat pipes ranging from 200 – 550 K, ammonia, acetone, and water are commonly employed. The typical working fluids being used in the high-temperature heat pipes are sodium, lithium, silver, and potassium. Furthermore, a more important factor in the selection of working fluid is the compatibility with the case and wick materials. Some results of compatibility tests of materials with some working fluids can be found from the reference [4].

Testing The test facility needs to be established to test the heat transfer performance and heat transport limitations. Both transient and steady-state tests should be conducted for a micro heat pipe. For low-temperature heat pipes, however, the steady-state test is of most concerned. A typical experimental system for low-temperature heat pipes similar to the one shown in Fig. 3 would normally be used. The test facility shown in Fig. 3 consists of the heat pipe, a heat power supply and measuring unit, a cooling unit, and a data acquisition unit for the temperature measurements. The operating temperature of heat pipe can be controlled by a cooling block connected to a cooling bath, where the temperature of the coolant is maintained at a constant temperature based on the designed operating temperature. The heat source is directly connected to the evaporator. Power input can be supplied by an AC or DC power supply and recorded by multimeters with signals sent directly to a personal computer which can be used to control the entire system. The heat source should be well insulated to reduce convective losses to the environment. A number of temperature sensors are attached to the heat pipe surfaces to measure the temperature distribution along the heat pipe and temperature variation with power input. All of the measured data are sent to a data acquisition system controlled by a personal computer. Prior to the start of the experiment, the system is allowed to equilibrate and reach steady-state such that the temperatures of the cooling media and the heat pipe are constant. When the desired steady-state condition has been obtained, the input power is increased in small increments. Previous tests indicate that a time of approximately 5 – 30 min is necessary to reach steady-state. To obtain the data for the next successive power level, the power is incremented every 5 – 30 min. During the tests, the power input and the temperature data are simultaneously recorded using a data acquisition system controlled by a personal computer.



Micro Heat Pipes, Figure 4 Some examples of wicks for micro/miniature heat pipes

Key Research Findings

Since the initial conceptualization in 1984 [3] and the first real micro heat pipe in 1992 [4], numerous analytical and experimental investigations of micro heat pipes have been conducted resulting in a wide variety of applications in microelectronic systems or components.

Vapor Flow Effect For a relatively large conventional heat pipe, the wick structures existing in the heat pipe help to reduce the vapor flow effect on the liquid flow. For a micro/miniature heat pipe, the vapor space in the micro heat pipe is so small and the ratio of the hydraulic diameter of the vapor flow channel to the hydraulic diameter of liquid flow in the corner regions is much larger than a conventional heat pipe. The vapor flow has a larger effect on the heat transport capability than the conventional heat pipe. Ma et al. [5] have conducted a detailed investigation of the vapor flow effect on the liquid flow. The friction coefficient Reynolds number product, i. e., $c_{f,l} \cdot \mathrm{Re}_l$, for the liquid flow in the corner region must include the vapor flow effect, which depends on the vapor flow rate,

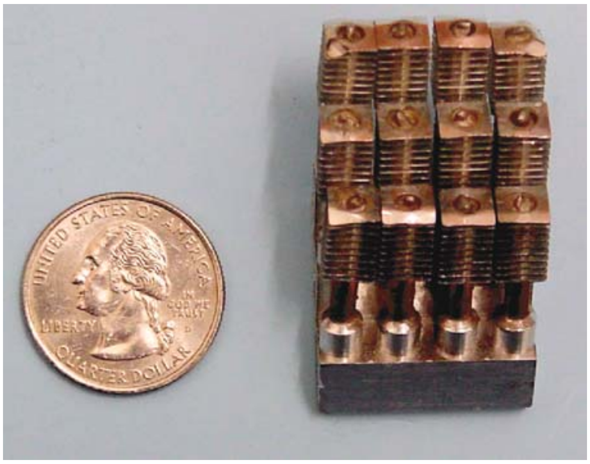
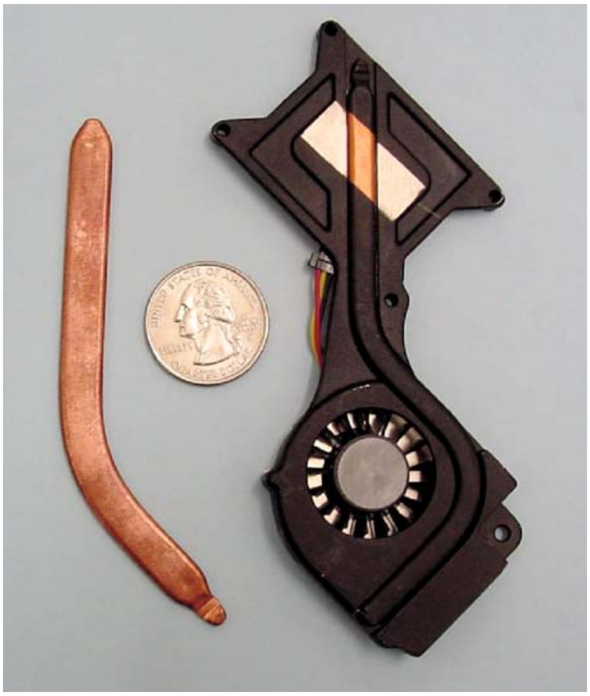
Micro Heat Pipes, Figure 8 Wetting characteristics effect on the heat transport capability in a miniature heat pipe

channel angle, contact angle, and fluid properties. Results show that the vapor flow effect significantly reduces the heat transport capability in a micro heat pipe. As a result, a number of new wick structures for micro/miniature heat pipes have been developed. Figure 4 illustrates several of these wick structures, which can significantly reduce the vapor flow effect.

Thin Film Evaporation When heat is applied to the evaporation region of a micro heat pipe, the heat will travel through the wall of the solid container and reach the working fluid. Most of the heat will pass through a thin-film region consisting of three regions: the non-evaporating thin film region, the evaporating thin film region, and the meniscus thin film region, as shown in Fig. 5. In the presence of a thin film, a majority of the heat will be transferred through a very small region [8]. When thin film heat transfer is compared to boiling heat transfer, it is found that thin film evaporation can provide significantly higher overall heat transfer coefficients. The heat transfer rate at the evaporating surface in a pool boiling system depends on the mechanisms of liquid supply to and vapor escape from the phase-change interface. Due to the presence of liquid, the resistance to vapor flow exists and directly limits the further enhancement of boiling heat transfer in the pool boiling systems. When the thin liquid film is formed in the micro heat pipe as shown in Fig. 5, the evaporating heat transfer rate through the evaporating thin film region can occur at a very small superheat. For example, the heat flux level through the thin film region can reach up to 1400 W/cm^2 with a superheat of 1.0 °C, as shown in Fig. 6. Thin film evaporation plays a key role in a micro heat pipe. There are several ways to increase the thin film evaporation. For example, when the surface wetting characteristics changes, while the capillary pumping capability increases, the thin-film-evaporation heat transfer can be significantly increased. For example, when the surface wetting characteristics changes, i. e., the contact angle changes from 56.8° to 33.1° as shown in Fig. 7, the



Micro Heat Pipes, Figure 9 Micro heat pipe arrays in electronics cooling



Micro Heat Pipes, Figure 10 Miniature heat pipes in a laptop computer cooling

heat transport capability in a miniature grooved heat pipe can be significantly increased as shown in Fig. 8.

Effective Thermal Conductivity The effective thermal conductivity provided by a heat pipe is the key factor for designing a highly-efficient heat pipe cooling device. For the conventional heat pipe, the thermal resistance in the heat pipe is mainly from the wick structure. Because the conventional wicks do not exist in a micro heat pipe, the prediction of thermal resistance occurring in the micro heat pipe is different from the conventional heat pipe. Peterson and Ma [9] developed a detailed mathematical model to predict the effective thermal conductivity, k_{eff}, in the micro heat pipe. While the expression of effective thermal conductivity, k_{eff}, for the micro heat pipe is similar to the conventional heat pipe, the thermal resistances occurring in the evaporating thin film and condensation film are the primary contribution to the total thermal resistance. Special attention will be given to the capillary flow [9, 10] and heat transfer occurring in the liquid films of both the evaporator and condenser sections. When the heat transfer rate is high, the thermal resistance occurring in the condenser section will become the primary factor affecting the heat transport capability in a micro heat pipe.

Samples of Application

Since Peterson [4] developed the first real micro heat pipe, a wide variety of micro/miniature heat pipes have been developed and utilized in microelectronic systems or components. Figure 9 illustrates an array of micro heat pipe application in an electronic component cooling. In order to reduce the vapor flow effect, increase the condensation heat transfer, and enhance the thin-film-evaporation heat transfer, the size of micro heat pipe must become larger. Figure 10 shows a micro or miniature heat pipe application in laptop computer chip cooling.

Future Directions for Research

Because the vapor space in the micro heat pipe is so small and the vapor flow directly acts on the liquid–vapor interface, the vapor flow significantly reduces the heat transport capability in a micro heat pipe. New kinds of structures for both liquid and vapor flows should be developed to reduce the vapor flow effect, in particular, when the heat transfer rate increases. And the new structures for the liquid flow should significantly increase the capillary pumping capability at the same time. The thin film evaporation in a micro heat pipe plays a key role and an extensive investigation to increase the thin film evaporating region should be conducted in order to significantly increase the evaporating heat transfer rate, in particular, for a high-heat-flux application. While the wetting characteristics will help to increase the capillary pumping capability, a better wetting surface will significantly enhance the evaporating heat transfer. Extensive investigations should be conducted to develop a cost effective approach treating the surfaces in the evaporator and condenser to significantly increase the heat transport capability in a micro/miniature heat pipe.

Nomenclature

A	cross-sectional area, m^2
C	constant
c_f	friction coefficient
h_{fg}	latent heat, J/kg
k	thermal conductivity, W/mK
K	permeability, m^{-2}
L	length, m
Ma	Mach number
$\dot{m}$	mass flow rate, kg/s
r	radius, m
R	universal constant, J/kg-K
p	pressure, N/m^2
P	perimeter, m
q	heat transfer, W
Re	Reynolds number
T	temperature, °C
x	coordinate, m

Greek Symbols

γ	ratio of specific heats
μ	dynamic viscosity, N-s/m^2
ρ	mass density, kg/m^3
σ	surface tension, N/m

Subscripts

a	adiabatic section
c	capillary, condensation, condenser
e	evaporation, evaporator
eff	effective
g	gravity
h	hydraulic
l	liquid
max	maximum
min	minimum
v	vapor
w	wall

Definition

Laser Doppler velocimetry is a technique for measuring the local velocities of flows.

Overview

In laser Doppler velocimetry (LDV) [1] based on the differential technique, two coherent laser beams, which are usually generated by beam splitting, are made to intersect at a small angle 2θ. In the area of intersection (the measurement volume) an interference fringe pattern with nearly parallel planes arises. The normal vector of these planes lies in the plane spanned by the LDV partial beams and is aligned perpendicular to the optical axis, which is the crossing half angle of the beams. The spacing d of the interference fringes is given by the laser wavelength λ and the crossing half angle of the partial beams θ:

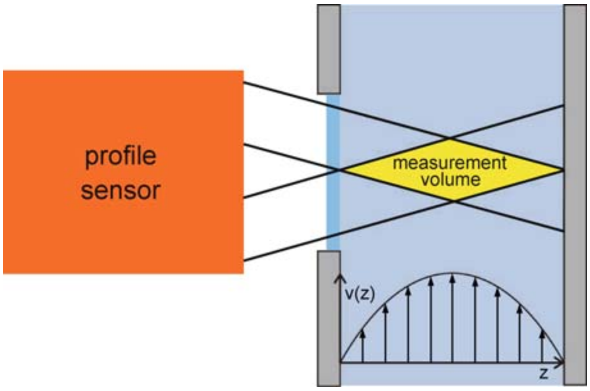
$$d = \frac{\lambda}{2 \sin \theta} \tag{1}$$

For flow measurements, the fluid usually has to be seeded with small particles ("tracers"), having typical diameters in the nano- or micrometer range and following the flow with negligible slip. As the particles pass through the interference fringes they scatter light at only the bright fringes such that the scattered light shows an amplitude modulation with the frequency f_D, which is known as the Doppler frequency. Photodetectors are used to generate an electrical signal from the scattered light. Signal processing techniques calculate the Doppler frequency from it. The velocity component lying parallel to the normal vector of the interference fringes is then given by

$$v_x = f_D \cdot d \tag{2}$$

In order to measure two or all three velocity components two or three different interference fringe systems have to be overlapped with orthogonal alignment of their optical axes in the ideal case. If the optical axes can for some reasons not be aligned orthogonally, a coordinate transform algorithm has to be included in the signal processing software. The different fringe systems have to be physically distinguishable and usually either wavelength division multiplexing (WDM) or frequency division multiplexing (FDM) is applied for this purpose.

For applications of conventional LDV in nano- and microfluidics the spatial resolution is a crucial point. Since usually no information about the position of the tracer particle can be gained, the spatial resolution is determined by the size of the measurement volume. A high spatial resolution can be achieved by beam stops or by strong focusing of the laser beams, e. g. by means of a microscope objective resulting in a small measurement volume of e. g. 20 μm × 20 μm × 20 μm. However, the focusing of the laser beams is accompanied by two disadvantages: a reduced working distance and an increased uncertainty of the velocity determination. The latter effect is caused by the wavefront curvature of the focused laser beams resulting in fringes being no longer parallel. This variation of fringe spacing will increase the relative velocity uncertainty by several percent. This uncertainty relation between spatial resolution and uncertainty of velocity strongly limits the application of conventional LDV for microfluidic tasks [2].

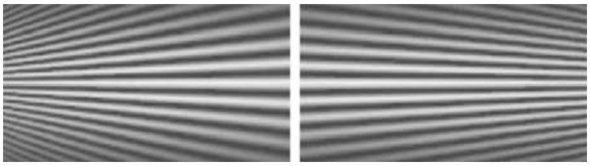


Micro Laser Doppler Velocimetry (μ-LDV), Figure 1 Application of a profile sensor(one concept of micro-LDV): velocity profile measurement in a microchannel

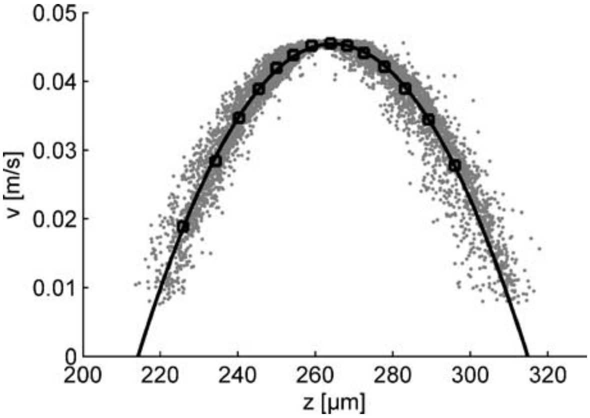
Micro-LDV was developed to overcome these drawbacks. One successful concept is the velocity profile sensor [3]. Along a line, which generally is the optical axis, the lateral velocity component of tracers is resolved with axial position resolution inside the measurement volume. Since the tracer particles are in general distributed statistically in the fluid, the velocity profile can be determined by measuring a sufficient number of tracers whose velocity and position are determined. Of note is the fact that the spatial resolution is no longer limited by the dimension of the measurement volume, so that a significantly higher spatial resolution up to about 100 nm results. Here, the measurement volume can be as large as the flow region of interest, e. g. the cross-section of a microchannel (see Fig. 1), and the velocity profile can be measured without mechanically traversing the sensor head.

Various principles exist as to how a profile sensor can be realized [2]. In the following the profile sensor invented by the authors of this overview will be described as an example [3, 4].

The profile sensor employs two superposed interference fringe systems (Fig. 2). In contrast to conventional LDV with parallel fringes, the fringe systems are fanlike with one being convergent and the other being divergent. They are described by the fringe spacing functions $d_{1,2}(z)$.



Micro Laser Doppler Velocimetry (μ-LDV), Figure 2 Fringe systems of the laser Doppler velocity profile sensor



Micro Laser Doppler Velocimetry (μ-LDV), Figure 3 Measured velocity profile of a laminar water flow in a 100 μm microchannel

The z-position of the tracers is determined by the quotient of two measured Doppler frequencies:

$$q(z) = \frac{f_2(v_x, z)}{f_1(v_x, z)} = \frac{v_x/d_2(z)}{v_x/d_1(z)} = \frac{d_1(z)}{d_2(z)} \qquad (3)$$

The calculated z-position allows one to determine the actual fringe spacings $d_1(z)$ and $d_2(z)$, resulting in a precise measurement of the velocity:

$$v_x(z) = f_1(v_x, z)d_1(z) = f_2(v_x, z)d_2(z) \qquad (4)$$

Figure 3 shows the measurement result of an application of the profile sensor at a microchannel flow obtained without traversing the sensor. Each point corresponds to a single tracer whose position and velocity were determined. A good agreement with the expected parabolic velocity profile of the laminar channel flow was achieved. The spatial resolution was approximately 3.5 μm (which is the standard deviation of the tracer position). It was limited by sensor properties and the size of the tracers, which was about 2 μm. Using submicrometer tracers as well as improved sensor properties a spatial resolution in the nanometer range will be possible.

An extension of the profile sensor is the field sensor, which measures a two-dimensional velocity distribution of a flow. It is based on the combination of two profile sensors, which are arranged orthogonally. The features are analogous to micro-PIV (particle image velocimetry). However, since the velocity image is determined without having to use a digital camera, the tracers do not need to be imaged and digitization effects do not occur. In particular, a high relative velocity resolution of around 0.1% and a high temporal resolution in the millisecond range can be achieved. Precise flux measurements are one task of the velocity field sensor in micro- and nanofluidics.

Definition

Micromolding is a set of fabrication techniques for replicating microstructures in polymers using molds (also commonly known as masters or tools) to define features. The three most common micromolding techniques are *injection molding*, *hot embossing*, and *casting*. Micromolding involves four primary steps: microfabrication of the mold containing a negative or inverse of the desired pattern geometry, introduction of polymer material to the mold, curing or cooling of the polymer material, and release or separation of the molded polymer from the mold.

Overview

Polymer microfabrication has become a popular alternative to the well-established silicon and glass-based microelectromechanical system (MEMS) fabrication technologies, particularly for microfluidic and Lab-on-a-Chip (LOC) applications. Polymers have several major advantages that are not immediately available in silicon and glass, including a wide range of material characteristics, biochemical compatibility, ease of processing and prototyping, and lower costs. Micromolding replication technologies are well suited for these applications because the principles behind these processes are already well established in the macroscale world. Microfluidic systems have been recently demonstrated in polymers for biomedical applications, including miniaturized electrophoresis chips, microfluidic mixers, pumps, valves, switches, and devices for cell culture or protein patterning [1–3].

Generally, micromolding encompasses three established polymer microfabrication technologies: injection molding, hot embossing, and casting.

Injection molding is probably the most well known technology due to its popularity in macroscale plastic processing. In injection molding, polymer pellets are melted in a heated screw and injected at high pressure into a mold (also known as master or tool) to replicate features. The process is typically automated and can be used to very rapidly fabricate LOCs, but is limited by the tool materials and the availability of appropriate substrate polymers. Polymers such as polymethylmethacrylate (PMMA) and polycarbonate (PC) are commonly used to fabricate LOCs by injection molding [4–6]. Although tools can be fabricated with conventional micromachining techniques, there are significant design considerations associated with equipment-specific molding tool design.

Casting is the most popular of the three micromolding methods for fabrication of microfluidic LOCs [7, 8]. This is by far the least expensive and simplest method, and its use is widespread in academia. The polymer (elastomer precursor) and the curing agent are typically mixed at a specific ratio and poured over the mold (also known as template or master). The system is thermally cured, allowing the elastomer to be peeled off once it sets. The most prominent elastomer is polydimethylsiloxane (PDMS), and the casting template can be fabricated with conventional micromachining techniques [9]. Micromolding in capillaries (MIMIC) [10] is a popular variation of the technique, in which PDMS is cast on a mold containing a relief pattern, which is then released and used as the mold in a second step. The mold is formed by placing the PDMS casting in conformal contact with a substrate to create a network of channels, which are then filled with a liquid pre-polymer by capillary action or vacuum and cured. Once cured, the mold is removed leaving the microstructures. MIMIC has been used to fabricate complex microstructures in thermally and UV-curable polymers.

Hot embossing is a reasonably fast and moderately expensive technique used to replicate microfluidic LOCs in thermoplastics [5, 6, 11]. In the embossing process, the polymer and mold (also known as master or tool) are heated above the glass transition temperature (softening point) of the thermoplastic and a controlled force is applied. The assembly is then cooled below the glass transition temperature (T_g) and de-embossed or de-molded. Hot embossing is used in a wide range of applications from rapid prototyping to high volume fabrication. Polymers such as PMMA, PC and cyclic olefin copolymer (COC) are commonly used to emboss microfluidic LOCs using tools fabricated with conventional micromachining techniques.

Material Properties of Micromolded Polymers

Polymers can be broadly classified into three groups, according to the interconnection of the monomer units in the polymer chain, which will substantially affect their properties and thus the molding behavior. The first category is the *thermoplastic polymers*, which consist of unlinked or weakly linked linear chain molecules. Above the glass transition temperature, these materials become plastic and can be molded into specific shapes, which they retain once cooled below the *glass transition temperature* (T_g). Thermoplastics that contain very long polymer chains with strong intermolecular interactions do not melt and flow, but remain soft until they decompose. The glass transition temperature may be lowered through the addition of softeners, or raised by adding plasticizers during the polymerization process. Thermoplastics are commonly used in hot embossing (e. g., PMMA and PC). Thermoplastics have also been dissolved in organic solvents and poured into molds, leaving rigid replicas once the solvent is driven out. The second group is the *elastomeric polymers*, which also contain weakly cross-linked polymer chains. Under an applied stress, molecular chains can be stretched to high extent, but relax and return to the initial state once the force is removed. Elastomers such as PDMS do not melt before reaching the decomposition temperature and are typically processed by casting. The third category are the *duroplastic polymers* (also known as *thermoset polymers*), which contain heavily cross-linked polymer chains and therefore do not easily change shape. Thermosets are normally cast or injection molded into the final shape, and are harder and more brittle than thermoplastics. The majority of the hot embossing work and microscale injection molding to date, particularly in microfluidic applications, has been performed in PMMA (also known as Plexiglas or Lucite) and PC (also known as Lexan, GE or Makrolon, Bayer). Both of these materials offer high optical transmission above 400 nm and have a long history as biomedical materials. PMMA is available in a broad range of molecular weights. This thermoplastic polymer has a relatively low T_g of 106 °C, which makes it better suited for hot embossing than PC ($T_g = 150$ °C). Other physical properties of the two materials, such as the density, modulus of elasticity, thermal conductivity, and water absorption, are quite similar. The refractive index of PC is 1.586, higher than that of PMMA, making PC a good material for applications using optical detection [12]. COC (also known as Topas, Ticona) is a relatively new polymer material that has been gaining popularity in hot embossing and micro injection molding due to its excellent physical and chemical properties [4, 6]. COC is a thermoplastic copolymer consisting of ethylene and bicyclic olefin (norbornene) monomers. Due to the olefinic characteristics, COC has a good chemical resistance to hydrolysis, acids and bases, and most organic polar solvents such as acetone, methanol, and isopropyl alcohol, although it is soluble in nonpolar organic solvents including toluene and naphtha. COC has a lower density than PMMA ($\rho_{COC} = 1010 - 1020\,kg/m^3$ vs. $\rho_{PMMA} = 1170 - 1200\,kg/m^3$) [5, 13], which makes it easier to emboss. However, its glass transition temperature is higher ($T_g = 134$ °C for Topas 5013S-04 and TKX-0001), requiring higher temperatures when injection molding. Overall, based on its material properties, COC is ideally suited for molding of microfluidic LOCs and devices, especially if optical signal detection is required [4, 5].

PDMS is perhaps the most widely used polymer for liquid casting of microfluidic channels with the Sylgard 184 (Dow Corning) formulation being the most frequently reported in the literature. This elastomer is optically transparent above ~230 nm, making it compatible with a variety of optical detection and microscopy techniques including DIC and epifluorescence. It is CO_2 permeable, relatively biocompatible, and has good chemical resistance, although it swells in many organic solvents [12, 13]. PDMS remains flexible and stable over a wide range of temperatures from −50 °C to +200 °C; a property not available in most materials. Furthermore, PDMS surfaces can be modified through adsorption of proteins or via plasma processing to obtain specific surface characteristics. Cured PDMS can easily be bonded to smooth PDMS or glass substrates using a brief O_2 plasma treatment.

Each micromolding method has specific constraints with regard to the material properties of the molded polymers. Detailed material properties and chemical resistances of polymers can be found in [13–16]. The most critical parameters to successful replication in hot embossing are T_g and the thermal expansion coefficient. Controlling the system temperature relative to T_g is critical. Raising the

temperature above T_g results in a viscous state, and the surface is easily deformed by the tool. For de-embossing, the material is cooled below T_g and becomes rigid, although the geometric stability of embossed features can suffer due to relaxation during de-embossing. Thermal expansion coefficient is also important in the microchannel sealing process where different materials are thermally bonded. In injection molding, shrinkage of the molded part following cooling is a major problem, especially if micrometer tolerances are necessary. This is remedied by adding reinforced fillers, such as glass beads which also increase stiffness. Critical material parameters in injection molding include the coefficient of thermal expansion, heat capacity, and the viscosity as a function of temperature. Critical processing parameters include precise temperature control of the melt and mold block, and the injection pressure. In casting, the most critical parameter is the low liquid pre-polymer viscosity, which is key to ensuring that template patterns are easily and completely filled. If liquid pre-polymer contains solvents, it is important that they do not degrade the mold materials. Finally, for all techniques, it is critically important that the micromolded polymer does not form chemical bonds or have strong adhesion to mold materials to facilitate mold release at the end of the process.

Basic Methodology

Fabrication of Masters

The underlying principle of micromolding is the replication of a microfabricated master, which represents the negative (inverse) structure of the desired polymer structure. Thus, microfabrication is only necessary one time for the fabrication of this master structure, which then can be replicated many times in the polymer substrate. This offers substantial cost advantages and freedom of design since master molds can be fabricated with a large number of different microfabrication technologies.

The success of any micromolding technique is largely dependent on the master since any surface defect will be replicated faithfully in the polymer. Thus, these processes have specific constraints with regard to masters that must be considered. First, since the molded part must be released from the master, undercuts in the pattern cannot be tolerated or the interlocking geometry would cause damage to the master or the molded part. Second, fidelity of the replication and lifetime depend strongly on the surface quality of the master. Smoother sidewall master surfaces result in lower frictional forces during separation or mold release. Roughness values below 100 nm RMS are necessary for reliable high-quality replication [5].

The master material should not form any kind of chemical or physical bond during replication. If mold release is difficult, release agents can be used. Some commonly used release agents include dilute liquid soap, silanization coatings, and plasma deposited fluorocarbon films. Specialized release agents are available from a variety of manufacturers. It is possible for release agents to modify the polymer surface or diffuse into the polymer matrix, which could adversely affect biological samples or increase the autofluorescence of the polymer, causing difficulties if the device uses fluorescence-based detection.

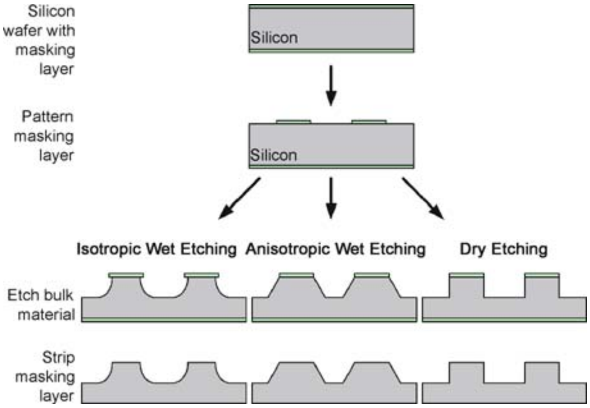
There are a number of methods used to fabricate tools, which can be broadly categorized as traditional micromachining methods (e. g., milling), bulk micromachining (e. g., etching Si), surface micromachining (e. g., nickel electroplating in photoresist or LIGA molds), and mold micromachining (e. g., PDMS or polyester tools). Surface morphology, adhesion properties to the molded materials, lifetime, feature sizes, and costs are critical factors to be considered in master fabrication.

Microscale Machining

Modern microscale machining technologies, such as sawing, cutting, and computerized numerically controlled (CNC) milling, are capable of producing masters with structures on the order of a few tens of micrometers. One key advantage of these techniques is the wide range of materials that can be machined, particularly stainless steel which cannot be processed with other microfabrication techniques but offers excellent master lifetimes. Relatively simple geometries with straight walls are a good fit for these techniques. However, high aspect structures (height vs. width ratio greater than 2), very deep holes, or very small structures (less than 10 μm) cannot be fabricated. Further, with surface roughness around several micrometers, these techniques typically do not produce smooth surface finishes. These machining methods are best for large features, often greater than 50 μm, with tolerances around 10 μm [5]. Because the master is machined from a single piece of material, adhesion problems between the substrate and features are entirely avoided. However, all of these prototyping fabrication processes are labor intensive and slow.

Bulk Micromachining

In bulk micromachining, the master is created by etching the substrate wafer, typically silicon. Silicon is an excellent material for use as an embossing master [5]. It has a high modulus of elasticity and high thermal conductivity, properties that are desirable in a hot embossing tool. In addition, there is a large variety of mature silicon microfabrication techniques available.



Micromolding, Figure 1 Bulk micromachining of silicon masters

To make a silicon master, a pattern is first created using CAD software, and the image is transferred to a photomask [9]. A Si wafer is coated with a masking material such as silicon dioxide or silicon nitride, and then coated with a layer of photoresist. The process is schematically illustrated in Fig. 1. Following UV exposure, the photoresist is developed revealing the transferred image. The image is then transferred to the exposed masking layer using either wet or dry etching. The exposed silicon is then etched anisotropically using potassium hydroxide (KOH), tetramethylammonium hydroxide (TMAH), or ethylenediaminepyrocatechol (EDP). If silicon with crystallographic orientation ⟨100⟩ is used, the resulting microstructure has a trapezoidal shape with a wall angle of 54.74°. The slant in the wall allows for good mold release and the surface roughness of well-oriented wet etched silicon wafers is excellent. The height and the width of the tool features are controlled by the amount of time the wafer is etched. In the final step, the mask layer is then stripped in hydrofluoric acid or phosphoric acid.

Dry etching methods, such as deep reactive ion etching (DRIE) and the Bosch process [9] can be used to fabricate deep structures with vertical sidewalls. However, scalloping or high surface roughness due to non-optimized or fast etches can result in problems during mold release. Typical depths range from 10 to 40 μm, although through holes have been achieved using the Bosch process.

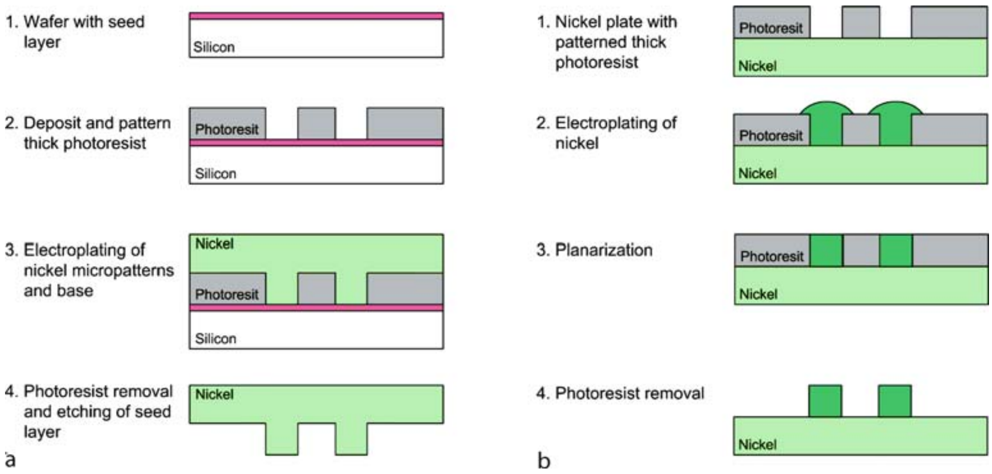
Although silicon masters are simple to fabricate and offer good resolution and surface properties, they suffer from a number of disadvantages. Silicon masters may be too fragile for typical hot embossing pressures and may need some form of reinforcement (e. g., by anodic bonding to glass wafers). Silicon masters may also adhere to polymers depending on their surface chemistry, which would reduce the number of possible replication cycles. For greater master durability and replication performance, masters are often surface micromachined.

Surface Micromachining

In surface micromachining, a master is created by first patterning a mold on the wafer surface, followed by electroplating nickel, and finally removing the mold producing the nickel master [9]. This is the most commonly used method for hot embossing tools, and has also been used to make tools for injection molding. It is popular since a nickel tool can be made with low surface roughness, high durability, and has the ability to replicate small and high aspect ratio features.

There are two reincarnations of this method, schematically illustrated in Fig. 2. The first method uses a silicon or glass wafer as a substrate material, while the second method uses a nickel plate. A silicon or glass wafer is coated by evaporation or sputtering with a conductive seed layer (∼100 nm) such as Ni or Cu or Au. A thin layer (∼50 nm) of Ti or Cr is used to enhance adhesion of the conducting layer to the silicon substrate. The wafer is then coated with a layer of photoresist, which is subsequently exposed to UV light and developed so that the areas to be electroplated are free of resist. The wafer is placed into a nickel galvanic bath, where due to the migration of metal ions between the electrolyte and the seed layer, nickel is deposited in the photoresist structure. Low stress nickel films are important for developing thick structures, and can be deposited from a nickel sulfamate galvanic solution. Such solutions are commercially available (e. g., Technics Inc.) or can be mixed (e. g., 375 g of nickel sulfamate, 7.5 g nickel bromide, and 37.5 g boric acid per 1 l of deionized water). Electrodeposition is performed at ∼50 °C to reduce stress, with current density on the order of 20 mA/cm^2. Plating is allowed to proceed long enough for the metal to grow higher than the resist and form the master base. To ensure that the plating takes place on top of the photoresist, a thin layer of seed metal can be sputtered on the top surface. Following metal deposition, the resist and seed layers can be dissolved and the resulting metal structure can be used for hot embossing or injection molding.

In the second incarnation, photoresist is deposited and patterned on a nickel substrate rather than Si. Electroplating is performed using the same conditions as described above until nickel completely fills all microstructures. In this method, it is necessary to mechanically polish the nickel microstructures to the desired height prior to embossing. Photoresist is stripped off to complete the fabrication process. The height of the metal structure is determined by the thickness of the photoresist mold. Positive thick



Micromolding, Figure 2 Fabrication of surface micromachined masters by photolithography and nickel electroplating using a silicon wafer as a substrate (**a**) and a nickel plate as a substrate (**b**).

photoresists allow structural heights in the order of 10–40 µm (e. g., AZ P4620, Clariant Inc.). Deep patterns, up to 1 mm, can be obtained using negative thick photoresist (e. g., SU-8, MicroChem Corp.). X-ray LIGA (German for Lithographie, Glavanoformung, Abformung) [9] is a well-established technique, where PMMA resist layers are exposed with synchrotron radiation, and can yield high aspect ratio structures and molds thicker than 1 mm. The electroplating method produces master surfaces with very low roughness (about 10 nm RMS for LIGA).

Conventional lithography, X-ray or UV LIGA followed by electroplating nickel or nickel alloys on silicon or nickel substrates is a common technique for fabricating tools with very small and complex features [4, 11, 17]. The electroplated nickel surface is very smooth and compatible with most polymers. However, electroplating of tall, high aspect ratio structures requires very long times and increasing the current density to speed up the process typically increases stress levels and surface roughness.

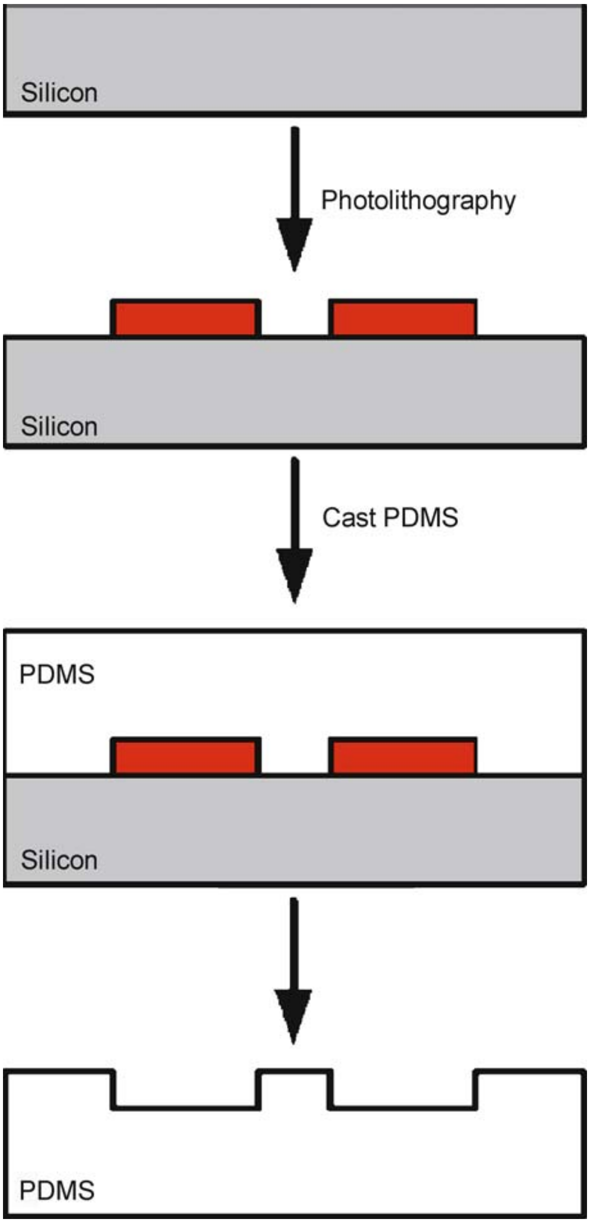
Polymer Casting

Casting liquid pre-polymers on microfabricated molds is the simplest and cheapest method of replication. Masters can be fabricated as discussed above or by simply defining structures in photoresist on a variety of substrate materials. Once the masters have been fabricated, they are often treated with a mold release agent prior to use. The liquid polymer is poured over the molds and placed under vacuum in order to completely fill the features and remove any air bubbles. Finally, the material is thermally cured and the replica is cut or peeled from the mold. This process is schematically represented in Fig. 3.

PDMS is one of the most popular polymers used in micromolding and is simple and inexpensive to process in any laboratory, requiring only a balance, a vacuum chamber, and a hot plate or oven [3]. PDMS is mixed at a 10 : 1 (m/m) ratio of base to curing agent, as recommended by the manufacturer, and remains a viscous liquid for several hours at room temperature. Liquid PDMS will easily fill sub-micron features, and any imperfections in the master, such as cracks, will be replicated. Therefore, a high quality replication requires a high quality master. In order to ensure that PDMS will release from the masters, molds may be treated with dilute soap, a fluorocarbon plasma, Sigma Cote (Sigma Aldrich, SL-2), or using perfluoro-1,1,2,2-tetrahydrooctyltrichlorosilane. PDMS is poured over the molds, which are then placed in a vacuum chamber until no air bubbles remain. Finally, the molds are heated to accelerate the curing process. PDMS will cure at room temperature, although it may take 24 h or longer depending on the thickness of the molded material. For PDMS with a thickness less than 5 mm, Table 1 provides typical curing times and temperatures. For increased thickness, either times or temperatures must be increased, however temperatures must be compatible with the mold materials, especially if photoresist molds are used. Once cured, PDMS castings are cut and peeled from the molds.

Micromolding, Table 1 PDMS curing times for 1–5 mm thick films

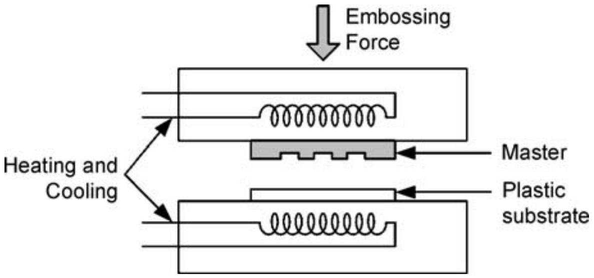
Temperature	Curing Time
20 °C	24 hrs
65 °C	4 hrs
80 °C	2 hrs
100 °C	1 hr



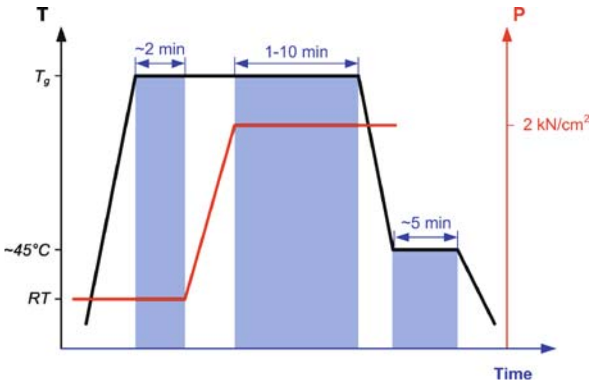
Micromolding, Figure 3 Process sequence for casting PDMS

Hot Embossing

The microfabrication process of hot embossing is rather straightforward. Once an embossing master is fabricated, it is mounted inside the embossing system together with a planar polymer substrate. An embossing machine, schematically illustrated in Fig. 4, consists of a vacuum chamber containing two temperature controlled plates, one of which is hydraulically actuated to deliver the embossing force. The embossing tool and the planar polymer sub-



Micromolding, Figure 4 Schematic diagram of the hot embossing machine

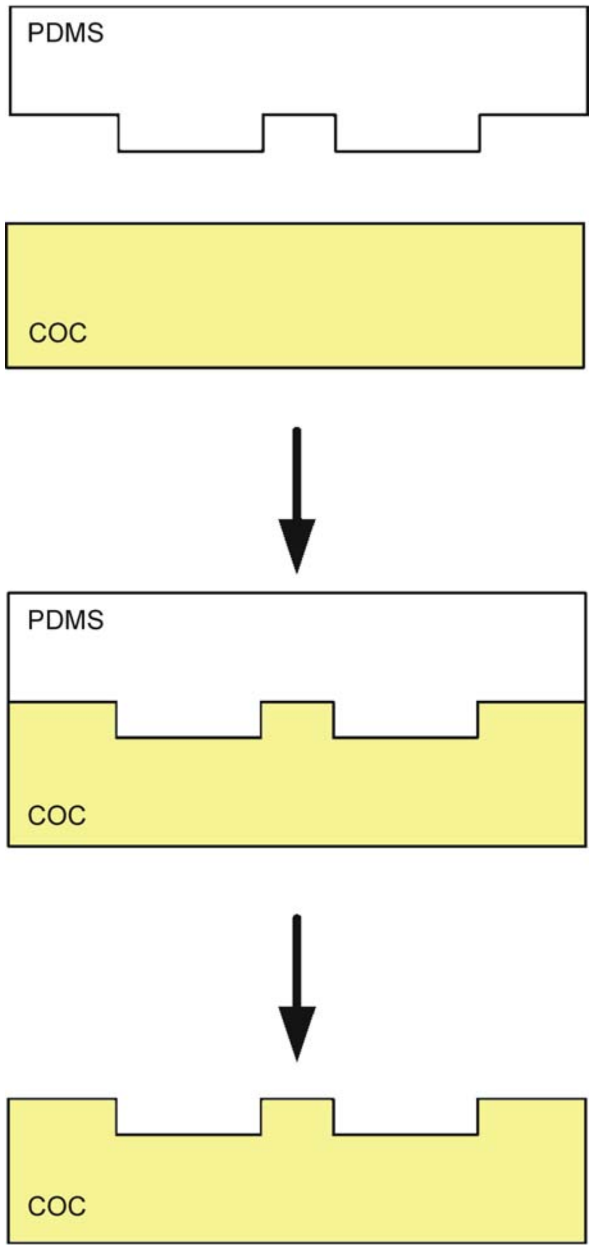


Micromolding, Figure 5 Graphical representation of the temperature and pressure program in a typical hot embossing process

strate are mounted between the plates, which are used for thermal cycling.

Conventional Hot Embossing Process

There are three basic steps in hot embossing, schematically represented in Fig. 5. At the beginning of the embossing cycle, the master and polymer substrate are heated independently in a vacuum chamber at < 100 mTorr to a temperature just above the T_g of the polymer. For most thermoplastics, this temperature is typically in the range of 100 – 180 °C. Vacuum is necessary to prevent trapping of air bubbles in microstructures and to remove water vapor driven out from the polymer substrate during the process. Vacuum also increases lifetime of metal masters by preventing corrosion at elevated temperatures. For most applications, the master and the substrate are heated to the same temperature. However, it is possible to independently control each heating plate to attain optimum embossing results.
In the second step, the master is brought into contact with the substrate and then embossed by applying a controlled force. Typical embossing pressures are on the order of $0.5 – 2\ \mathrm{kN/cm^2}$. While applying the embossing pressure, the tool-substrate sandwich is cooled to just below T_g. In



Micromolding, Figure 6 Hot embossing of COC with a PDMS tool

order to minimize thermally induced stress in the material and replication errors due to mismatch in thermal expansion coefficients of the master and the substrate, the temperature differential in the thermal cycle should be as small as possible. Typical values of the thermal expansion coefficient of polymers are on the order of $7 \times 10^{-5}\,\mathrm{K}^{-1}$, while silicon is approximately $2.5 \times 10^{-6}\,\mathrm{K}^{-1}$ and nickel is around $1.3 \times 10^{-5}\,\mathrm{K}^{-1}$.

In the final step, the embossed substrate is cooled to a temperature below the T_g, where the plastic material transitions back to the rigid state. After reaching this lower cycle temperature, the embossing master is mechanically separated from the polymer substrate that now contains the desired microfeatures. Separation is a critical step due to the large forces that act on the polymer structure and mold. This is particularly true for microstructures with vertical sidewalls and high aspect ratios. The overall cycle time of the embossing process is typically 1 – 10 min.

For every microfluidic chip design, however, the process conditions vary slightly. Geometry of the structures is an important factor that includes feature size, aspect ratio, radius of curvature, and whether the structure is freestanding or connected, and can significantly influence the process parameters. Layout properties of the design, such as the distribution of large and small features over the wafer area and the total wafer area to be processed, also must be considered.

Hot Embossing with Polymer Masters

Recently, polymer masters have been demonstrated for molding plastics. Microstructures formed in thick negative resist on silicon can be used directly as a tool for replicating parts in PC and PP [18]. However, lifetime of these tools was very short, only a few replications, due to the poor adhesion of SU-8 to the underlying base substrate during de-embossing. Alternatively, photoresist (AZP 4620 or SU-8) can be used to define a template for casting PDMS to form the embossing tool. The process is schematically illustrated in Fig. 6.

Mechanical properties of PDMS affect the hot embossing process. PDMS masters are not rigid like the nickel or silicon tools discussed earlier and have a much lower Young's modulus [16]. Thus, embossing pressure is very important. PDMS has a higher thermal expansion, and will expand and deform considerably more than conventional tools. Thus optimizing temperature is equally important in order to reduce discrepancies in replication. Overall, the use of PDMS masters can substantially reduce time, complexity, and costs involved in fabricating prototype microfluidic chips, but limits the master lifetime to approximately 20 cycles.

Injection Molding

Injection molding is the most widely used production technique for molding thermoplastics, and is also capable of molding thermosets and elastomers. Injection molding is perhaps the most expensive and complex process used to produce microstructures in polymers due to the specialized equipment, tooling, and process variables. In an injec-

Screw speed:	$n_S = 50 - 200$ rpm
Injection speed:	moderate to fast (50 mm/sec – 150 mm/sec)

tion molding process, a molten polymer is injected into a mold at high pressure and temperature and then cooled to solidify the part before the mold is opened and the part is ejected. While there are several different configurations of injection molding machines, a reciprocating screw driven system is the most common. Detailed discussion of injection molding systems is given in [19].

A reciprocating screw driven injection molding machine is schematically illustrated in Fig. 7. Solid polymer pellets are first loaded into the hopper which feeds into the barrel. The barrel contains a rotating screw which transfers the polymer from the hopper to the mold, and shears and compresses the material at the same time through a tapered geometry. Injection barrels are water jacketed or contain electrical heating elements for temperature control through multiple zones, transitioning from room temperature to the process injection temperature. The temperature at the nozzle is often set to the maximum processing temperature of the plastic. Hydraulics then actuate the reciprocating

injection which facilitates improved/complete filling of the cavity and eliminates trapped air bubbles. A mold block consists of two halves, one of which is stationary and maintained at the injection temperature, while the other is actuated using hydraulics and contains the relief pattern and ejection pins. Tooling containing the micropatterns is installed in the mold base, and is micromachined using the methods discussed previously. As in hot embossing, a positive draft angle is required along with minimal surface roughness to facilitate mold release upon ejection.

Process variables for injection molding are specific to the molded polymer. These parameters are typically provided by the polymer and machine manufacturers, although minor adjustments will be necessary to fine tune the process for different machines and mold geometries. For example, injection molding parameters for Topas COC grade 5013S-04 in a typical system are summarized in Table 2. Perhaps the greatest challenge in injection molding is filling high aspect ratio microstructures, and often simulation software is used to assist in the design of tooling and process parameters. While injection molding can be advantageous in high volumes, it may be cost-prohibitive for rapid prototyping or small runs if a new mold base is required to accommodate unique geometries. An injection molding process can be completed in a time frame of seconds to tens of minutes depending on the geometry of the mold and polymer material properties.

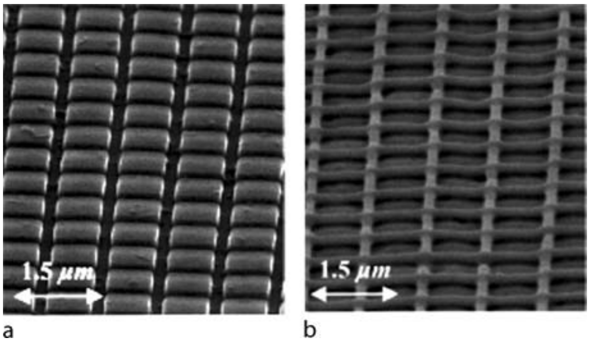
Key Research Findings

Microstructures in a wide range of shapes and aspect ratios can be replicated with micromolding techniques. For example, replication through liquid casting of PDMS has been used to make microchannels with a wide range of geometries [3, 7, 8, 10, 13]. Figure 8 shows an array of microchannels in PDMS which was cast using a photoresist master. The channels are 100 µm wide, 5 µm deep, and separated by 10 µm ridges. Channels in PDMS can be made with islands of various shapes for passive mixing, as illustrated in Fig. 8c. In most cases masters are planar, yielding planar microfluidic devices. Nevertheless, multilayer 3D microfluidic systems can be formed using multilayered photoresist structures created by repeating the photolithography process or by staking patterned thin films of PDMS.

High-resolution transparencies can be used as photomasks to rapidly prototype patterned photoresist masters, from which PDMS films can be replicated. Using transparency photomasks, the feature sizes are usually limited to ∼10 µm and larger. For smaller feature sizes, a chrome mask, which can be substantially more expensive (approximately 100×) is typically required.

Representative results of microdevices fabricated with hot embossing are illustrated in Fig. 9. An SEM of a microchannel array of a flow cytometry system embossed in PC using an RIE etched silicon master [17] is illustrated in Fig. 9a. Small micrometer sized channels (50 µm × 50 µm in cross-section) and large (hundreds of micrometers) reservoirs can be replicated equally well. Fig. 9b illustrates the high aspect ratio capabilities of the process. The test structure was embossed in PC using a master fabricated with LIGA and nickel electroplating [17]. The channel in the circular middle structure has an aspect ratio of 7, and is 20 µm wide and 140 µm deep. Fig. 9c illustrates a silicon tool for a two-dimensional channel array for 2D-capillary electrophoresis. The ridges are 0.8 µm wide and 5 µm high with a 5 µm pitch. The resulting sub-micrometer channel array pattern replicated in PMMA is shown in Fig. 9d. Similar results can be obtained with micro injection molding. Figure 10 illustrates a high aspect ratio injection molding tool fabricated using nickel electroplating and the resulting microchannel structure in COC [20].

High structural resolution and density are achievable micromolding. Figure 11 illustrates images of a grid pattern of approximately 150 nm wide trenches spaced at a 1 µm obtained with hot embossing [21]. The height of the silicon master fabricated using an advanced silicon etch process and height of the resulting PMMA structures are 200 nm.



Micromolding, Figure 11 SEMs of (**a**) a silicon master and (**b**) the resulting PMMA structure. Features are 150 nm wide and 200 nm deep at 1 µm spacing. From [21]

Figure 12 shows examples of PDMS masters and the embossed microstructures in PMMA and COC [22, 23] Both large and small features can be replicated using this technique. For example, the PDMS master in Fig. 12(a) is 90 µm thick with an array of 150 µm wide features at 250 µm center-to-center spacing. The PMMA structure is 250 µm deep, containing an array of 600 µm wide microchannels at 1 mm center-to-center spacing. Figure 12 also illustrates a 5 µm thick PDMS master with 10 µm wide ridges and 10 µm spacing, and a 20 µm deep COC pattern with 30 µm wide channels at 10 µm spacing.

The use of PDMS tools can also be extended to fabrication of multi-height structures [24]. This is schematically shown in Fig. 13a. The process involves two lithography steps, (e. g., one with SU-8 and one with AZP 4620 photoresists). A passive micromixer fabricated using this process is shown in Fig. 13b. The mixing channel width is 200 µm at the widest point and 100 µm at the narrowest, with diamond obstructions 100 µm in width. Channel height is 55 µm with 15 µm high obstructions.

Future Directions for Research

Future directions for micromolding research, especially in hot embossing and injection molding, are involved with accurate replication of features with high aspect ratios, reduction of the process cycle time, and the investigation of new polymer materials and additives with improved characteristics. Rapid and accurate replication of nanoscale features, especially over large area, is another critical issue in micromolding that will need to be addressed in the future.

Injection molding; Polymer replication; Compression molding

Definition

Micromolding is one of the key technologies for microfluidic device production because of its mass-manufacturing capability and relatively low component cost. Micromolding is defined as a process similar to traditional commercial injection molding and/or compression molding that allows researchers and manufacturers to produce small features, typically ranging from 1 – 1000 µm, for microfluidic and microelectromechanical applications. This process typically involves the injection or compression of

a molten thermoplastic/thermoset material into a mold cavity that contains tooling with the features to be replicated into the plastic. These features can be channels, ridges, posts, vias, and/or any other component that lends functionality to the manufactured microfluidic device. These features can typically achieve tolerances of 0.01 to 5 μm, depending on the size of the replicated dimension of interest.

Overview

One of the primary drivers behind the commercial success of any microfluidic device and/or component is the cost of manufacturing. While glass is currently the dominant fabrication material in the microfluidics community, the process costs associated with these devices can be prohibitively high. Polymer micromolding offers an attractive alternative fabrication route to low-cost, high-performance microfluidic devices. This approach has been demonstrated to be highly effective in replicating the very fine features that lie at the core of any microfluidic device. Micromolding has its foundation in the commercial manufacturing of plastic parts, primarily injection and compression molding. Injection molding is a process in which a thermoplastic is heated above its glass transition temperature, injected into a mold cavity that contains the features to be replicated, and then cooled below its glass transition temperature to allow for efficient demolding. Compression molding is a process in which a thermoset is compressed in a mold cavity and then cured to consolidate the part and replicated features. In both cases, the tooling that contains the very fine features to be replicated is a critical compo-

nent that must be created through established microfabrication techniques.

Two other significant costs in the manufacture of micromolded parts are material costs and operational costs. The material cost associated with micromolding is primarily the cost of the plastic from which each part is made. Therefore, the excess volume of the part should be minimized so as to use the minimum amount of material. The operational cost is directly related to the cycle time for each part. In typical micromolding runs, 70 – 80 % of the total machine cycle time is spent waiting for the molten thermoplastic to cool and solidify in the mold before part ejection. In addition to cost, the production of microfluidic devices through micromolding offers other advantages. These include a wide range of materials to select from with tailored properties for the specific application, the fabrication of composite parts with embedded functionalities (i. e., embedding a sensing such as a fiber optic cable within the polymer substrate itself during micromolding) that enhance performance, and increased mechanical properties when compared with silicon or glass microfluidic devices.

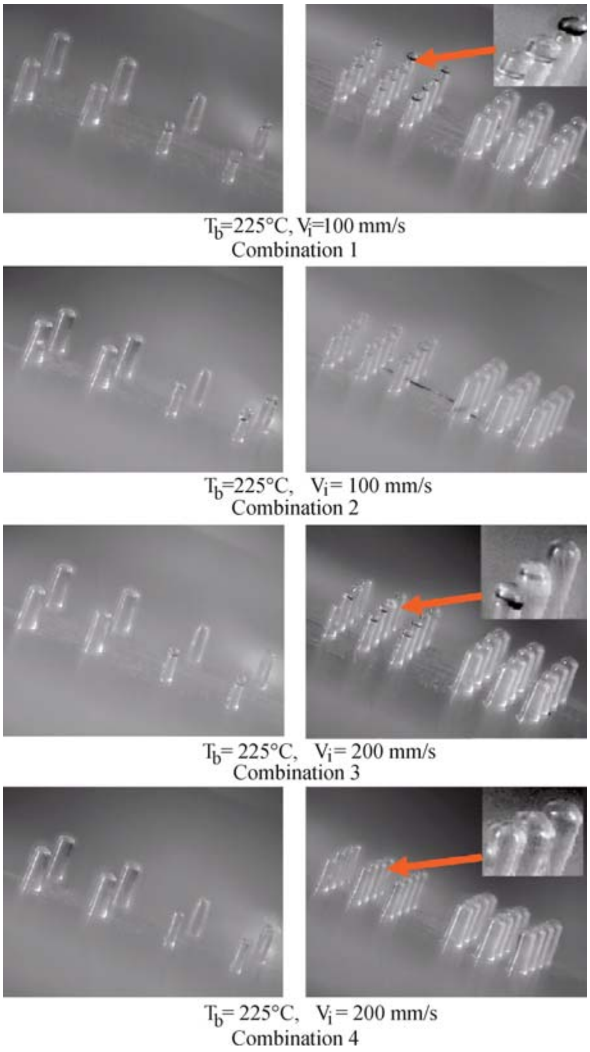
Basic Methodology

Micromolding represents the most efficient method of producing microfluidic devices through mass manufacturing. The process by which tooling can be developed is presented in Fig. 1. We present here a summary of the injection and compression molding techniques that can be used for micromolding applications.

Injection Molding

Injection molding is a plastic-forming process used in the production of most commercially available of plastic parts. Injection molding is generally used in the high-speed manufacture of low-cost, high-volume parts, such as videocassette cases, plastic cups, or children's toys. There are several advantages associated with injection molding: the lower price per part, the wide selection of properties available in molded plastics cannot be duplicated by any other practical process, optically transparent materials can be molded with a smooth finish to produce microfluidic devices that are amenable to optical, fluorescent, and UV diagnostics, and the fabrication of delicate and flexible parts may be easily realized through injection molding that are difficult to consistently achieve hold for conventional machining processes. Injection molding is generally a high-volume manufacturing process, with one mold producing millions of parts. A small change in the design of a mold, or a defect that is present in the initial features to be replicated, is therefore significantly amplified during this process. There are several thousand types of plastic material that can be used in this process, including polymethylmethacrylate (PMMA), polycarbonate (PC), polyethylene (PE), polystyrene (PS), polyamide (PA), polypropylene (PP), polyphenylene ether (PPE), polyester terephthalate (PET), polyetheretherketone (PEEK), polyetherimide (PEI), cycloolefin copolymer (COC), and polyimide (PI). To date, polycarbonate and polymethylmethacrylate are the most widely used materials for injection molding of microfluidic devices.

There are several types of injection molding machines (Fig. 2) that are available from numerous commercial vendors (Nissei, Sumitomo, Polimoon, Milacron, Mikrotech, and Makuta, to name a few). These machines can vary greatly in terms of size, clamping pressure, hydraulic or electrical drives, and degrees of automation and robotic handling. There are two basic types of mold operation: vertical and horizontal. Both have advantages in terms of process flexibility that must be matched to the microfluidic device to be replicated. Injection molding machines can



Micromolding (Injection and Compression Molding), Figure 4 Images taken of injection molded polypropylene replicates as a function of barrel temperature (T_b) and injection velocity (V_i) (Images taken from [13])

be classified as semiautomatic, in which the press follows a programmed cycle but the operator manually loads and unloads the press and/or places inserts into the mold cavity; and automatic, which operate under a fully automatic press cycle with robotic loading and unloading.

Any injection molding machine (Fig. 3) can be broken down into the following basic components: (1) injection units, (2) clamping unit, (3) control system, and (4) tempering devices. The process of injection molding typically consists of the following steps:

- Filling the injection barrel: The screw rotates and transports the molten thermoplastic from a hopper to the screw chamber.
- Closing the mold: The clamping unit moves forward until the two platens are in close contact to provide a barrier to polymer leakage. Typical clamping pressures range from 25 to 5000 t.
- Injection: The screw moves forward and injects the molten thermoplastic into the mold cavity. The polymer material fills the mold cavity and the features of the microfluidic device are replicated into the melt.
- Cooling: The melt is allowed to cool below the glass transition temperature and the part solidifies.
- Ejection: The mold opens and the cooled part containing the replicated features is ejected from the mold.

The mold defines the overall shape of the part, as well as the path by which the molten plastic flows from the barrel into the mold cavity. In most microfluidic applications, the mold cavity is in the form of a wafer or a die that will contain the microfluidic features on one of its exterior surfaces. The mold is the most complex element present in the injection molding process and typically represents the highest cost element. A simple mold has several features:

- Fixed and moving platens – These are rectangular blocks of aluminum or steel into which the shape of the part is cut.
- Cavity – When the fixed and moving platens are compressed together, the space formed by the cut-out portions, called the *cavity*, defines the overall shape of the part.
- Sprue – The sprue is a hole cut into the center of the fixed platen. Molten plastic flows from the sprue to fill the cavity.
- Runners – Runners are channels cut into the platens that direct molten plastic from the sprue to the gates.
- Gates – Gates are small openings between runners and cavities. These are the points at which plastic enters the cavity. They are generally small so that the finished part may be easily broken away from the useless sprue and runner material. (You can tell if a plastic part is manufactured by injection molding because it will have a small nubs where the gates were located.)
- Tooling – This mold insert contains the fine features of the microfluidic device to be replicated. This tooling can be created using micromachining, microlithography, or electroforming.

Several injection molding operating parameters must be optimized in order to produce a microfluidic device with a high degree of feature fidelity. Figure 4 presents the impact of the feature fidelity of different micron-sized post features as a function of barrel temperature and injection velocity. It is also important to note that computational modeling can be employed to predict optimal injection molding conditions.

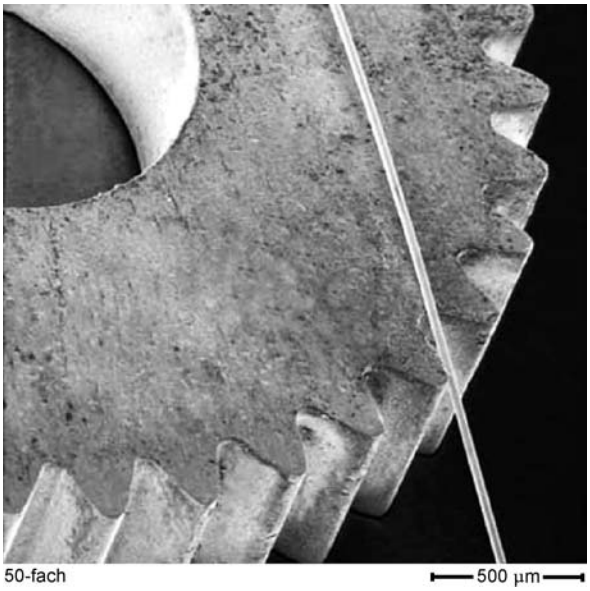
In addition to the standard processes of injection molding, there exist variants that may be applicable to a particular microfluidic device. These include reaction injection molding (a.k.a. RIM) where a monomer mixture is injected directly into a production mold where it polymerizes in the mold cavity and is then injected; resin transfer molding (a.k.a. RTM); gas-assisted injection molding; transfer molding; intrusion injection molding; ceramic injection molding.

Compression Molding

Compression molding is an old and widely used molding process for thermosetting plastics. These materials cure



Micromolding (Injection and Compression Molding), Figure 7 SEM image taken of a micromachined part created through wire-EDM process (taken from [14])

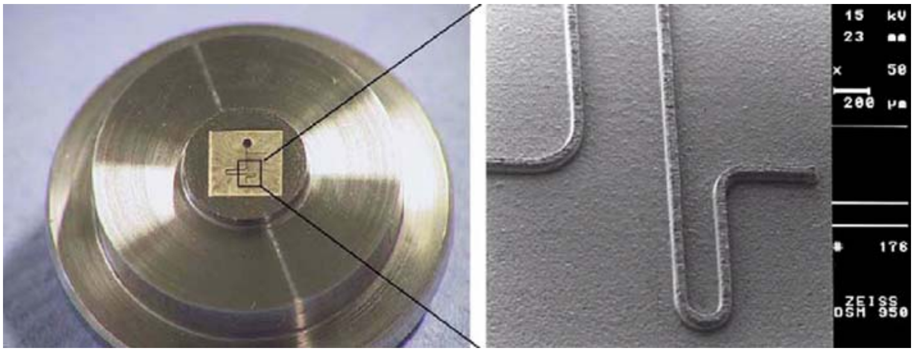
at elevated temperatures and are then consolidated into a bulk material as a function of time. This technique can be used to create microfluidic devices with unique chemical and mechanical properties. Other applications of this technique include phonograph records, rubber tires, and various polymer matrix composite parts. The process (Fig. 5) typically consists of (1) loading a precise amount of molding compound, called the charge, into the bottom half of a heated mold; (2) bringing the mold halves together to compress the charge, forcing it to flow and conform to the shape of the cavity; (3) heating the charge by means of the hot mold to polymerize and cure the material into a solidified part; and (4) opening the mold halves and removing the part from the cavity. The initial charge of molding compound can be in any of several forms, including powders or pellets, liquid, or cut preforms of material. The amount of polymer must be precisely controlled to obtain repeatable consistency in the molded product. It is common practice to preheat the charge prior to its placement into the mold; this softens the polymer and shortens the production cycle time. Preheating methods include infrared heaters, convection heating in an oven, and use of a heated rotating screw in a barrel. The latter technique (borrowed from injection molding) is also used to meter the amount of the charge.

Compression molding presses are oriented vertically and contain two platens to which the mold halves are fastened. The presses involve either of two types of actuation: (1) upstroke of the bottom platen or (2) downstroke of the top platen, the former being the more common machine configuration. They are generally powered by a hydraulic cylinder that can be designed to provide clamping capacities up to several hundred tons. Molds for compression molding are generally simpler than their injection mold counterparts. There is no sprue and runner system in a compression mold (in direct contrast to an injection molding system), and the process itself is generally limited to simpler part geometries and channel configurations due to the lower flow capabilities of the starting thermosetting materials. However, provision must be made for heating the mold, usually accomplished by electric resistance heating, steam, or hot oil circulation. Compression molding machines can be classified as hand molds, used for trial runs; semiautomatic, in which the press follows a programmed cycle but the operator manually loads and unloads the press; and automatic, which operate under a fully automatic press cycle (including automatic loading and unloading).

Materials for compression molding typically include phenolics, melamine, urea-formaldehyde, epoxies, urethanes, and elastomers. All of these possess intrinsic chemical and mechanical properties that can be used to tailor the performance of the microfluidic device depending on the specific application. Typical commercial compression molding thermoset plastic parts include electric plugs, sockets, and housings; pot handles, and dinnerware plates. Advantages noted for compression molding in these applications include: (1) molds that are simpler, less expensive, and require low maintenance; (2) minimal residual material; and (3) low residual stresses in the molded that may enable thin-film polymeric microfluidic devices. A typical disadvantage is longer cycle times and therefore lower production rates than injection molding.

Micromolding Tooling Fabrication Techniques

The most expensive and time consuming part of the entire process is the making of the mold, for once the mold is made, a great number of parts may be produced very rapidly. It is this speed of production, and the fact that the cost of the mold can be amortized over a large number of parts, that makes injection molding an inexpensive process for producing large numbers of parts. An injection molding machine is capable of producing 100 or more parts per hour, compared to conventional machining which may produce a half dozen parts per hour. There are several techniques available to produce stamps suitable for micromolding. The most common of these is electroforming, where microfluidic features that have been created using standard microfabrication techniques such as wet



Micromolding (Injection and Compression Molding), Figure 8 Images taken of micromachined tooling to be used to create polymeric channels through micromolding that has been created through plunge-EDM process (taken from [14])

etching and reactive ion etching are used as the master. A metal seed layer is deposited on the surface of these features to create an electroplating base. The coated wafer is then placed in an electroplating bath (Fig. 6) where a bulk metal, typically nickel, is electroplated on top of the original features. After the electroplating process is complete, the Ni is released and then used as a replication tool for injection or compression molding. Another common micromachining technique is electrode discharge machining (EDM, Figs. 7 and 8). This technique creates robust, fine features in a bulk material (typically graphite or copper) that is suitable for use in micromolding machines.

Key Research Findings

It is clear from an extensive examination of the literature, as well as the available information from numerous commercial vendors, that micromolding is an efficient and cost-effective approach for the mass production of polymeric microfluidic devices. The economic advantages, from a manufacturing perspective, are tremendous when compared with other microsystem fabrication techniques. This technique is capable of producing microfluidic devices very rapidly with a high degree of fidelity, with feature deviation typically in the range of $0.1-2\%$. The number of devices that can be produced by micromolding on a time-averaged basis is at least an order of magnitude higher than any other microfluidic manufacturing technique. The highest cost associated with this process is the initial capital cost of purchasing the micromolding equipment, followed by the costs associated with developing the proper tooling that allows for high-fidelity replication. Several different techniques exist to create robust tooling, such as micromachining, lithography, and electroforming. All of these techniques can reliably manufacture the micro-scale features that are required for proper microfluidic device operation. Injection molding is by far the most common technique of producing large numbers of polymeric microfluidic devices. Compression molding is a specialized technique that is very powerful in applications where non-traditional thermoplastics and elastomers are the material of choice.

Future Directions for Research

Micromolding is a proven and growing area in microfluidic device fabrication. As this field becomes more mature in terms of commercial applications, the drivers for low-cost mass manufacturing will continue to grow. As such, there will be increased demand for micromolding manufacturing techniques. The majority of the future directions for research in this field will be found in producing advances in tool design and manufacture, systems engineering and process flow improvements, process design that enable mutli-component (fluidic interconnects, optical lenses, optical fibers for on-chip instrumentation, and multi-level features) integration within a single manufacturing step. One nascent field is the development of micromolding techniques that can efficiently replicate nanometer features for nanofluidic devices.

Micro/Nano Anemometers

Synonyms

Thermal flow sensors

Definition

Hot-wire anemometers have traditionally been applied in the fields of experimental fluid mechanics and aerospace engineering. Despite the possibilities to measure real-time physical parameters such as temperature, velocity, flow rates, and shear stress, the spatial resolution is limited to the device dimension. The advent of MicroElectroMechanical system (MEMS) and nano-scale thermal sensors has revolutionized the spatial and temporal resolution critical to gain entry into micro-fluidics, micro-circulation, biomedical sciences, and cardiovascular medicine. These micro/nano devices are fabricated with the semiconductor-based sensing elements having the physical property of a resistor and the dimension at one tenth (or hundredth) of a string of hair. Basede on the Joule effect, these resistant elements are heated by passing electric current through the elements. As air or fluid flow past by the surface of the elements, the changes in temperature alter the resistivity of the sensing elements, from which physical parameters are obtained.

Micro- and Nanoscale Anemometry: Implication for Biomedical Applications, Figure 2 The operating principle of hot-wire anemometry. The electric current is passed to the hot wire via the electrodes. The changes in resistance of the hot wire in response to the fluid flow are calibrated for temperature, flow rate, and shear stress

air or fluid flows past their surfaces, the decrease in temperature alters the resistance of the sensing elements, from which physical parameters can be obtained.

Overview

The concept of hot-wire or hot-film anemometry was first conceived in the early 1900s [1]. Due to the technical difficulty in developing and testing hot-wire anemometers, published experimental data have remained scarce. Boussinesq was one of the first to have validated the theory of hot-wire anemometry [2], followed by other investigators, including Ziegler [1] who was the first to develop the constant-temperature anemometer to enhance the sensitivity. Later, King designed hot-wire anemometers coupled with the theory of heat convection using cylinders immersed in a fluid flow [3]. Recently, Ho and coworkers [4] as well as Sheplak et al. [5] have developed MEMS thermal sensors for aerospace applications. Overall, these investigators have contributed to the basics of hot-wire anemometry for biomedical and clinical applications [6–8]. By virtue of their high temporal and spatial resolution, micro- and nanoscale thermal sensors have ushered in the possibility to acquire the time- and spatial-varying components of physical parameters in vivo.

Shear stress is measured by direct and indirect methods [9]. One of the direct methods is floating element sensing based on both piezoresistive [10] and capacitive [9] readout schemes. The floating element sensors are complicated to fabricate, consisting of fragile mechanical devices and requiring accurate transduction of minute motions. The piezoresistive readout schemes in response to shear stress under low Reynolds numbers or creeping flow are likely below the threshold of the percent changes in piezoresistive elements. The high impedance and capacitive readout scheme also generates high levels of drift in resistance when the sensor is exposed to turbulence in environments such as a wind tunnel.

The indirect methods include ultrasonic Doppler, magnetic resonance imaging (MRI) and thermal anemometry, which measure the shear stress indirectly by correlating this parameter to flow rate. The ultrasonic Doppler method and MRI are non-invasive; however, the spatial resolution near the wall is not as good. Another indirect method is to correlate shear stress with convective cooling of a heated element based on the heat transfer principle. The advent of MEMS technology has made possible advances in microfluidics and biomedical applications.

The advantages of MEMS thermal anemometry are twofold:

- simplicity in the microfabrication and
- high sensitivity in detecting the shear stress through the correlation with heat transfer coefficient.

In response to pulsatile blood flow in complicated arterial geometry, MEMS sensors are able to provide spatial resolution to minimize flow disturbance and time resolution to measure shear stress in unsteady flow fields.

Basic Methodology

Operating Principle

Traditionally, hot-wire or hot-film anemometry has been developed to directly measure the fluid velocities under unsteady state or in the presence of turbulent flow [11].

Hot-wire anemometry consists of an electrical conductive wire or wires functioning as the thermistance that is heated by passage of electrical current (Fig. 2). The heated wire forms a thermal boundary layer in the flow field mainly by convective heat transfer. In this context, the changes in electrical resistance of the hot wire in response to fluid flow past the hot wire are calibrated electrically for obtaining flow velocity, pressure, shear stress, and temperature. Assuming that the rate of heat loss due to conduction to the electrodes and radiation is negligible, a relation for energy balance is described as follows:

Stored thermal energy
= Electrical energy input
− Thermal loss due to heat convection .

This relation is further expressed in terms of power as follows:

$$C\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{V^2}{R} - P_1 \quad (1)$$

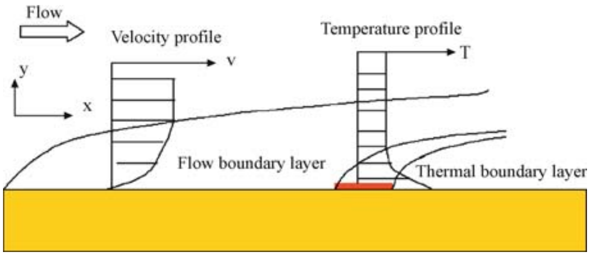
where C denotes the specific heat of the wire, t the time, T the temperature, V the electrical voltage, R the electrical resistance, and P_1 the thermal loss to the fluid.

For a practical micro- or nanoscale anemometer, the sensor consists of a resistive element patterned on the surface of a supporting substrate (Fig. 3). The thermal element resides within the velocity boundary layer in which the velocity changes from zero at the wall to the mean flow velocity of the upper boundary. The rate of heat loss from the heated resistive element to the medium flow (air or liquid) depends on the velocity profile in the boundary layer. The temperature gradient develops above the sensing element, and a thermal boundary layer forms in response to air or fluid flow (Fig. 3). Within the thermal boundary layer, the thermal gradient decreases away from the heated element surface until the temperature reaches that of the mean stream flow [4].

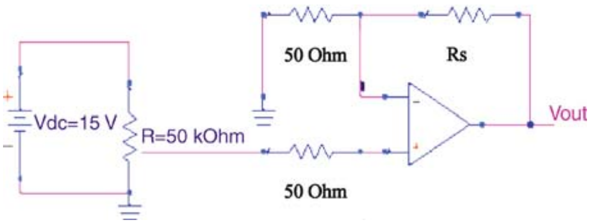
The relationship between τ and the temperature of the heated resistor has been extensively studied under the assumption that the thermal boundary layer of the thermal element lies within the velocity boundary layer [4]. The ▶ wall shear stress is defined to be linearly proportional to the stream-wise pressure gradient. Given that electrical power (P) is expressed as $P = V^2/R$, a linear relationship between V^2 and $\tau^{1/3}$ is established as [4]:

$$P = \frac{V^2}{R} = \left(A_\mathrm{T} + B_\mathrm{T}\tau^{1/3}\right) \quad (2)$$

where A_T represents a combination of effective area and length of the thermal element, heat capacity, thermal conductivity, and ▶ viscosity of the fluid, B_T denotes the conductance of heat loss to the surface and R the electrical resistance at the fluid temperature. The relationship between shear stress and heat transfer element is valid under the assumption that the thermal boundary layer of the thermal element lies within the velocity boundary layer, and that the thickness of the thermal boundary layer is small in relation of the dimension of the sensing element. However, this assumption may not be valid for certain microscale devices. By empirical data parameterization and modeling, others have arrived at a linear relations as expressed by $\Delta p \propto \tau^{0.77}$ for microscale sensors [12], where Δp denotes power.



Micro- and Nanoscale Anemometry: Implication for Biomedical Applications, Figure 3 Two-dimensional physics model for MEMS/nanoscale anemometry. The fluid flow is denoted in the x-direction. At steady state, a parabolic velocity profile reflects the fully developed flow. The heat generating/sensing element is denoted in a red rectangular block which is heated by the electric current to form a thermal boundary layer



Micro- and Nanoscale Anemometry: Implication for Biomedical Applications, Figure 4 Constant current circuit. Note that Rs denotes the sensing element

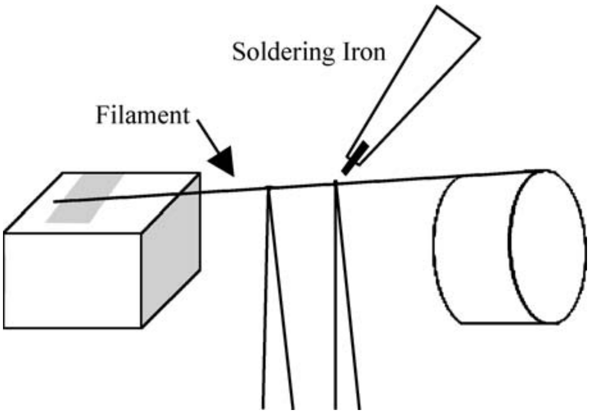
The relationship in Eq. (2) further allows for the measurement of shear stress through the hot-wire resistance as follows:

$$\frac{R}{R_0} = 1 + \alpha(T - T_0) \quad (3)$$

where R_0 is the resistance at ambient temperature T_0 and α is the ▶ temperature coefficient of resistance (TCR). The resistance overheat ratio is expressed as $(R - R_0)/R_0$.

To detect the resistance changes due to the thermal loss to the fluid, many laboratories have designed electrical circuits for

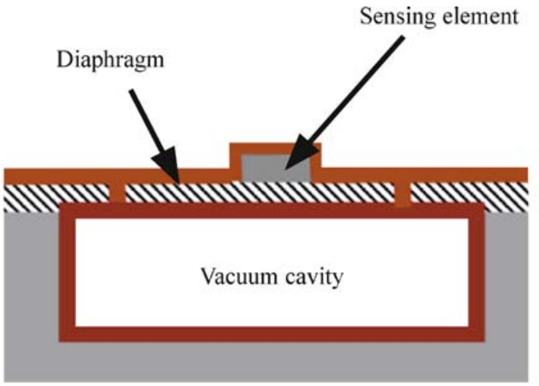
- constant temperature (CT),

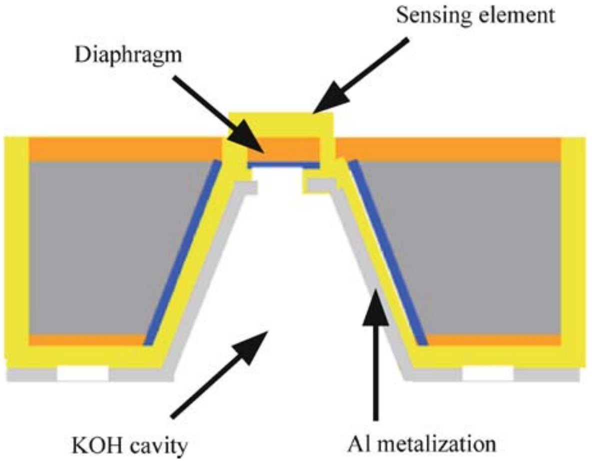


Micro- and Nanoscale Anemometry: Implication for Biomedical Applications, Figure 5 The conventional hot-wire anemometry fabrication by soldering the hot wire to the electrodes

- constant current (CI),
- constant voltage (CV), and
- pulsed signal (PS) methods.

The first three circuit designs entail the use of a single wire working as both heating source and sensing element for direct measurement, whereas the PS mode requires more than two wires, one for the source and another for the sensing element. Specifically, the first wire receives the pulsed input while the second detects the output of voltage responses so that the time delay and amplitude are calibrated to the fluid velocity. Albeit it has complicated circuitry, the CT mode is able to achieve high frequency bandwidth ideal for investigation of turbulent flow.





Micro- and Nanoscale Anemometry: Implication for Biomedical Applications, Figure 6 (**a**) MEMS shear stress sensor with vacuum cavity underneath. (**b**) Backside wire bonding for reducing the disturbance to the flow

Fabrication

Traditionally, anemometer wire is made of tungsten, platinum or a platinum–iridium alloy. Tungsten is presently the more popular hot wire material. Soldering and acidic bubble are the two methods (Fig. 5). Because of low resistance in the metal, a high current is required to drive the device. Several experimental disadvantages remain with the utilization of the conventional anemometers:

- low sensitivity,
- high power dissipation due to ineffective insulation of the heating filament from the substrate, and, most notably,
- local flow disturbance in the region of direct measurement.

MEMS Thermal Sensors and Nanofabrication

The semiconductor-based micro- and nanoscale sensors have ushered in the possibility to resolve the engineering challenges in developing and applying the conventional hot-wire anemometer. By virtue of their small dimension, the inherent issues such as flow disturbance and packaging have been minimized. Furthermore, fabrication of multiple devices has been made possible for high-throughput analyzes. The heavily doped polysilicon strip or nanowire for the sensing element has given rise to a higher resistivity than that of metal, resulting in superior sensitivity at low power consumption.

A vacuum cavity was created by both surface and bulk microfabrication to insulate the sensing element from the solid substrate (Fig. 6a). The presence of a cavity further maximizes unidirectional heat transfer in the flowing medium. A KOH-etched cavity was created by bulk micromachining to generate backside wire bonding (Fig. 6b). The design of backside wire bonding has advanced the application of MEMS devices for cardiovascular medicine where catheter-based sensors are deployed into the arterial circulation. While the surface of the sensing element is exposed to the biological fluid, the microelectronics is

(**b**) Shear stress sensors are coated in a 1 cm × 2 cm flexible parylene skin. The arrays of sensors reside on the opaque silicon islands. (**c**) Two flexible sensor skins are wrapped around a cylinder

insulated on the back side via contact between the backside aluminum metalization and the sensing element.

Finally, packaging micro- and nanoscale sensors is critical to translate the bench laboratory technology to biomedical applications. Parylene C is a commonly used biocompatible polymer for surface coating. Given its conformal property, this polymer has recently been explored as a structural and packaging material for flexible MEMS devices (Fig. 7). Parylene can be conformed on the non-flat surface of micro- and nanoscale devices, thereby opening an entry point to the complicated anatomic structures such as human arterial circulation.

Key Research Findings

The hot-wire anemometer has been extensively applied in the area of fluid mechanics. It allows for direct measurement of physical parameters such as flow rate and temperature, from which fluid shear stress can be calibrated for a known geometry. The dimension of a conventional hot wire lies in the range 4 – 10 μm in diameter and 1 mm in length, and its frequency response is relatively low. The advent of micro- and nanofabrication has enabled the miniaturization of hot-wire anemometers to 2 μm in width and 40 μm in length, and the semiconductor-based property of the sensing elements has enabled devices to operate at a high frequency cut-off of 71 kHz [13]. Micromachined thermal shear stress sensors for underwater applications have been developed by applying silicon nitride as the insulating layer on the diaphragm [14]. Parylene C coating and backside wire bonding techniques are two engineering solutions to insulate microelectronics for underwater applications. These techniques have enabled the sensors to be used for naval submarines and cardiovascular circulation. Because of their high spatial and temporal resolution, micro- and nanoscale sensors have enabled investigators to overcome engineering challenges otherwise difficult with conventional technology, and to advance the fields in cardiovascular research, aerospace engineering, and flexible packaging for biological systems.

Applications for Cardiovascular Research

Cardiovascular disease, namely coronary artery disease, remains the leading cause of death in the developed nations. Over the last few years, MEMS sensors have advanced the understanding of blood flow, namely fluid shear stress, in arterial circulation. Fluid shear stress is defined as the frictional force acting tangentially on the surface of a blood vessel wall. Furthermore, the measurement of wall shear stress is important to study the durability of prosthetic valves, and to monitor thrombosis or blood clots in cardiopulmonary bypass machines, artificial hearts, and left ventricular assist devices. Luminal shear stress measurement predicts the development of atherosclerotic plaque in patients at risk for acute heart attacks. In this context, the application of microscale hot-wire anemometry bridges fluid mechanics of blood flow with vascular biology.

Real-time wall shear stress is difficult to monitor precisely because it varies in space and time. MEMS sensors provide high spatial resolution to resolve variations in shear stress in a 3D bifurcation model for small-scale hemodynamics. The application of MEMS sensors with backside wire bonding (Fig. 6b) captured the spatial variations in shear stress in a 3D bifurcation model (Fig. 8). The measured skin friction coefficients at various positions correlated well with values derived from the exact Navier–Stokes solution of the flow within the bifurcation [13]. Therefore, the development of MEMS sensors has enabled the precise measurements of spatial variations in shear stress for small-scale hemodynamics otherwise difficult with conventional technologies such as computed tomography (CT scan), magnetic resonance imaging (MRI), ultrasound, and laser Doppler velocimetry.

Applications for Aerodynamics

The design and development of aerodynamic vehicles require precise measurements of shear stress and boundary layer for turbulence control. The application of MEMS sensors has enabled the localization of flow separation where drastic variation in shear stress develops on the air foils. Ho and Tai [11] have demonstrated the utilization of the MEMS shear stress sensors for an aerodynamic aircraft by fabricating an IC-integrated skin, which is flexible and conformal to the surface of air foils [15]. For instance, a network of sensors has been implemented in different structural sections of a delta-wing (Fig. 9a) via ►flexible shear stress sensors (Fig. 9b) in an unmanned

aerial vehicle (UAV). This application of MEMS sensors has advanced the investigation of the air flow separation on the leading edge of the delta-wing.

Flexible Polymer Packaging for Shear Stress Sensors

Packaging micro- and nanoscale devices entails two main challenges:

- insulation of the electronics and
- design of flexible devices conformal to the biological systems.

As a biocompatible coating [16], parylene C has recently been explored as a structural and packaging material for miniaturized biomedical devices. Parylene protects the sensors and serves as electrical isolation. In order to package an array of sensors in a catheter, a microelectric interconnect has been established via a flexible polymer (Fig. 10). The electrical leads are attached to sensors embedded in parylene film (Fig. 10b). Platinum or gold wires are sandwiched in the parylene film to make the connections to the sensors either by wire bonding or flip-chip bonding (Fig. 10c).

Future Directions for Research

The emerging role of micro- and nanoscale hot-wire anemometry would likely accelerate the translation of in vitro devices to in vivo applications, thereby bridging the lab-to-patient gap. Real-time measurements of intravascular physical parameters, specifically shear stress, temperature, pressure, and flow rate, provide a basis to link hemodynamics with biochemical events in blood vessels. The complex curvature of the vascular system requires small, minimally invasive sensors to discretely measure in real time intravascular physical parameters with minimal blood flow disturbance. To achieve this, flexible micro- and nanoscale sensors would allow for steering in the complicated anatomy in biological systems (Fig. 11). In summary, the utilization of micro- or nanoscale sensors provides a quantitative assessment of vascular hemodynamics. This approach lends itself to applications in broad areas of medicine and physiology and is particularly relevant to quantitative studies of cancer biology as well as cardiovascular medicine. Future development and application of micro- and nanoscale sensors for the in situ assessment of biochemical markers in blood vessels would provide a basis for physical and chemical analyzes of oxidative stress, drug delivery, and regenerative therapy.

Kinetic theory of gases; Kinetic Boltzmann equation

Definition

► Knudsen number (Kn) is the ratio of mean free path ℓ of fluid molecules to a typical dimension of gas flow a, i. e. $\mathrm{Kn} = \ell/a$. ► Rarefaction parameter δ is the inverse Knudsen number. ► Velocity distribution function is defined so that the quantity $f(t, \boldsymbol{r}, \boldsymbol{v})\, \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{v}$ is the number of particles in the phase volume $\mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{v}$ near the point $(\boldsymbol{r}, \boldsymbol{v})$ at the time t.

Chemical and Physical Principles

The main parameter determining the gas rarefaction is the *Knudsen number* $\mathrm{Kn} = \ell/a$, where ℓ is the ► mean free path of fluid molecules and a is a typical dimension of gas flow. If the *Knudsen number* is sufficiently small, say $\mathrm{Kn} < 10^{-2}$, the Navier–Stokes equations are applied to calculate gas flows. For intermediate and high values of the *Knudsen number* the Navier–Stokes equations break down and the implementation of ► rarefied gas dynamics methods is necessary. In practical calculations usually the *rarefaction parameter* defined as the inverse *Knudsen number*, i. e.

$$\delta = \frac{a}{\ell} = \frac{1}{\mathrm{Kn}} \tag{1}$$

is used to characterize the gas rarefaction. Here, the ► equivalent mean free path will be used, which is calculated via the shear viscosity as

$$\ell = \frac{\mu v_0}{P}, \qquad v_0 = \left(\frac{2k_\mathrm{B} T}{m}\right)^{\frac{1}{2}}, \tag{2}$$

where v_0 is the most probable molecular speed, $k_\mathrm{B} = 1.380662 \times 10^{-23}$ J/K is the Boltzmann constant, m is the molecular mass of the gas in kg, T is the temperature of gas in K, P is its pressure in Pa, and μ is the shear viscosity in Pa s. For instance, if nitrogen is maintained at $P = 1$ atm and $T = 300$ K, then $\ell = 0.073$ µm.

The state of a monoatomic gas is described by the one-particle *velocity distribution function* $f(t, \boldsymbol{r}, \boldsymbol{v})$, where t is the time, $\boldsymbol{r}$ is the position vector, and $\boldsymbol{v}$ is a velocity of molecules. The function $f(t, \boldsymbol{r}, \boldsymbol{v})$ is defined so that the quantity $f(t, \boldsymbol{r}, \boldsymbol{v})\, \mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{v}$ is the number of particles in the phase volume $\mathrm{d}\boldsymbol{r}\, \mathrm{d}\boldsymbol{v}$ near the point $(\boldsymbol{r}, \boldsymbol{v})$ at the time t. All macro-characteristics of gas flow can be calculated via the *velocity distribution function*:

number density

$$n(t, \boldsymbol{r}) = \int f(t, \boldsymbol{r}, \boldsymbol{v})\, \mathrm{d}\boldsymbol{v}, \tag{3}$$

hydrodynamic (bulk) velocity

$$\boldsymbol{u}(t, \boldsymbol{r}) = \frac{1}{n} \int \boldsymbol{v} f(t, \boldsymbol{r}\boldsymbol{v})\, \mathrm{d}\boldsymbol{v}, \tag{4}$$

temperature

$$T(t, \boldsymbol{r}) = \frac{m}{3nk_\mathrm{B}} \int V^2 f(t, \boldsymbol{r}, \boldsymbol{v})\, \mathrm{d}\boldsymbol{v}, \tag{5}$$

pressure tensor

$$P_{ij}(t, \boldsymbol{r}) = m \int V_i V_j f(\boldsymbol{r}, \boldsymbol{v})\, \mathrm{d}\boldsymbol{v}, \quad i, j = x, y, z, \tag{6}$$

heat flux vector

$$\boldsymbol{q}(t, \boldsymbol{r}) = \frac{m}{2} \int \boldsymbol{V} V^2 f(t, \boldsymbol{r}, \boldsymbol{v})\, \mathrm{d}\boldsymbol{v}, \tag{7}$$

where $\boldsymbol{V} = \boldsymbol{v} - \boldsymbol{u}$ is the peculiar velocity. The *velocity distribution function* obeys the ► Boltzmann equation which in the absence of external forces reads

$$\frac{\partial f}{\partial t} + \boldsymbol{v} \cdot \frac{\partial f}{\partial \boldsymbol{r}} = Q(ff_*), \tag{8}$$

where $Q(ff_*)$ is the collision integral having a cumbersome expression.

If the gas is in equilibrium then the *velocity distribution function* is given by the absolute Maxwellian

$$f_0^\mathrm{M} = n_0 \left(\frac{m}{2\pi k_\mathrm{B} T_0}\right)^{\frac{3}{2}} \exp\left(-\frac{mv^2}{2k_\mathrm{B} T_0}\right), \tag{9}$$

where n_0 and T_0 are equilibrium number density and temperature, respectively. We also will use the local Maxwellian distribution function given by

$$f^{\mathrm{M}}(n,T,\boldsymbol{u}) = n(t,\boldsymbol{r})\left[\frac{m}{2\pi k_{\mathrm{B}}T(t,\boldsymbol{r})}\right]^{\frac{3}{2}} \cdot \exp\left\{-\frac{m[\boldsymbol{v}-\boldsymbol{u}(t,\boldsymbol{r})]^2}{2k_{\mathrm{B}}T(t,\boldsymbol{r})}\right\}, \quad (10)$$

where the density $n(t,\boldsymbol{r})$, temperature $T(t,\boldsymbol{r})$, and the bulk velocity $\boldsymbol{u}(t,\boldsymbol{r})$ are functions of the time t and position $\boldsymbol{r}$.

Usually, the so-called ▶model kinetic equations are applied in practical calculations. They maintain the main properties of the exact collision integral and, at the same time, they reduce significantly the computational efforts. The most usual *model kinetic equation* was proposed by Bhatnagar, Gross and Krook (BGK) [1]

$$Q_{\mathrm{BGK}}(ff_*) = \nu\left[f^{\mathrm{M}} - f(t,\boldsymbol{r},\boldsymbol{v})\right], \quad (11)$$

Note, the local values of the number density $n(t,\boldsymbol{r})$, bulk velocity $\boldsymbol{u}(t,\boldsymbol{r})$ and temperature $T(t,\boldsymbol{r})$ being a part of the local Maxwellian f^{M} are unknown. They are calculated via the function $f(t,\boldsymbol{r},\boldsymbol{v})$ in accordance with the definitions (3)–(5). Thus, Eq. (8) together with (11) is non-linear integro-differential equation. The quantity ν is the collision frequency assumed to be independent of the molecular velocity. The expression

$$\nu = P/\mu \quad (12)$$

is most used because it provides the correct description of shear stress flows. However, this model does not describe correctly a heat transfer.

The S-model proposed by Shakhov [10] is a modification of the BGK model providing the correct description of both momentum and heat transfer. The collision integral of this model is written down as

$$Q_{\mathrm{S}}(ff_*)\nu\left\{f^{\mathrm{M}}\left[1+\frac{2m}{15\,n\,(k_{\mathrm{B}}\,T)^2}\,\boldsymbol{q}\cdot\boldsymbol{V}\left(\frac{mV^2}{2k_{\mathrm{B}}T}-\frac{5}{2}\right)\right] - f(t,\boldsymbol{r},\boldsymbol{v})\right\}. \quad (13)$$

Thus, if one needs to calculate isothermal flows one may use the BGK model. Otherwise, the S-model must be used.

On a boundary surface the *velocity distribution function* of incident particles f^- is related to that of reflected molecules f^+ as

$$v_{\mathrm{n}} f^+(\boldsymbol{v}) = -\int_{v'_{\mathrm{n}}\le 0} v'_{\mathrm{n}} f^-(\boldsymbol{v}') R(\boldsymbol{v}',\boldsymbol{v})\,\mathrm{d}\boldsymbol{v}', \quad v_{\mathrm{n}} \ge 0, \quad (14)$$

$v_n = \boldsymbol{v}\cdot\boldsymbol{n}$ is a normal velocity component, $\boldsymbol{n}$ is the unit vector normal to the surface directed to the gas, $R(\boldsymbol{v}',\boldsymbol{v})$ is a ▶gas-surface scattering kernel satisfying the normalization condition

$$\int_{v_{\mathrm{n}}\ge 0} R(\boldsymbol{v}',\boldsymbol{v})\,\mathrm{d}\boldsymbol{v} = 1, \quad (15)$$

and the reciprocity property,

$$|v'_{\mathrm{n}}|\exp\left[-\frac{m(\boldsymbol{v}'-\boldsymbol{u}_w)^2}{2k_{\mathrm{B}}T_w}\right]R(\boldsymbol{v}',\boldsymbol{v}) = |v_{\mathrm{n}}|\exp\left[-\frac{m(\boldsymbol{v}+\boldsymbol{u}_w)^2}{2k_{\mathrm{B}}T_w}\right]R(-\boldsymbol{v},-\boldsymbol{v}'), \quad (16)$$

where T_w and $\boldsymbol{u}_w$ are the surface temperature and velocity, respectively.

The well known diffuse scattering (cosine law) corresponds to the following kernel

$$R_{\mathrm{d}}(\boldsymbol{v}',\boldsymbol{v}) = \frac{2v_{\mathrm{n}}}{\pi}\left(\frac{m}{2k_{\mathrm{B}}T_w}\right)^2\exp\left(-\frac{m\,v^2}{2k_{\mathrm{B}}T_w}\right). \quad (17)$$

The specular reflection is given by the kernel

$$R_{\mathrm{s}}(\boldsymbol{v}',\boldsymbol{v}) = \delta(\boldsymbol{v}'_{\mathrm{t}}-\boldsymbol{v}_{\mathrm{t}})\delta(v'_{\mathrm{n}}+v_{\mathrm{n}}), \quad (18)$$

where $\boldsymbol{v}_{\mathrm{t}}$ is the two-dimensional vector of the tangential velocity. The diffuse-specular kernel

$$R_{\mathrm{ds}}(\boldsymbol{v}',\boldsymbol{v}) = \alpha R_{\mathrm{d}}(\boldsymbol{v}',\boldsymbol{v}) + (1-\alpha)R_{\mathrm{s}}(\boldsymbol{v}',\boldsymbol{v}) \quad (19)$$

is widely used. Here, α is the part of molecules reflected diffusely. However, some experimental data contradict to theoretical results based on the kernel (19). Recently, more physical *gas-surface scattering kernels* became to be applied. One of them is the Cercignani–Lampis (CL) [6] model given as

$$R_{\mathrm{CL}}(\boldsymbol{v}',\boldsymbol{v}) = \frac{v_{\mathrm{n}}}{\pi^2\alpha_{\mathrm{n}}\,\alpha_{\mathrm{t}}(2-\alpha_{\mathrm{t}})}\left(\frac{m}{2k_{\mathrm{B}}T_w}\right)^2 \times\exp\left\{-\frac{m[v_{\mathrm{n}}^2+(1-\alpha_{\mathrm{n}})v_{\mathrm{n}}'^2]}{2k_{\mathrm{B}}T_w\alpha_{\mathrm{n}}} - \frac{m[\boldsymbol{v}_{\mathrm{t}}-(1-\alpha_{\mathrm{t}})\boldsymbol{v}'_{\mathrm{t}}]^2}{2k_{\mathrm{B}}T_w\alpha_{\mathrm{t}}(2-\alpha_{\mathrm{t}})}\right\} \times\int_0^{2\pi}\exp\left(\frac{m\,v_{\mathrm{n}}\,v'_{\mathrm{n}}}{k_{\mathrm{B}}T_w}\frac{\sqrt{1-\alpha_{\mathrm{n}}}}{\alpha_{\mathrm{n}}}\cos\phi\right)\mathrm{d}\phi,$$

where $0 \le \alpha_n \le 1$ has the physical sense of the accommodation coefficient of energy corresponding to the normal velocity v_n, $0 \le \alpha_t \le 2$ is the accommodation coefficient of the tangential momentum. In the particular case $\alpha_n = \alpha_t = 1$ this kernel coincides with the diffuse one (17). If $\alpha_n = \alpha_t = 0$ the CL kernel becomes the specular one (18). The combination $\alpha_n = 0$ and $\alpha_t = 2$ corresponds to the back scattering, which can occur on a rough surface.

The linearized kinetic equation will be written in terms of following dimensional coordinates and molecular velocity

$$\tilde{\boldsymbol{r}} = \boldsymbol{r}/a, \qquad \boldsymbol{c} = \boldsymbol{v}/v_0\,, \tag{20}$$

respectively. Here a is a characteristic size used in the definition of the gas rarefaction (1).

If the state of the gas is weakly non-equilibrium, we may linearize the *Boltzmann equation* representing the *velocity distribution function* as

$$f(\tilde{\boldsymbol{r}}, \boldsymbol{c}) = f_R^M [1 + \xi\ h(\tilde{\boldsymbol{r}}, \boldsymbol{c})]\,, \qquad \xi \ll 1\,, \tag{21}$$

where ξ is a small parameter of the linearization, f_R^M is the reference Maxwellian given by Eq. (10) with the reference number density n_R, temperature T_R and bulk velocity $\boldsymbol{u}_R$, i. e.

$$f_R^M = f^M(n_R, T_R, \boldsymbol{u}_R)\,. \tag{22}$$

Substituting (21) into (8) the linearized *Boltzmann equation* is obtained as

$$\boldsymbol{c} \cdot \frac{\partial h}{\partial \tilde{\boldsymbol{r}}} = \hat{L}h + g(\tilde{\boldsymbol{r}}, \boldsymbol{c})\,, \tag{23}$$

where $\hat{L}$ is the linearized dimensionless collision operator and g is the source function given as

$$g(\tilde{\boldsymbol{r}}, \boldsymbol{c}) = -\frac{\boldsymbol{c}}{\xi} \cdot \frac{\partial \ln f_R^M}{\partial \tilde{\boldsymbol{r}}}\,. \tag{24}$$

The quantities n_R, T_R and $\boldsymbol{u}_R$ are chosen so that to reduce the computational efforts. Particularly, they can be constant and equal to their equilibrium values. The operator $\hat{L}$ in its exact form has a cumbersome form, that is why just the model linearized operators will be given. With the help of Eqs. (1), (11), (12), and (20) the linearized BGK collision operator takes the form

$$\hat{L}_{BGK}h = \delta\left[\varrho + 2\boldsymbol{c} \cdot \tilde{\boldsymbol{u}} + \tau\left(c^2 - \frac{3}{2}\right) - h\right]. \tag{25}$$

By the same way the linearized S-model is obtained from Eq. (13)

$$\hat{L}_S h = \delta\left[\varrho + 2\boldsymbol{c} \cdot \tilde{\boldsymbol{u}} + \tau\left(c^2 - \frac{3}{2}\right) + \frac{4}{15}\tilde{\boldsymbol{q}} \cdot \boldsymbol{c}\left(c^2 - \frac{5}{2}\right) - h\right],$$

where ϱ, τ, and $\tilde{\boldsymbol{u}}$ are the deviations from their reference values, i. e.

$$\varrho = \frac{n - n_R}{\xi n_R}\,, \quad \tau = \frac{T - T_R}{\xi T_R}\,, \quad \tilde{\boldsymbol{u}} = \frac{\boldsymbol{u} - \boldsymbol{u}_R}{\xi v_0}\,. \tag{26}$$

Moreover, the dimensionless heat flux and stress tensor are introduced

$$\tilde{\boldsymbol{q}} = \frac{\boldsymbol{q}}{\xi P_0 v_0}\,, \qquad \tilde{P}_{ij} = \frac{P_{ij}}{2\xi P_0}\,, \tag{27}$$

where $P_0 = n_0 k_B T_0$ is the equilibrium pressure.

Substituting (21) into Eqs. (3)–(7) with the help of Eqs. (26) and (27) we express the moments in terms of the perturbation function as

$$\varrho = \frac{1}{\pi^{3/2}} \int e^{-c^2} h\, d\boldsymbol{c}\,, \tag{28}$$

$$\tilde{\boldsymbol{u}} = \frac{1}{\pi^{3/2}} \int \boldsymbol{c}\, e^{-c^2} h\, d\boldsymbol{c}\,, \tag{29}$$

$$\tau = \frac{1}{\pi^{3/2}} \int \left(\frac{2}{3}c^2 - 1\right) e^{-c^2} h\, d\boldsymbol{c}\,, \tag{30}$$

$$\tilde{P}_{ij} = \frac{1}{\pi^{3/2}} \int c_i c_j\, e^{-c^2} h\, d\boldsymbol{c}\,, \quad i, j = x, y, z\,, \tag{31}$$

$$\tilde{\boldsymbol{q}} = \frac{1}{\pi^{3/2}} \int \boldsymbol{c}\left(c^2 - \frac{5}{2}\right) e^{-c^2} h\, d\boldsymbol{c}\,. \tag{32}$$

The linearized boundary conditions are obtained substituting (21) into (14) combining with (15) and (16)

$$h^+ = \hat{A}\, h^- + h_w^+ - \hat{A}\, h_w^-\,, \tag{33}$$

where h_w is the perturbation of the surface Maxwellian

$$h_w = \frac{1}{\xi}\left[\frac{m}{k_B T_R}\boldsymbol{v} \cdot (\boldsymbol{u}_w - \boldsymbol{u}_R) + \frac{T_w - T_R}{T_R} \cdot \left(\frac{mv^2}{2k_B T_R} - \frac{5}{2}\right)\right]. \tag{34}$$

The scattering operator $\hat{A}$ is defined as

$$\hat{A}h^- = -\int_{v'_n \le 0} \frac{v'_n}{v_n} \exp\left[\frac{m(v^2 - v'^2)}{2k_B T_0}\right] h(\boldsymbol{v}')R(\boldsymbol{v}', \boldsymbol{v})\, d\boldsymbol{v}' \,. \tag{35}$$

To solve numerically the linearized kinetic Equations (23) with the boundary condition (33) a set of values of the velocity $\boldsymbol{c}_i$ is chosen. The collision operator $\hat{L}h$ is expressed *via* the values $h_i(\tilde{x}) = h(\tilde{x}, \boldsymbol{c}_i)$. Thus, Eq. (23) is replaced by a system of differential equations for the functions $h_i(\tilde{x})$, which can be solved numerically by a finite difference method. First, some values are assumed for the moments being part of the collision operator. Then, the distribution function moments are calculated in accordance with Eqs. (28)–(32) using some quadrature. The differential equations are solved again with the new moments. The procedure is repeated up to the convergence.

Key Research Findings

Plane Poiseuille Flow in Microchannels

Consider two infinite plane plates fixed at $x = \pm a/2$. A monoatomic gas confined between them flows along the axis y due to a pressure gradient, which is used as the small parameter, i. e.

$$\xi = \frac{a}{P}\frac{dP}{dy} \,. \tag{36}$$

We are interested in the velocity profile $u_y(x)$ and mass flow rate $\dot{M}$ through a cross section of the channel defined as

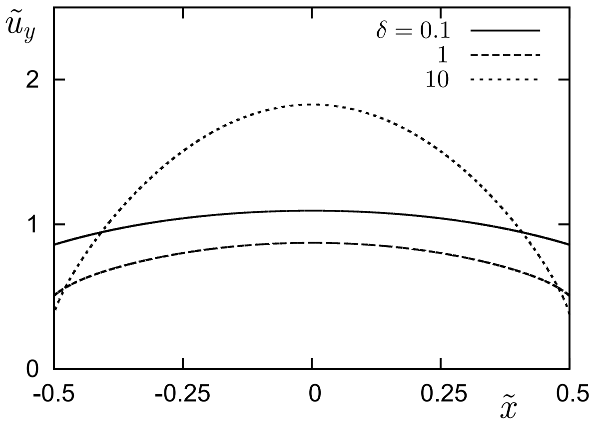
$$\dot{M} = \int_{\frac{-a}{2}}^{\frac{a}{2}} m\, n\, u_y(x)\, dx \,. \tag{37}$$

Such a flow is known as Poiseuille flow.

The following reference quantities being part of the Maxwellian (22) are as used in the linearization: $n_R = n_0\,(1 + \xi\, y/a)$, $T_R = T_0$, $\boldsymbol{u}_R = 0$. According to Eqs. (26) we have $\varrho = 0$ because $n = n_R$ and $\tau = 0$ because the flow is isothermal. Then, the perturbation function depends only on the coordinate $\tilde{x}$, i. e. $h = h(\tilde{x}, \boldsymbol{c})$. The source function defined by Eq. (24) takes the form $g = -c_y$. Since the flow is isothermal we use the BGK model, which is reduced to

$$c_x \frac{\partial h}{\partial \tilde{x}} = \delta\left(2c_y \tilde{u}_y - h\right) - c_y \,, \tag{38}$$

where $\tilde{u}$ is given by Eq. (29) and related the the bulk velocity by Eq. (26). Note, the solution of this equation is even



Micro- and Nanoscale Gas Dynamics, Figure 1 Velocity profiles $\tilde{u}_y$ in Poiseuille flow

with respect to c_y, i. e.

$$h(\tilde{x}, c_x, c_y, c_z) = -h(\tilde{x}, c_x, -c_y, c_z) \,. \tag{39}$$

Since $\boldsymbol{u}_w = \boldsymbol{u}_R = 0$ and $T_w = T_0 = 0$, the surface perturbation $h_w = 0$ according to Eq. (34). Thus, the boundary condition (33) is reduced to

$$h^+ = \hat{A}h^- \quad \text{at} \quad \tilde{x} = \pm\frac{1}{2} \quad \text{and} \quad c_y \lessgtr 0 \,. \tag{40}$$

In case of the diffuse reflection we obtain $\hat{A}\, h^- = 0$ using the property (39).

Solving the integro-differential Eq. (38) with the boundary condition (40) we obtain the velocity profile $\tilde{u}$ and then the reduced flow rate

$$G_P = -2\int_{-1/2}^{1/2} \tilde{u}(\tilde{x})\, d\tilde{x} \,, \tag{41}$$

which is called as ► Poiseuille coefficient and related to the mass flow rate as

$$\dot{M} = -G_P \frac{aP}{v_0}\xi = -G_P \frac{a^2}{v_0}\frac{dP}{dy} \,. \tag{42}$$

The last expression is obtained with the help of Eqs. (20), (26), (36), and (37). Note, the coefficient G_P is always positive.

Typical velocity profiles are presented in Fig. 1. For the large value of the *rarefaction parameter* ($\delta = 10$) the profile is very close to the parabolic shape. In the transition ($\delta = 1$) and small ($\delta = 0.1$) values the profiles are practically flat.

The *Poiseuille coefficient* G_P for the diffuse scattering is presented in Table 1. It tends to infinity in both limits

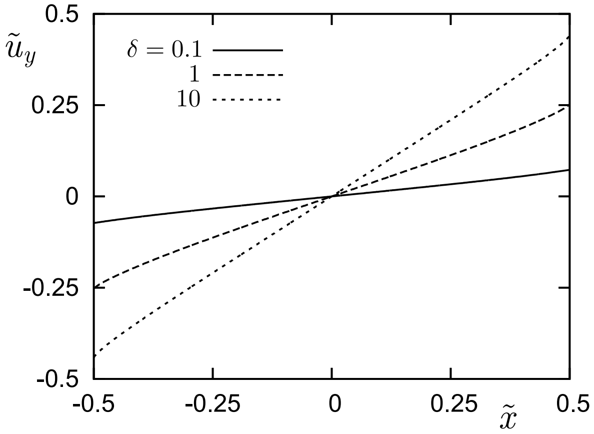
$\delta \to \infty$ and $\delta \to 0$. In the transition regime the coefficient G_P has the well known Knudsen minimum.

To give an idea how does the gas-surface interaction affect the flow rate, some values of G_P for the CL scattering kernel obtained in [13] are given in Table 2. In all regimes the influence of the energy accommodation coefficient α_n on the flow rate is weak, while the momentum accommodation coefficient α_t affects significantly the flow rate in the transition ($\delta = 1$) and near the free molecular ($\delta = 0.01$) regimes.

Momentum Transfer in Microscale

Here, we again consider the two plates fixed at $x = \pm a/2$, but the pressure is constant between them. The gas is disturbed by a motion of the plates, namely, the left plate is moving down with a speed $u_w/2$, while the right one is moving up with the same speed. This is the so-called Couette flow. We are interested in the velocity profile $u_y(x)$ between the plates and the shear stress P_{xy}. If we assume the plate speed u_w to be significantly smaller than the most



Micro- and Nanoscale Gas Dynamics, Figure 2 Velocity profiles $\tilde{u}_y$ in plane Couette flow

probable speed v_0, the ratio

$$\xi = \frac{u_w}{v_0} \tag{43}$$

can be used as the small parameter for the linearization. The reference quantities in the Maxwellian (22) are as follows $n_R = n_0$, $T_R = T_0$, $\boldsymbol{u}_R = 0$. According to Eqs. (26) we have $\varrho = \tau = 0$ because the density and temperature are constant. Then, the source function (24) is given as $g = 0$. Since the flow is isothermal the BGK model is applied, which reads

$$c_x \frac{\partial h}{\partial \tilde{x}} = \delta \left(2 c_y \tilde{u}_y - h\right) . \tag{44}$$

From Eq. (34) we obtain $h_w = \pm c_y$ on the right/left plate. In case of the diffuse reflection we obtain the explicit boundary condition

$$h = \pm c_y \quad \text{at} \quad \tilde{x} = \pm \frac{1}{2} \quad \text{and} \quad c_y \lessgtr 0 . \tag{45}$$

Solving Eq. (44) with the boundary condition (45) the perturbation function h is obtained. Then the bulk velocity $\tilde{u}_y$ and shear stress $\tilde{P}_{xy}$ are calculated according to Eqs. (29) and (31), respectively.

Typical velocity profiles are presented in Fig. 2. For the large value of the rarefaction ($\delta = 10$) the velocity $\tilde{u}_y$ varies linearly from -0.5 to 0.5, i. e. it is close to the solution in the hydrodynamic regime. By decreasing the *rarefaction parameter* δ the slope of the velocity profile becomes smaller. The shear stress is shown in Table 3. Note, it is negative because the velocity gradient

Micro- and Nanoscale Gas Dynamics, Table 3 Shear stress $\tilde{P}_{xy}$ vs. rarefaction parameter δ

δ	$-\tilde{P}_{xy}$	δ	$-\tilde{P}_{xy}$
0.001	0.2818	1.0	0.1695
0.01	0.2797	2.0	0.1252

0.4	0.2189	100.0	0.0049

is positive. The magnitude of the shear stress monotonely decreases by increasing the *rarefaction parameter* δ.

Heat Transfer in Microscale

Now, we consider the plates being at rest but the left one is maintained at the temperature $T_0 - \Delta T/2$, while the right one has the temperature $T_0 + \Delta T/2$. We are interested in the temperature profile $T(x)$ between the plates and the heat flux q_x. Assuming that $\Delta T \ll T_0$ the ratio

$$\xi = \frac{\Delta T}{T_0} \tag{46}$$

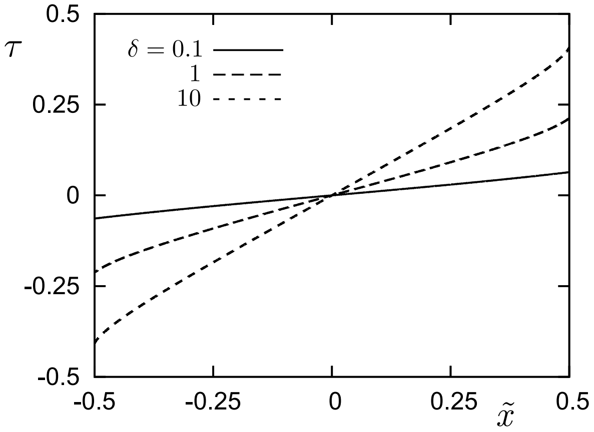
can be used as the small parameter for the linearization. The reference quantities in the Maxwellian (22) are equal to their equilibrium values $n_R = n_0$, $T_R = T_0$, $\boldsymbol{u}_R = 0$. Then, the source function (24) is given as $g = 0$. Since the gas is being at rest we have $\tilde{\boldsymbol{u}} = 0$. For the problem in question the S-model is more appropriate because we are interested in the heat transfer. Finally, the kinetic Eq. (23) is reduced to

$$c_x \frac{\partial h}{\partial \tilde{x}} = \delta \left[\varrho + \tau \left(c^2 - \frac{3}{2} \right) + \frac{4}{15} c_x \tilde{q}_x \left(c^2 - \frac{5}{2} \right) - h \right] . \tag{47}$$

From Eq. (34) we obtain $h_w = \pm(c^2 - 3/2)$ on the right/left plate. In case of the diffuse reflection we obtain the explicit boundary condition

$$h = \pm(\varrho_w + c^2 - 2) \quad \text{at} \quad \tilde{x} = \pm\frac{1}{2} \quad \text{and} \quad c_y \lessgtr 0 , \tag{48}$$

where $\varrho_w = (2/\pi) \int_{c_x \geq 0} c_x e^{-c^2} h \, d\boldsymbol{c}$ at $\tilde{x} = 1/2$. Typical temperature profiles are presented in Fig. 3. Their behaviors are quite similar to those of the velocity profiles in the previous example. The heat flux $\tilde{q}_x$ is shown in Table 4. It is negative because the temperature gradient is positive.



Micro- and Nanoscale Gas Dynamics, Figure 3 Temperature profiles τ between parallel plates

The magnitude of the heat flux decreases by increasing the *rarefaction parameter* δ.

Examples of Application

Consider two parallel plates with the clearance $a = 0.217\,\mu\text{m}$ between them containing helium at the pressure $P = 10^5$ Pa and at the temperature $t = 20\,°\text{C}$. Under such conditions the gas viscosity is $\mu = 19.73 \times 10^{-6}$ Pa s and the most probable speed is $v_0 = 1.10 \times 10^3$ m/s. Substituting these values into Eq. (2) the *equivalent mean free path* is obtained $\ell = 0.217\,\mu\text{m}$, i. e. the *rarefaction parameter* δ defined by Eq. (1) is equal to unity. According to Tables 1, 3, and 4 for $\delta = 1$ we have $G_P = 1.539$, $\tilde{P}_{xy} = -0.1695$, and $\tilde{q}_x = -0.4001$, respectively. Let us assume the dimensionless pressure gradient $\xi = -0.01$, see Eq. (36), to be maintained along the plates. Using Eq. (42) the mass flow rate is calculated as $\dot{M} = 3.04 \times 10^{-7}$ kg/(m s). Now, let us consider the constant pressure, but one plate moves parallelly the other with a relative speed $u_w = 10$ m/s, then according to Eq. (43) we have $\xi = 9.09 \times 10^{-3}$. With the help of Eq. (27) the shear stress magnitude is obtained

$P_{xy} = 308$ Pa. If one plates has its temperature $t = 10\,°C$ and the other is maintained at $t = 30\,°C$ then, $\xi = 0.0682$ in accordance with Eq. (46). Substituting the corresponding values into Eq. (27) the heat flux magnitude is obtained $q_x = 3.00 \times 10^6$ W/m^2.

Definition

Micro- and nanoscale gas fluidics concerns the behavior of gas flows and the heat transfer mechanisms in micro- and nanoscale devices. Correct understanding and accurate prediction of the characteristics of micro- and nanoscale gas flow and heat transfer are very important for optimization and design of micro- and nanoscale systems. In micro- and nanoscale gas flow, the Knudsen number is high owing to the very small characteristic length, even though the gas density may be not low, which leads to behavior similar to the well-known rarefied-gas flow. Atomistic numerical methods, such as direct-simulation Monte Carlo methods, are available for microscale gas flows and heat transfer. However, when the gas density is so high that the perfect-gas assumption breaks down, both the theories and the simulation methods for rarefied gases are not valid anymore. A generalized Enskog Monte Carlo method has been developed to take account of the effects of a dense, nonideal gas. Using this method, gas microfluidics and nanofluidics have been analyzed.

Overview

The flow of rarefied gases has been investigated in detail because of its important applications in aeronautical and astronautical engineering. Rarefied-gas flows differ from those of classical gas dynamics in that the continuum hypothesis is no longer valid; therefore, the continuum hypothesis cannot be used to analyze rarefied-gas flows. Rarefied-gas flows are characterized by the Knudsen number, which is defined as the ratio of the molecular mean free path to a characteristic geometric length or a length over which very large variations of a macroscopic quantity may take place [1]. Flow regimes can be classified on the basis of the Knudsen number as:

- continuum flow ($\mathrm{Kn} \le 0.001$),

- near-continuum flow ($0.001 < \mathrm{Kn} < 0.01$),
- slip flow ($0.01 < \mathrm{Kn} < 0.1$),
- transition flow ($0.1 < \mathrm{Kn} < 10$),
- free molecular flow ($\mathrm{Kn} \geq 10$).

In recent years, micro/nanoelectromechanical systems (M/NEMS) have been rapidly developed for important applications in navigation, space flight, and industry [2]. The characteristics of microscale gas flows differ from those of macroscale flows. For example, at normal temperatures and pressures, velocity slip and temperature jumps, which are considered as rarefied-gas effects, occur at the wall surfaces in microchannels. Rarefied-gas flows and microscale gas flows exhibit many other similar phenomena. Previous work has shown that most traditional simulation and analysis methods used for rarefied-gas flows are also effective for analyzing microscale gas flows [2]. Various studies have analyzed the similarities between microscale gas flows and macroscale rarefied-gas flows. Since the Knudsen numbers of microscale gas flows are as high as those of rarefied-gas flows, it is very important to build a bridge between them so that the large number of achievements in the field of rarefied-gas flow can be applied in the analysis of microscale gas fluidics. On the other hand, although the Knudsen number of a microscale gas flow may be of the same magnitude as that of a rarefied-gas flow, the reasons in the two cases are different. In microscale flows, the large Knudsen number is caused by the small characteristic length, whereas in rarefied-gas flows, the large Knudsen number is due to the large molecular mean free path. Therefore, the mechanisms may be different despite the fact that the phenomena are similar. How to analyze and predict gas flow and heat transfer in these situations is a very important but challenging problem, in terms of both theory and practice.

Basic Methodology

Direct-Simulation Monte Carlo (DSMC) Method

The DSMC method is a molecule-based statistical simulation method for rarefied-gas flows introduced by Bird [3]. The method solves the dynamical equations for the gas flow numerically, using thousands of simulated molecules. Each simulated molecule represents a large number of real molecules. Assuming molecular chaos and a rarefied gas, only binary collisions need be considered, and so the molecular motion and the collisions are uncoupled if the computational time step is smaller than the physical collision time. Interactions with boundaries and with other molecules conserve both momentum and energy. The macroscopic flow characteristics are obtained by statistically sampling the molecular properties in each of the cells used in the method. At the beginning of the calculation, the simulated particles are uniformly distributed in the cells. During each time step, all particles move according to their individual velocities, interact with the boundaries, and are then indexed. A number of collision pairs are selected in each cell using the no-time-counter (NTC) method for the calculation of collisions. These steps are repeated with increased sample sizes until the statistical errors are small. The DSMC method can simulate nonequilibrium and unsteady gas flows. A steady-state flow field is obtained with a sufficiently long simulation time. The variable-hard-sphere (VHS) model that is most popular in DSMC simulations incorporates the hard-sphere scattering law for collisions and treats the molecular cross sections as functions of the relative translational energy during the collision. In this model, the gas molecules are actually treated as hard spheres with only a repelling force, which is consistent with the perfect-gas assumption. The time step used in the DSMC method should be less than the mean collision time, and the cell (or subcell) size should be less than the mean free path in the simulated situation. Violation of this condition may produce solutions that are not physically realistic [4].

For an isothermal wall, when a simulated particle collides with the wall, a diffuse-reflection model is used to determine the result of reflection, whereby the outgoing velocity is randomly assigned according to a half-range Maxwellian distribution determined by the wall temperature. This is also known as the full thermal and momentum accommodation method.

In traditional DSMC simulations of supersonic flows, the Dirichlet type of velocity boundary conditions has generally been used. This approach is often applied in external-flow simulations, which require the downstream boundary to be far away from the base region. However, the flows in microscale systems are often subsonic flows, and the boundary conditions which can be obtained from the experiment always refer to pressure and temperature, instead of velocity and number density. Wang and Li [5] have proposed a new implicit treatment for a pressure boundary condition, inspired by the characteristic theory of low-speed microscale flows. This new implementation of boundary conditions not only overcomes the instability of particle-based approaches, but also has a higher efficiency than any other existing methods. The new method is easy to extend to gas flows where the downstream and upstream directions are not opposite, such as in L-shaped and T-shaped channels.

Generalized Enskog Monte Carlo (GEMC) Method

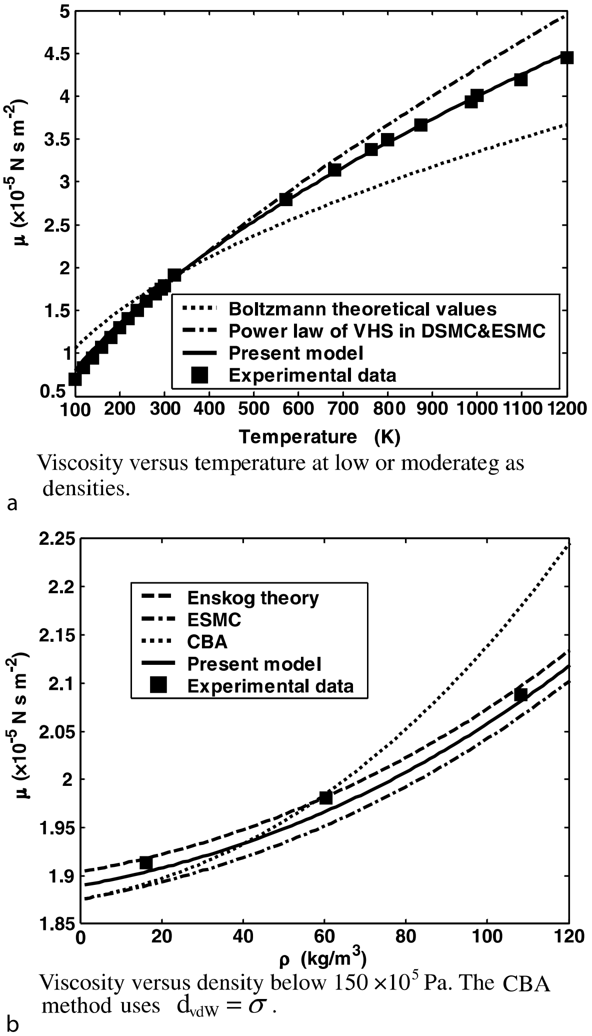
High-Knudsen-number nonideal-gas flows have two distinctive characteristics that require a different type of anal-

ysis from rarefied-gas flows: the collisions are much more frequent and the van der Waals force cannot be ignored. Alexander et al. [6] have developed a consistent Boltzmann algorithm (CBA) to expand the DSMC method to dense gases and even liquids by introducing an additional displacement after the molecular collisions. This modification uses the gas properties described by the van der Waals equation instead of those described by the equation of state for a perfect gas. This method has been applied to the modeling of nonideal-gas flows in micro- and nanochannels [7]. However, the additional displacement changes not only the equation of state but also the gas transport characteristics. As a result, when the ratio of the molecular volume of the gas to the whole volume is relatively high, the gas transport characteristics become unrealistic and the predictions fail [8]. Other methods have been developed on the basis of the Enskog dense-gas theory. Enskog developed the Enskog equation for hard spheres to incorporate finite-density effects, where the two significant changes were the finite distance between the centers of a colliding pair and the increased collision frequency due to excluded-volume effects [9]. Montanero and Santos [10] then developed an Enskog simulation Monte Carlo (ESMC) method, which extended Bird's DSMC method to a hard-sphere fluid at finite densities. However, the ESMC method did not include attractive interactions between molecules, and therefore the transport properties predicted by the ESMC method did not agree well with either the experimental data or the theoretical values. Recently, a generalized Enskog Monte Carlo method has been developed [11]. In the new method, a Lennard–Jones (L–J) potential between molecules is introduced, with a generalized collision model, into the Monte Carlo method, and the effects of finite density on the molecular collision rate and transport properties are considered so as to obtain an equation of state for a nonideal gas. The resulting transport properties agree better with the experimental data and theoretical values than do those obtained by any other existing method.

In actual gases, the force between two molecules is repulsive at small distances and weakly attractive at larger distances. This behavior is most simply described by an L–J (6–12) potential [12],

$$\varphi(r) = 4\varepsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right], \tag{1}$$

where σ denotes the low-velocity diameter and ε is the depth of the potential well, these being constants characteristic of the chemical species of the colliding molecules, and r is the intermolecular separation. This potential has been found to be adequate for a number of nonpolar



a Viscosity versus temperature at low or moderateg as densities.

b Viscosity versus density below 150 ×10^5 Pa. The CBA method uses $d_{vdW} = \sigma$.

Micro- and Nanoscale Gas Fluidics, Figure 1 Viscosities predicted by the present method compared with experimental data and other models

molecules. Many efforts have been made to establish collision models that include an L–J potential in the molecular interaction process [13, 14]. These models have defined the total collision cross section as

$$\frac{\sigma_T}{\sigma^2} = \sum \alpha_j \left(\frac{E_t}{\varepsilon}\right)^{-\omega_j}, \tag{2}$$

where σ_T is the total collision cross section, E_t denotes the relative translational energy, the parameters ω_j are related to the L–J potential, and the α_j are determined from transport property data, depending on whether the interaction is between like or unlike molecules.

The coefficients of viscosity and self-diffusion of a simple gas, to a first approximation, can be expressed as functions

of temperature by [12]

$$\mu = \frac{5}{16}\left(\frac{(\pi mkT)^{\frac{1}{2}}}{\pi\sigma^2\Omega^{(2,2)*}}\right) , \quad (3)$$

$$D = \frac{3}{16}\left(\frac{(2\pi kT/m_r)^{\frac{1}{2}}}{n\pi\sigma^2\Omega^{(1,1)*}}\right) , \quad (4)$$

where m is the particle mass, k is the Boltzmann constant, n is the number density, and $\Omega^{(1,1)*}$ and $\Omega^{(2,2)*}$ are integrals for calculating the transport coefficients using an L–J potential. For an L–J gas model with a total collision cross section given by Eq. (2), the self-diffusion and viscosity integrals are

$$\Omega^{(1,1)*} = \frac{1}{\pi(\alpha^* + 1)} \sum \alpha_j \Gamma(3 - \omega_j) T_*^{-\omega_j} , \quad (5)$$

$$\Omega^{(2,2)*} = \frac{\alpha^*}{\pi(\alpha^* + 1)(\alpha^* + 2)} \sum \alpha_j \Gamma(4 - \omega_j) T_*^{-\omega_j} , \quad (6)$$

where α^* denotes the scattering coefficient for a soft-sphere model, $T_* = kT/\varepsilon$, and $\Gamma(\ldots)$ denotes the gamma function. These parameters can be determined by numerical fitting using data on $\Omega^{(2,2)*}$ [12]. This task has been done in the case of the GSS model [14]. We have employed the following set of parameter values: $\alpha_1 = 3.962$, $\alpha_2 = 4.558$, $\omega_1 = 0.133$, $\omega_2 = 1.25$, and $\alpha^* = 1.5$. These values are generally suitable for simple nonpolar gases.

On the basis of the Enskog equation for dense gases, when a gas is so dense that the *co*volume of the molecules is comparable to the total volume of the system, the assumptions of point particles and binary collisions are no longer applicable. After considering the scattering and screening effects of intermolecular scattering and screening effects, a collision enhancement factor dependent on the gas density has been derived, with the following third-order form [9]:

$$\chi(\eta) = 1 + 0.625\eta + 0.2869\eta^2 + 0.1103\eta^3 , \quad (7)$$

where $\eta = 2\pi n\sigma^3/3$ represents the molecular volume ratio. In the standard Enskog theory, the pressure in a dense gas is

$$p = knT[1 + \eta\chi] . \quad (8)$$

However, Enskog preferred a different procedure, based on the close relation between $\eta\chi$ and the compressibility. He observed that if hard-sphere molecules were surrounded by weak attractive fields of force, the equation of state would be modified to the following form:

$$p + a_v\rho^2 = knT[1 + \eta\chi] , \quad (9)$$

where a_v denotes the strength of the attraction, which is independent of the temperature and dependent on the gas properties; it is given by

$$a_v = \frac{27}{64}\frac{R^2T_c^2}{p_c} , \quad (10)$$

where R denotes the gas constant, T_c the critical temperature, and p_c the critical pressure.

This method solves the Enskog equation for a dense gas statistically while keeping the gas transport properties in good agreement with experimental data. The viscosity obtained from this method is compared with predictions from other methods and experimental data [12] in Fig. 1a, which shows the variation of viscosity with temperature at low and moderate gas densities. The present method gives much better agreement with experimental data at both lower and higher temperatures than does the Boltzmann theory or the viscosity–temperature power law used in the VHS model in the DSMC and ESMC methods. The variation of viscosity with density below a pressure of 150×10^5 Pa is shown in Fig. 1b. The results of the present method agrees well with the experimental data and the Enskog theory, whereas the results of the CBA and DSMC methods deviate from the experimental data at high gas densities. Therefore, the present method gives the best agreement with the experimental data over a large of temperatures and densities.

Since the main procedure in this GEMC method is similar to other Monte Carlo methods for gas flows, the program for it can therefore use many techniques borrowed from the DSMC method, such as the indexing and sample techniques; the codes were developed on the basis of the standard DSMC code of Bird [3]. The internal energy exchange model, i. e. the Borgnakke–Larsen model, for the generalized collision model was also modified on the basis of Parker's formula [13].

Key Research Findings

Similarity Analysis

Both microscale gas flows and rarefied-gas flows have three dimensionless numbers that characterize the flow: the Reynolds number Re, the Mach number Ma, and the Knudsen number Kn. However, these three parameters are not independent in rarefied-gas flows but instead are

related by

$$\mathrm{Kn} = \sqrt{\frac{\pi\gamma}{2}}\frac{\mathrm{Ma}}{\mathrm{Re}} . \tag{11}$$

Several researchers have used this relationship for rarefied-gas flows in the analysis of microscale gas flows [2]. However, this relationship has limited application to microscale gas flows. Wang and Li [15] found that Eq. (11) is based on a relationship between the viscosity and the mean free path. On the basis of the kinetic theory of gases, when the gas molecules are treated as smooth, rigid spheres with only a repelling force, the kinetic viscosity can be simply related to the molecular mean free path by

$$\nu = \frac{1}{2}\lambda v_{\mathrm{m}} , \tag{12}$$

where v_{m} is the mean molecular speed, which is somewhat higher than the speed of sound a:

$$v_{\mathrm{m}} = \sqrt{\frac{8}{\pi\gamma}}a . \tag{13}$$

With this assumption for Eq. (12), if the gas is a perfect gas, the three dimensionless numbers are not independent. As a result, gas flows at different scales can be similar (if other similarity conditions are also satisfied, such as similar geometries and boundary conditions). Since rarefied-gas flows have been studied extensively, owing to their important applications in astronautics and aeronautics, many theories and much experimental data can be used for the analysis of microscale gas flow by making use of this similarity, which has been numerically validated by a series of standard DSMC simulations [15].

However, the perfect-gas assumption does not always hold for micro- and nanoscale gas flows. When the gas density is high or the temperature is low, intermolecular attractions become significant as the effect of denseness changes the characteristics of the gas flow. According to Enskog's theory, the molecular mean free path in a dense gas, λ, is given by [12]

$$\lambda = \left[\sqrt{2}\pi n\chi\sigma^2\right]^{-1} . \tag{14}$$

The dynamic viscosity μ' of a dense gas is related to the dynamic viscosity μ of a perfect gas by

$$\mu' = \mu \cdot \eta\left[(\eta\chi)^{-1} + 0.8 + 0.7614(\eta\chi)\right] . \tag{15}$$

From classical thermodynamic theory, the speed of sound in a dense gas is enhanced as follows:

$$a' = a\left[1 + 8\eta\chi + \frac{4}{5}\eta^2\left(8\chi^2 + 3\frac{\mathrm{d}\chi}{\mathrm{d}\eta}\right)\right]^{\frac{1}{2}} . \tag{16}$$

For convenience, let us assume that Re and Ma have the same values in two systems; we can then obtain the ratio of the Knudsen numbers of the two systems as follows:

$$\frac{\mathrm{Kn}_1}{\mathrm{Kn}_2} = \frac{\sqrt{T_1}}{\sqrt{T_2}} \cdot \frac{\left[1 + 8\eta_1\chi_1 + \frac{4}{5}\eta_1^2\left(8\chi_1^2 + 3\frac{\mathrm{d}\chi_1}{\mathrm{d}\eta}\right)\right]^{\frac{1}{2}}}{\left[1 + 8\eta_2\chi_2 + \frac{4}{5}\eta_2^2\left(8\chi_2^2 + 3\frac{\mathrm{d}\chi_2}{\mathrm{d}\eta}\right)\right]^{\frac{1}{2}}} \cdot \frac{\left[1 + 0.8\eta_2\chi_2 + 0.7614\,(\eta_2\chi_2)^2\right]}{\left[1 + 0.8\eta_1\chi_1 + 0.7614\,(\eta_1\chi_1)^2\right]} . \tag{17}$$

A detailed data analysis has indicated that the characteristic lengths must be the same if the two dense-gas flows are to be treated similarly. That is to say, the three dimensionless parameters for two dense-gas flows with different scales cannot be the same in both flows. The similarity fails for dense-gas flows.

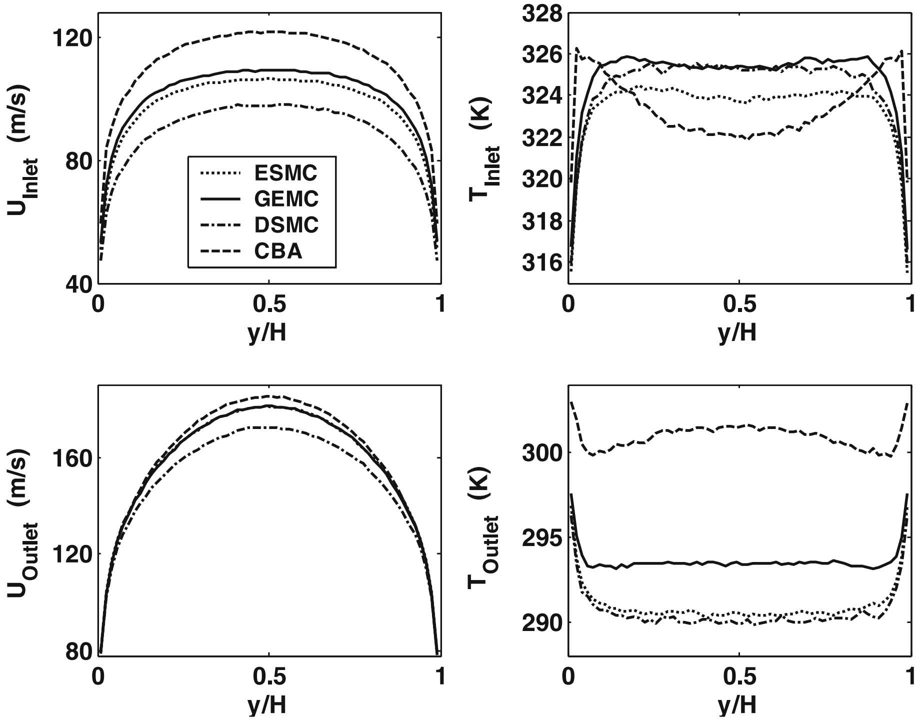
The high gas density influences the properties of the gas such as the viscosity and the speed of sound. Therefore, a critical density can be specified such that for densities below this critical density, the perfect-gas assumption and the similarity between gas flows hold. The critical density can be calculated for a specified error tolerance of 5%. For nitrogen gas, the critical density for the perfect-gas assumption is

$$\rho_{\mathrm{c}} \approx 4.5\rho_0 , \tag{18}$$

where ρ_0 is the density in the standard state. Equation (18) indicates that the effect of denseness must be considered when the density of the microscale flow is larger than 4.5 times the standard-state density.

High-Knudsen-Number Nonideal-Gas Flow

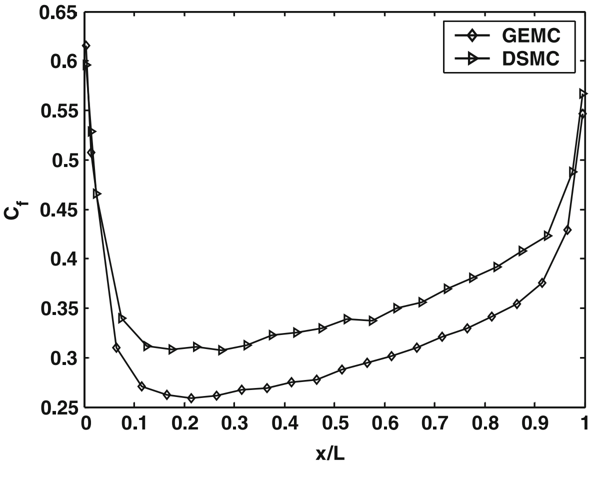
With the rapid development of M/NEMS techniques, gas flows in micro- and nanochannels are often encountered in practice. The large flow resistance caused by the huge aspect ratios of micro- and nanochannels usually requires a large driving pressure, which actually make the gas dense. However, the small characteristic length of the channel leads to a high Knudsen number, which causes continuum-based theories and prediction methods to break down. Such flows with both high Knudsen numbers and high densities have never been effectively and correctly predicted, though many efforts have been made in the past decade [6–8, 10]. In the present contribution, we describe the results of simulation of dense-gas flow in micro- and



Micro- and Nanoscale Gas Fluidics, Figure 2 Effect of density on gas flow and heat transfer calculated by the GEMC method at $\eta_\infty = 0.135$ and $Kn_\infty = 0.06$, compared with DSMC, CBA, and ESMC results

nanochannels by the GEMC method, and the results are compared with previous studies.

We considered the flow of nitrogen gas in a microchannel. The density and temperature of the incoming gas were $n = 100\,n_0$ and $T = 300$ K, which lead to $\eta_\infty = 0.135$ and $Kn_\infty = 0.06$. The velocity of the incoming gas and the wall temperature were $U = 200$ m/s and $T_w = 300$ K, respectively. Figure 2 compares the simulation results for the velocity and temperature profiles at the inlet and outlet. Results obtained from the ESMC, DSMC, and CBA methods are also plotted in the figure. The results show that the high gas density affects the flow and heat transfer characteristics, which deviate from those predicted by the perfect-gas assumption. The ESMC algorithm modified the enhanced particle collision greatly but made little change to the internal energy exchange. Therefore, its results agreed well with the GEMC results for the velocity profiles at the inlet and outlet but deviated greatly from the GEMC results for the temperature field. At the same time, the reversal of the temperature distribution near the wall surface that occurred in the CBA simulations did not occur in the GEMC results [7], which indicates that the collision process needs to be modified to deal with the interaction between molecules and wall surfaces after the additional displacement that occurs in the CBA method. As a result, the present GEMC method works better than the other two numerical methods for modeling high-Knudsen-number nonideal-gas flows.



Micro- and Nanoscale Gas Fluidics, Figure 3 Distributions of the skin friction coefficient along the wall surfaces predicted by the GEMC and DSMC methods at $\eta_\infty = 0.135$ and $Kn_\infty = 0.06$

Figure 3 compares the distributions of the skin friction coefficient along the wall surfaces predicted by the GEMC

and DSMC methods. The results show that the density effect reduces the friction below the predictions of the perfect-gas assumption; this will need more theoretical and experimental validation.

Gas Flow and Heat Transfer in N/MEMS Devices

Since the development and application of atomistic computational methods in recent years, our understanding of gas microfluidics and nanofluidics has been greatly improved. If the flow and thermal behavior can be correctly analyzed and accurately predicted, optimal design of microsystems is possible. Related work can be found in analyses of the performance of microscale air slide bearings in hard disk drives [16], the propulsion efficiency of micronozzles in microsatellites [17], flows through orifices and orthogonal channels in microchips [5], gas mixing in microchannels, and heat transfer in vacuum-packaged MEMS devices [4]. Micro- and nanoscale gas fluidics has been a *hot* area, and numerous papers are being published every month owing to its importance, and therefore we cannot list all of the achievements in this area in these limited pages.

Future Directions for Research

Although the numerical tools for the simulation and analysis of gas microfluidic systems are now well developed, there are still many hard challenges ahead. Here, we list a few imperative and promising directions for the near future:

- *Hybrid multiscale simulation.* Although hybrid continuum/DSMC methods for multiscale gas flows have been proposed and developed for over ten years [19], these methods are far from completely established. The balance between accuracy and efficiency is still a problem. Recently, it has been found that the full-particle hybrid method may provide the best accuracy for the problem of coupling. The approach of finding efficient solvers for both continuum and high-Knudsen-number flows and then coupling them is promising. Another promising direction is coupling of the DSMC method for microscale gas flow to the MD method for special interfaces so as to deal with the unknown boundary conditions at the interfaces [20].
- *Multiphase processes.* Although the above Monte Carlo methods were developed for simulations of gas flows, they can also be used to analyze gas–particle interactions in granular flows, gas–liquid phase interactions in a liquid drop, and particle coagulation and aggregation. The proposed GEMC method will be very helpful for the analysis of multiphase processes in microscale gas flows.

Definition

Microneedles are a type of micromachined structure that promote the transport of substance through an interface or media, via enhanced permeability or microchannels. In most cases, microneedles are similar in shape to hypodermic needles, but are much smaller in size, enabling localized and painless delivery of drugs into cells or tissues. Microneedles, which can be either singular or grouped in arrays, are prepared using micro electro mechanical systems (MEMS) technology, and therefore can be produced in large batches from inexpensive metal, semiconductor, and polymer materials.

Overview

The microneedle concept was first proposed as a technique for transdermal drug delivery in the 1970s [1], and the recent advances in the microelectronics industry have provided the technical capability to make microneedles into reality. The first microneedle experiments were reported in 1998 [2]. Since then, there has been a rapid increase of interest in the field. Much of this effort concerns the development of novel needle fabrication technologies by adopting various needle designs and materials for use in biological and pharmaceutical applications.

Modern pharmaceutical technology is exploring a new generation of macromolecular medicines that are intended for applications in DNA research or directly as protein drugs. For these types of applications oral delivery is not a viable option because of the degradation of macromolecules in the stomach, intestines, or liver. In contrast, microneedles provide the means to locally and precisely deliver drugs, to take biomedical/neural measurements, and to perform microbiological sample analysis.

Currently, the smallest needles commercially available for injections are 30 gauge needles used in conventional syringes (305 um outer diameter), and 31 gauge used in pen injectors (254 um outer diameter). Microneedles, created by modern microfabrication technology, can be orders of magnitude smaller in diameter. The fabrication of microneedles involves one or more of the technologies in the area of MEMS (micro-electro-mechanical systems) including wet etching, reactive ion etching, chemical vapor deposition, and electroplating for casting of materials such as metals, and polymers. These needles are produced with high precision and, typically, are comparable to (or smaller than) the diameter of a human hair. Because of their small sizes, the injection is highly localized and damage to the tissue is minimal.

Applications

The applications of microneedles are many and varied. In the fields of genetic engineering, molecular and cell biology, it is desired to develop a method to introduce peptides, proteins, oligonucleotides, DNA and other probes into cells to alter their functions. For this purpose, microneedles can be applied for the delivery of molecules through impermeable membranes into cells. It has been demonstrated that microfabricated needle arrays could be used to deliver DNA into plant and mammalian cells, inducing cell transformation.

Another important application of microneedles is minimally invasive drug delivery. The small cross sectional area of microneedles, typically several hundreds of square micrometers, reduces any possibility of detrimental effects. At the same time, the drug delivery can be limited to a specific and localized region or tissue in the body. For this reason, microneedles have been used to study neural activities with very limited trauma to the tissue [3]. The short shaft of microneedles presents another advantage in drug delivery. Microfabrication technology allows the length of needle shafts to be controllable at a microscopic scale. The needles can be designed to penetrate just under the stratum corneum (the outer layer of the skin that has very low permeability). Since the nerve endings occur at a depth of about 100 μm, delivery at this location will reduce pain, infection or injury as well. In addition, because of the presence of a large number of capillaries in this layer of skin, the drug will be readily absorbed into the body, thereby enabling rapid treatment.

Microneedles can also be used to extract samples, thus finding significant applications in the field of health monitoring and biochemical analysis. For example, with diabetic patients, frequent use of needles is necessary for blood sampling to test glucose levels and to administer multiple doses of insulin. The use of microneedles can make it a virtually pain-free and a much more palatable experience to patients.

The applications of microneedles have expanded into electronics and sensors. They have been used as probes for surface modification and profiling, for example, in atomic force and scanning tunneling microscopes, and *Millipede* data storage. Microneedles have being applied in microdialysis where the microneedles are made permeable only to small molecular weight compounds. This protects the sensors from higher molecular weight compounds like proteins helping maintain the operational viability of the medical monitors. Other applications include printer heads and electrospray emitter nozzles.

Types of Microneedles

Microneedles can be classified into two groups, *solid microneedles* and *hollow microneedles*, depending on whether or not they contain a hollow bore for fluid transport. Solid microneedles increase the permeability of the skin or membrane by punching microscopic holes in the material. The transport of drugs or chemicals happens by diffusion or is assisted by applying an electric field, i. e., iontophoresis. These holes act as molecular pathways, readily permitting the transport from macromolecules to microparticles. On a clinical length scale, the holes are tiny compared to those from regular hypodermic needles and are therefore expected to be safer than their larger counterparts. With solid microneedles, transdermal drug delivery can basically be implemented in two approaches. One is to first make holes with microneedles to increase skin permeability, then remove the needles and apply drugs on the skin such as a patch. The other method is to coat the needles with drugs, then insert the needles into the skin and leave them there to release drugs. For the second method, people have investigated making microneedles with biodegradable polymers, into which drugs are incorporated. Once inside the skin, the polymer microneedle will disintegrate and be absorbed by living tissues gradually as a means of drug release.

Hollow microneedles work in a way similar to regular hypodermic microneedles. Fluids flow through the needle bore and into the tissue. The rate of fluid delivery is much faster than with solid microneedles, and the flow rate can be monitored and controlled over time. Using microfabrication technology, it is possible to build several bores or channels within one needle shaft with outlet ports at different locations along the shaft, so that more than one fluid can be injected at close spacing [4]. Also it is possible to integrate micropumps with microneedles onto a single microchip to further miniaturize the drug delivery system [3].

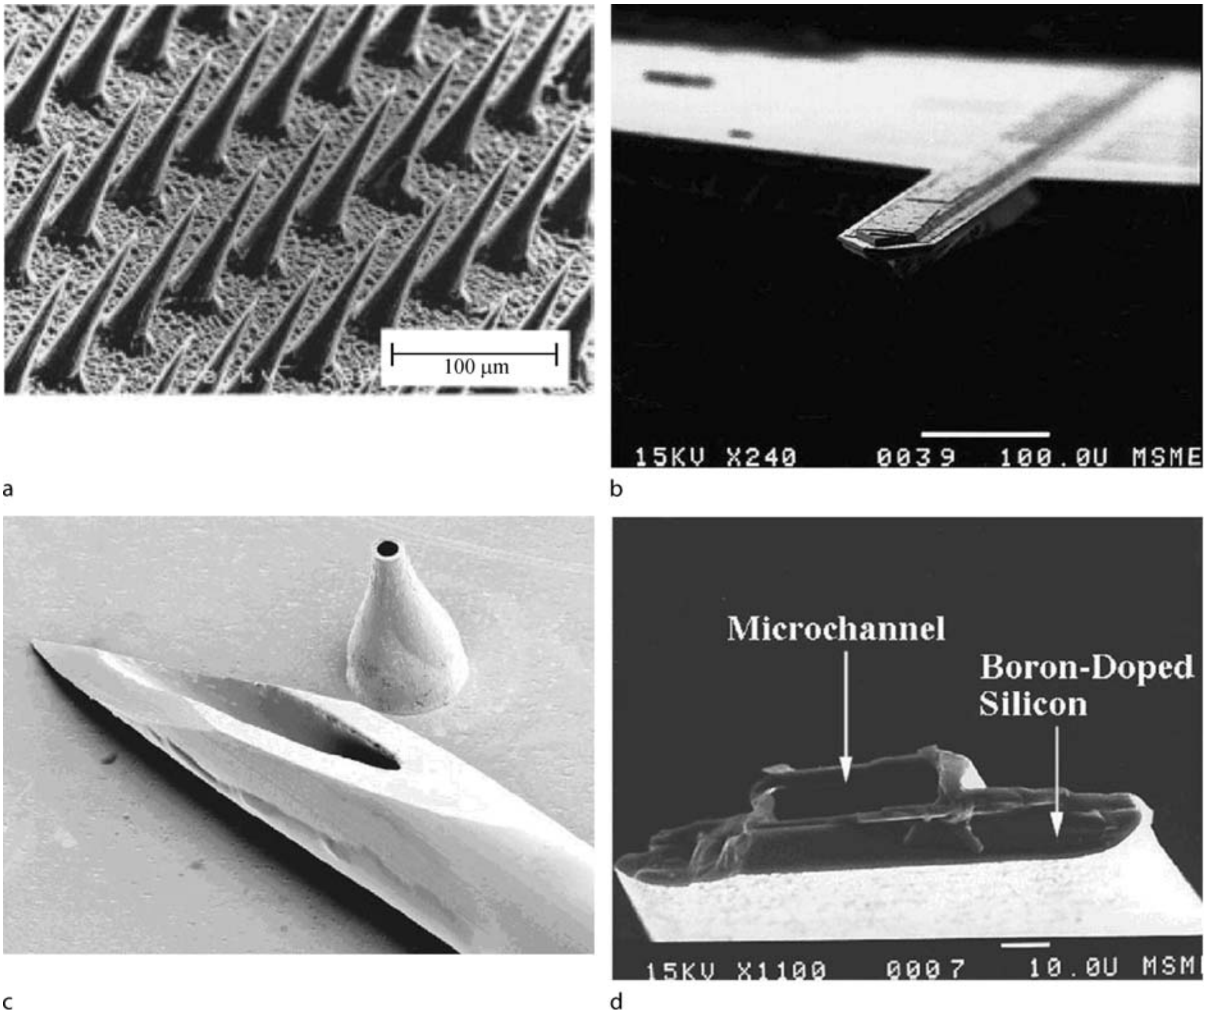
As far as microfabrication is concerned, especially with silicon-based processes, microneedle design can be classified as *out-of-plane* or *in-plane* depending on the orientation of the needle relative to that of the substrate material. Out-of-plane design refers to the microneedle configuration that protrudes perpendicularly from the plane of the substrate material (e.g. a silicon wafer), while in-plane refers to the design where the resulting needle lies lengthwise in the substrate plane. Examples of various microneedles (solid and hollow, out-of-plane and in-plane) are shown in Figs. 1a–d.

Because microfabrication is a two-dimensional (2D) technology in essence, microstructures are built from planar patterns projected onto the substrates by photolithography. Consequently, out-of-plane microneedles tend to have the same geometry along their length, since photolithography projects the needle cross-section onto the substrate. In contrast, in-plane microneedles can have various needle shapes, such as a bended needle shaft, because it is the needle side view being projected onto the substrate. In-plane needles have the possible advantage of building electrical, microfluidic, or optical functionalities on the needle shaft, which up to now has not been done with out-of-plane microneedles. With out-of-plane design, the micro-needle length is limited to be less than the substrate thickness, which is usually several hundred micrometers. If long microneedles are required, for example in the millimeter range, then the in-plane design is preferred. If it is desired to have a 2D array of microneedles that have repetitions of single needles in both x and y directions, then it is probably more efficient to fabricate with the out-of-plane design. With in-plane design, building a 2D-array requires additional fabrication steps, such as wafer bonding, which can be difficult and time consuming.

Failure Mechanisms

Penetration of microneedles into the tissue is essential to transdermal drug delivery. During the insertion, mechanical stress is induced onto the microneedles and causes them to break (fail). The failure modes of microneedles include buckling (compressive force), bending (from transverse tip force) and shear, since needles may not be perfectly aligned during insertion. Analysis has shown that shear is the least likely to cause failure, and bending is determined to be the critical failure mode [4]. For a 2 mm

M



Microneedles – Applications & Devices, Figure 1 (**a**) Solid out-of-plane microneedle array [2]; (**b**) Hollow in-plane microneedle [8]; (**c**) In-plane microneedle [3]; (**d**) Microchannel of the in-plane microneedle, produced by silicon surface micromachining [3]

long silicon microneedle with a cross-sectional area of 100 µm by 100 µm, the maximum transverse force at the tip (out-of-plane bending) is 0.124 N (force required to break the microneedle shaft). For in-plane buckling, it can sustain a force of 6.28 N compared to the 0.0809 N needed to penetrate chicken breasts [5].

Flow Characteristics

Flow rate of fluids through hollow microneedles is an important design criterion in meeting the dosing requirements of drugs. Therefore it is important to model fluid flow characteristics within the bores/channels of microneedles. Typically, channels within microneedles have dimensions around a few micrometers. The flow within such a microchannel is laminar, i. e., the fluid flow follows streamlines and is free of turbulence. The transition between laminar and turbulent flow generally occur when the Reynolds number is around 2300. Reynolds number is defined as

$$R_\mathrm{e} = \frac{\rho u D_\mathrm{h}}{\mu} ,$$

where ρ is the fluid mass density (kg/m^3), u is the average flow velocity through the channel (m/s), D_h is the hydraulic diameter (= 4×Cross-sectional Area/Perimeter) (m) and μ is the dynamic viscosity (Ns/m^2). Representative values of the Reynolds number in a microchannel ranges from 1 to 100, well below the transition number.

When external pumps are used to deliver fluids through the needles, the flow within the microchannel is pressure

driven *Poiseuille* flow at steady state. The pressure losses from flowing through a microchannel can be divided into three regions: entrance losses, pressure decrease due to the drag that fully developed flow exerts on the duct walls, and losses due to specific microneedle geometry (expansions, constriction, bends, etc.).

At entry point, the fluid flow profile can be significantly different from the parabolic profile of *Poiseuille* flows. There is a characteristic distance before the steady state *Poiseuille* profile can be established. This distance, between the entry point and the fully establishment of *Poiseuille* flow, is called the *entrance length*. At the end of the entrance length, the pressure gradient matches that of the fully developed flow. The entrance length, l_e, can be expressed in term of the dimensionless *entrance length number El*:

$$l_e = El \times D_h \,.$$

For laminar flow, the entrance length number is correlated with the Reynolds number as

$$El_{la\min ar} = 0.06 R_e \,.$$

So l_e can be expressed as

$$l_e = 0.06 \frac{\rho u D_h^2}{\mu} \,.$$

The entrance pressure drop (Pa, N/m^2) can be found by the following relationship:

$$\Delta P_{ent} = \frac{2.656}{D_h} \sqrt{\rho \cdot \mu \cdot u^3 \cdot l_e} \,,$$

where l_e is the entrance length or the channel length, whichever is shorter.

After the entrance length, the pressure loss in the fully developed parabolic region can be found by the *D'Arcy–Weisbach* equation:

$$\Delta P_{dev} = \lambda \cdot \frac{L - l_e}{D_h} \cdot \frac{\rho \cdot u^2}{2} \,,$$

where λ is *D'Arcy–Weisbach friction coefficient* and L is the length of microchannel (m).

Pressure loss due to geometry can be generally expressed as

$$\Delta P_{geom} = K_{Loss} \cdot \frac{\rho \cdot u^2}{2} \,,$$

where K_{Loss} is the geometric loss factor. The overall pressure loss is the sum of these factors.

$$\begin{aligned} \Delta P_{tot} &= \Delta P_{ent} + \Delta P_{dev} + \Delta P_{geom} \\ &= \frac{2.656}{D_h} \sqrt{\rho \cdot \mu \cdot u^3 \cdot l_e} + \lambda \cdot \frac{L - l_e}{D_h} \cdot \frac{\rho \cdot u^2}{2} \\ &\quad + K_{Loss} \cdot \frac{\rho \cdot u^2}{2} \end{aligned}$$

Basic Methodology

The fabrication of microneedles, in and of itself, is the the main challenge in microneedle development. The task involves finding fabrication techniques that are capable of defining materials precisely in three-dimensions at the micro scale and are amenable to mass production. Addtionally, the material used to produce the microneedles must be compatible with the fabrication tools and offer sufficient resistance to buckling, bending and shear forces. Microfabrication techniques (a.k.a. MEMS techniques) that evolved from integrated circuit technologies provide the capability to define needle features with submicron precision for both in-plane and out of plane needle design, providing a high degree of flexibility with respect to the creation of different needle designs. These technologies also allow many needles to be fabricated on a single substrate, thereby achieving repeatability and reproducibility.

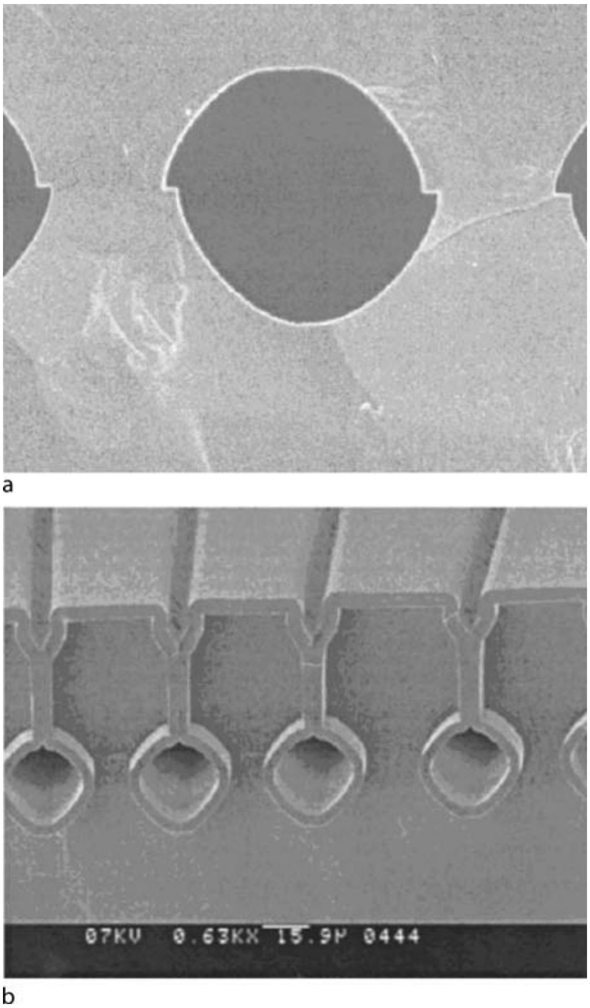
Microfabrication

Microfabrication techniques can be roughly categorized into surface micromachining, bulk micromachining, and micromolding. Surface micromachining is an additive process, which consists of depositing thin films, such as silicon nitride, polycrystalline silicon and other materials, onto substrates and dissolving sacrificial materials to form micromechanical structures. The thickness of the microstructures is limited to no more than several microns. The thickness restriction is directly related to the time period for processing that is determined by the deposition rate, etch rate, etc., and internal stresses introduced during the processing. As a result, surface micromachined structures tend to be fragile. In microneedle fabrication, surface micromachining is largely used for making microchannels. Bulk micromachining is a subtractive process that selectively removes significant amounts of material from a substrate to form microstructures. In bulk micromachining, the desired pattern is transferred onto the surface of a substrate from the mask by photolithography, and then, starting at the surface of the substrate, the pattern is etched into the substrate until the desired depth is reached. In most cases, the body of the microneedle is defined by bulk micromachining, i. e., three-dimensional features are etched into the bulk of the crystalline or

non-crystalline material. Finally, the microstructures are released from the substrate by dicing or dissolving the excess substrate material. Bulk micromachining can be achieved by using both dry and wet etching processes. Both surface and bulk micromachining techniques have been derived from their application in silicon-based technologies. Silicon was initially the material of choice in microfabricated devices because of its favorable electrical and mechanical properties. Recently, other materials, such as metals and polymers, have been applied in the fabrication of microdevices because of their desirable properties (e. g. biocompatibility and price). For those materials, techniques from outside the realm of silicon processing can be used, such as laser drilling, electroplating or a combination of techniques. Among them, micromolding is becoming increasingly popular as an unconventional fabrication method. With this method, typically a mold needs to be built first, which can be made from metal or silicon by bulk micromachining. The needle material is then cast into the mold to produce microneedles. With micromolding, microneedles can be easily mass-produced with a variety of materials.

Microchannel Fabrication

Hollow microneedles have microchannels to transport fluids, and those microchannels are enclosed within the microneedle shafts. To produce a closed microchannel, the following methods have been reported: substrate-to-substrate bonding such as anodic bonding, surface micromachining with a sacrificial layer, and a type of bulk micromachining known as *buried channel technology* by de Boer et al. [6]. Figure 2 and Fig. 1d show the microchannels produced by the above-mentioned methods, respectively. Bonding processes form a closed channel by joining two substrates with chemical or physical means. Alignment and a clean environment are critical to the bonding process, since particles and micro voids may be introduced during the process, which can change or even destroy the functional performance of the device. Surface micromachining produces closed microchannels by overlaying thin-film microstructures around a suitable sacrificial material on the surface of a substrate. The sacrificial material is later dissolved to leave an enclosed microchannel, thus avoiding the need for aligned bonding. The dimensions of such channels are generally restricted by the maximum sacrificial layer thickness. The third method, called buried channel technology (BCT), is a bulk micromachining method that makes trenches into the substrate, then selectively expands the trench bottoms into channels. Depositing a layer of dielectric over the substrates seals the channels.



Microneedles – Applications & Devices, Figure 2 (**a**) Microchannel formed by bonding [6]; (**b**) Microchannels formed by buried channel technology (BCT) [6]

Key Research Findings

Effectiveness of Microneedles

The most prevalent use of microneedles is in the delivery of drugs. It has been shown that solid microneedles can increase skin permeability to a broad range of molecules and nanoparticles in vitro by up to four orders of magnitude [7]. In vivo animal studies have demonstrated delivery of oligonucleotides and vaccines (Macroflux®), as well as induction of immune responses from protein and DNA vaccines [8, 9]. The functionality of hollow microneedles has also been demonstrated, including fluid transport in vitro and microinjection of insulin in diabetic rats to induce reduction of blood glucose levels [10]. Microneedles have also been used to extract interstitial fluid from skin for glucose measurement [11].

Mechanics of Microneedle Insertion

The mechanics of microneedle insertion are fundamentally important to practical applications. Only microneedles with the correct geometry and physical properties can be inserted into tissues. When the force required for insertion is too large compared with needle strength, microneedles can break or bend before insertion occurs. Two mechanical events play a critical role in microneedle insertion: the force required to insert microneedles and the force needles can withstand before fracturing. The fracture force must be larger than the insertion force for the microneedles to be functional.

Davis et al. [12] have investigated the insertion of microneedles over a range of geometries (tip radii between 30 – 80 μm and constant length of 500 μm). In their experiments, the insertion force was found to vary linearly with the interfacial area of the needle tip. Thin-walled hollow needles and solid needles with the same outer tip radii required the same force of insertion. Measured insertion forces ranged from approximately 0.1 – 3 N, which is sufficiently low to permit insertion by hand. The force required to fracture microneedles was found to increase with increasing wall thickness, wall angle, and possibly tip radius. For almost all geometries considered, the ratio of fracture force to insertion force, termed the margin of safety, was much greater than one and was found to increase with increasing wall thickness and decreasing tip radius. Thus, the margin of safety was found to be optimal for needles with small tip radius (to facilitate insertion) and large wall thickness (to provide strength).

Future Directions for Research

Up to now, the development of microneedles has focused on microfabrication techniques for Si and other biocompatible materials. Currently, there are several commercially available microneedle products, such as MTS® (Microstructured Transdermal System) by 3M, Macroflux® by ALZA and Micro-Trans™ by BioValve Technologies, and most of them are designed to increase skin permeability and adopt passive delivery methods (i. e., capillary force). As the feasibility of microneedles is well established, the next step is to understand the characteristics of fluid transport by microneedles, especially in vivo, and to interface microneedles with external dosing control for active drug delivery. A very important aspect in microneedle development is to become closely involved with pharmaceutical research. Microneedle injection can control well the depth of drug delivery to receptive intradermal, junctional or subcutaneous tissues, and some medicines of large molecule seem to have better and faster absorption when given intradermally rather than subcutaneously. Also the pharmacokinetics may change, e.g. medicine may preferentially migrate to the lymphatic system, and this could potentially help in the treatment of many types of cancer, including certain types of leukemia, lymphomas, melanomas, etc. By investigating microneedle design and fabrication in conjunction with drug delivery mechanism, revolutionizing changes may be brought about in the medicine field.

Brownian noise

Definition

Brownian motion of submicron-sized tracer particles is a significant source of error in µPIV measurements, which can be substantially reduced by ensemble averaging over multiple images. This unbiased noise can be measured to obtain temperature, viscosity, or particle size information.

Overview

Microparticle imaging velocimetry (µPIV) is an established nonintrusive technique to obtain accurate velocity data with high spatial resolution and is widely used as a design tool for most microfluidic devices. In typical µPIV experiments, the fluid is seeded using submicron-sized particles, which are small enough to exhibit Brownian motion. It was recognized very early on that the random movement of these particles contributed a significant source of error for low-velocity flows. This undesirable error was substantially minimized through ensemble averaging over multiple images. The precise effect of Brownian motion on the spatial cross-correlation function must be understood in order to make useful measurements.

Basic Methodology

In PIV analysis, the cross-correlation function between two ideal images would have a single peak. The location of the peak gives an estimate of the mean velocity of the fluid, and the shape of the cross-correlation function contains information about the particle size, and about any fluctuations in the velocity. Brownian motion of the tracer particles introduces an error into the location of the correlation peak. Since Brownian motion is an unbiased noise source, ensemble averaging over multiple correlation peaks should help to minimize this error. However, as a result of the averaging process, the peak width of the correlation function is broadened. Olsen and Adrian [9] performed a theoretical study of the effect of Brownian motion on the µPIV correlation signal peak and derived a function quantifying the broadening of the correlation function.

Brownian Motion in a Stationary Fluid

As described by Hohreiter et al. [6], the idea of PIV *diffusometry* is based on the theory of Brownian motion. The Eq. (1)

$$D = \frac{\mathrm{k}T}{3\pi \mu d_{\mathrm{p}}} \tag{1}$$

defines the diffusivity D of particles with diameter d_{p} immersed in a liquid with absolute viscosity μ and temperature T; k is Boltzmann's constant. The mean square of the expected distance traversed by a particle with diffusivity D within a time Δt is given by the Eq. (2)

$$\left\langle s^2 \right\rangle = 2D\Delta t \tag{2}$$

In a typical PIV experiment, two snapshots of the flow field are obtained at times t_1 and $t_2 = t_1 + \Delta t$. If these two images are denoted by $I_1(X)$ and $I_2(X)$, then the cross-correlation function can be obtained using the convolution integral (Keane and Adrian [7])

$$R(s) = \int I_1(X) I_2(X+s)\,\mathrm{d}X\,. \tag{3}$$

$R(s)$ can be decomposed into three components as follows:

$$R(s) = R_{\mathrm{C}}(s) + R_{\mathrm{F}}(s) + R_{\mathrm{D}}(s)\,, \tag{4}$$

where $R_{\mathrm{C}}(s)$ is the convolution of the intensities of the two images with its diameter equal to the particle diameter, $R_{\mathrm{F}}(s)$ is the fluctuating noise component, and $R_{\mathrm{D}}(s)$ is the displacement component of the correlation function and gives the distance traveled by the particle during a time Δt. Hence $R_{\mathrm{D}}(s)$ is the component of the correlation function which contains the velocity information.

The displacement and width of the correlation function depend on the probability function $f\left(x', t_2; x, t_1 \middle| u(x), T\right)$, where f denotes the probability that a particle initially at (x, t_1) will move into the volume $(x', x' + \mathrm{d}x)$ at t_2 for a known velocity field $u(x)$ and temperature T. In the absence of Brownian motion, $\Delta x = u(x, t_1)\Delta t$ is the displacement undergone by a particle at (x, t_1). Since for a given velocity field there can only be one final location for the particle, the probability function f becomes the delta function

$$f\left(x', t_2; x, t_1 \middle| u(x), T\right) = \delta\left(x' - x - \Delta x\right)\,. \tag{5}$$

However, in the presence of Brownian motion, an exact value of the displacement Δx cannot be defined and, as a result, f is no longer a delta function. Instead, f is now a probability distribution function centered at $x' = x + \Delta x$, and its shape is defined by the space–time correlation for Brownian motion given by Chandrasekhar [5],

$$f\left(x', t_2; x, t_1 \middle| u(x), T\right) = (4\pi D\Delta t)^{-3/2} \times \exp\left[-\frac{\left(x' - x - \Delta x\right)^2}{4D\Delta t}\right] . \quad (6)$$

This change in f due to Brownian motion has the effect of broadening the correlation function and reducing its height. The increase in the width of the correlation function contains information that yields the temperature. This effect is demonstrated in Fig. 1, which shows correlation functions with and without Brownian motion.

Olsen and Adrian [9] derived analytical expressions to define the shape and height of the correlation function in the presence of Brownian motion for both light-sheet PIV and volume-illumination PIV. In both cases, the correlation function assumes a Gaussian shape and its center is located at the mean particle displacement. In light-sheet PIV, the field of view of the camera can be set to be greater than the thickness of the laser sheet so that all of the particles in the image can have the same diameter and peak intensity. The characteristics of the imaging optics play an important role in defining the relationship between the actual cross section of a particle and that of its image (Adrian [1]). Given a diffraction-limited lens, the image of a particle is the convolution of the geometric image of the particle and the point response function of the imaging system. The point response function is an Airy function with a diameter given by

$$d_s = 2.44(1 + M) f^{\#} \lambda , \quad (7)$$

where M is the magnification of the lens, $f^{\#}$ is the f-number of the lens, and λ is the wavelength of the light used to image the particles. Adrian and Yao [2] found that the Airy function and the image of a particle can be approximated by Gaussian functions, in which case the diameter of the particle image can be expressed by the formula

$$d_e = \left(M^2 d_p^2 + d_s^2\right)^{1/2} , \quad (8)$$

where d_p is the particle diameter and M is the magnification of the lens used.

In volume-illumination PIV (for example μPIV), the particle images are more complex. Since the entire channel is illuminated, all of the particles within the depth of field of the camera contribute to the resulting image. The particles close to the focal plane form sharp images, while the particles away from the focal plane form dim, blurred images. Olsen and Adrian [10] proposed that the particle image diameter in μPIV can be approximated by

$$d_e = \left(M^2 d_p^2 + d_s^2 + d_z^2\right)^{1/2} , \quad (9)$$

where

$$d_z = \frac{M z D_a}{x_0 + z} \quad (10)$$

and D_a is the aperture diameter of the microscope objective, z is the distance of the particle from the focal plane, and x_0 is the object distance.

From an analysis of cross-correlation PIV, Olsen and Adrian [10] found that for light-sheet PIV, the width of the correlation peak Δs_0, taken as the diameter of the Gaussian function measured at a height of $1/e$ times the peak value, can be expressed as

$$\Delta s_{o,a} = \sqrt{\frac{2 d_e^2}{\beta^2}} \quad (11)$$

in the absence of Brownian motion. When Brownian motion is present, the peak width $\Delta s_{o,c}$, can be expressed as

$$\Delta s_{o,c} = \sqrt{\frac{2\left(d_e^2 + 8M^2\beta^2 D\Delta t\right)}{\beta^2}} . \quad (12)$$

Equation (12) reduces to Eq. (11) when the Brownian motion $(D\Delta t)$ is assumed to be zero. The constant β is a parameter arising from approximating the Airy function by a Gaussian function and was found to be equal to $\beta^2 = 3.67$ (Adrian and Yao [2]).

In the case of volume illumination, Eqs. (11) and (12) still hold, except that the term for the particle image diameter d_e must be replaced by an integral over the depth of the device. The cumbersome calculation of the integral term for d_e can be avoided by manipulation of Eqs. (11) and (12). Squaring Eq. (11) and subtracting it from the square of Eq. (12) gives the equation

$$\left\langle s^2 \right\rangle = \frac{\Delta s_{o,c}^2 - \Delta s_{o,a}^2}{8M^2} = \frac{2k\Delta t}{3\pi d_p} \cdot \frac{T}{\mu} , \quad (13)$$

which can be used directly to calculate the temperature.

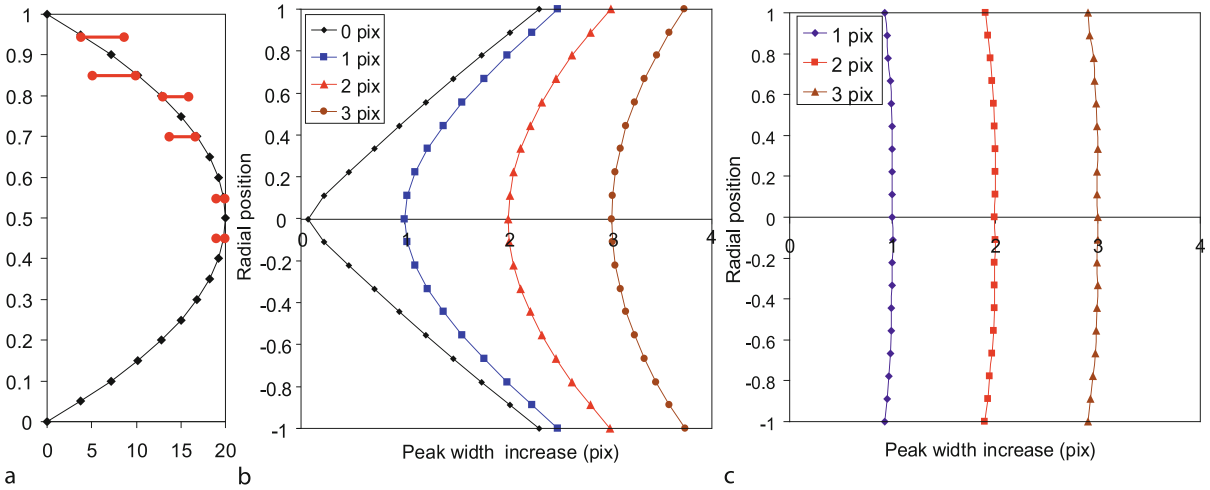
Brownian Motion in a Moving Fluid

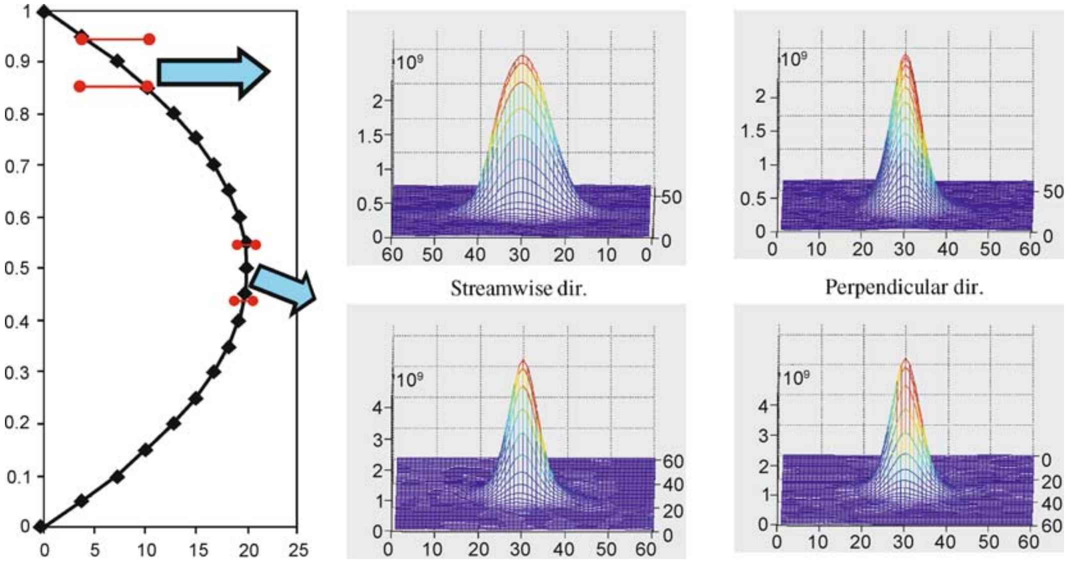
In the presence of a nonuniform velocity field, if there is a velocity gradient present across the interrogation window, the correlation function is deformed accordingly. In the case of a Poiseuille flow, the velocity gradient is nonuniform across the channel. As a result, the probability distribution function f has a Brownian-motion component and a velocity distribution component. For simple flows, if the velocity profile is known, the probability distribution of velocities and the resulting broadening of the cross-correlation function can be computed. This can be subtracted from the total measured value to obtain the broadening due to Brownian motion alone. In this analysis, a steady flow is assumed.

The feasibility of this method will be illustrated here with the help of a numerical experiment, as described below. Figure 2a shows the velocity profile across the channel; the red lines show the velocity gradients present in the interrogation window at different locations. A uniform Brownian motion (temperature profile) is assumed across the channel. Figure 2b shows the broadening in the cross-correlation function for different amounts of Brownian motion. The x-axis shows the increase in the peak width in pixels, and the y-axis shows the radial location across the channel. It can be seen that the peak width increase is greatest near the walls, where the maximum velocity gradient is also present. In the absence of Brownian motion, the increase in peak width is due only to the velocity gradients present. As the amount of Brownian motion increases, the curve becomes flatter. The peak width increase due to Brownian motion alone can be obtained by subtracting the peak width increase caused by the velocity gradient alone. Figure 2c shows this subtracted value. It can be seen that by subtracting the velocity gradient information, information about the Brownian motion can be obtained.

The peak widths of the cross-correlation function in the streamwise direction and the perpendicular direction are shown in Fig. 3. The cross-correlation function in the streamwise direction near the wall is broader than the cross-correlation function near the center of the channel, owing to the high velocity gradients near the walls. Since there are no velocity gradients present in the radial component of velocity, the peak width of the cross-correlation function in the perpendicular direction is uniform across the channel.



Micro-PIV-Based Diffusometry, Figure 2 Broadening of the correlation function due to a velocity gradient



Micro-PIV-Based Diffusometry, Figure 3 Illustration of the effect of a velocity gradient on the cross-correlation function

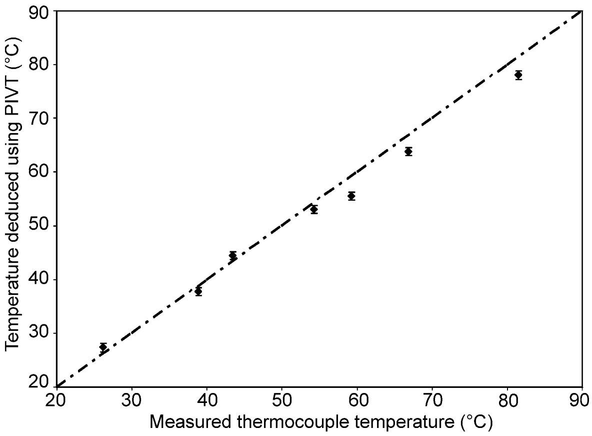
Prior knowledge of the velocity field is required for this method to work. In practice, this can be achieved by measuring the velocity field first and then using that information to measure the temperature field. Since the velocity information is decoupled from the temperature information, this does not pose a problem.

Key Research Findings

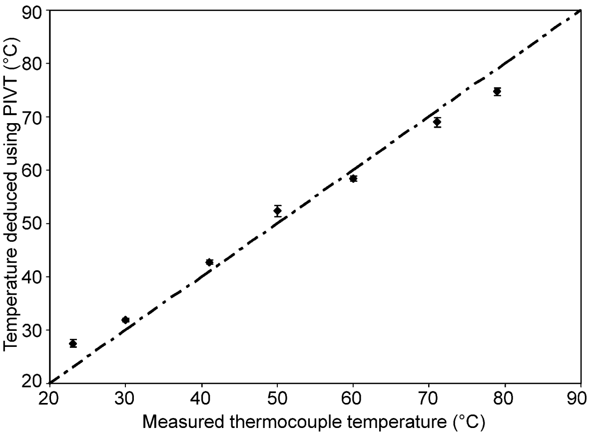
Temperature Measurement Using Brownian Motion

Combining Eqs. (1) and (2), it can be seen that, if all other variables are held constant, the mean square displacement $\langle s^2 \rangle$ is dependent only on the temperature, as given by the relationship $\langle s^2 \rangle \alpha T/\mu$, since the absolute viscosity μ is a strong function of temperature. For a gas, increasing the temperature increases the absolute viscosity, which in turn, might increase or decrease the value of T/μ, depending on the fluid. For a liquid, increasing the temperature decreases the absolute viscosity, and hence the value of T/μ is always increased. Hence, if the diffusion coefficient of a particle and its diameter are known along with the viscosity of the fluid, the temperature of the fluid can be determined.

This method was proposed by Santiago et al. [11] and experimentally verified by Chamarthy et al. [3]. The image was split into smaller windows of a specified size. An



Micro-PIV-Based Diffusometry, Figure 4 Temperatures in a stationary fluid deduced using the PIV based Thermometry (PIVT) method plotted against the temperatures measured with a thermocouple. The average difference between the predicted and measured temperatures was ±2.1 °C



Micro-PIV-Based Diffusometry, Figure 5 Temperatures in a moving fluid deduced using the PIV based Thermometry (PIVT) method plotted against the temperatures measured with a thermocouple. The average difference between the expected and average temperatures was ±2.6 °C

interrogation window size of 128×128 px was used so that there would be particles present in every window. Evaluation functions were then read and processed in MATLAB. The evaluation functions were averaged over the entire image, and a 2D Gaussian fitting program was used to measure the peak width of the evaluation function. In order to fully characterize a 2D Gaussian function, given by the Eq. (14)

$$G(x, y) = A \exp\left(\frac{-(x - x_0)^2}{2\sigma_x^2}\right) \cdot \exp\left(\frac{-(y - y_0)^2}{2\sigma_y^2}\right), \tag{14}$$

five parameters must be defined: the peak height A, the coordinates locating the peak center x_0 and y_0, and the values of the standard deviation in the x and y directions σ_x and σ_y. If σ_x is equal to σ_y then the Gaussian function has a circular cross section; otherwise, it has an elliptical cross section. The standard deviation is related to the peak width by $\Delta s^2 = 8\sigma^2$, and contains the Brownian-motion information. In the case described here, since the images were taken far from the walls of the channel, the Brownian motion should be identical in all directions, resulting in a circular Gaussian function.

The temperatures were calculated using Eq. (13) and are plotted in Fig. 4. The advantage of this method is that a high concentration of particles can be used as long as the particles do not interact with each other, yielding the highest possible number of data points. Also, for the purpose of measuring temperature in the presence of a flow field, this method would be much less cumbersome than a particle-tracking technique. The main disadvantage of this method is the error introduced into the measurement of the shape of the correlation function owing to uneven illumination and background noise in the image. Standardized image-processing techniques must be used to eliminate this noise. Also, advanced algorithms such as those for central difference image correction (CDIC) and continuous window shifting (CWS) cannot be used, as they distort the shape of the correlation function.

PIV-based temperature measurement in a moving fluid was experimentally verified by Chamarthy et al. [4]. Since the Brownian motion along each coordinate axis is independent of that along the other axes, the diffusion in the x and y directions was measured separately at each location. The x-axis was taken as the axial direction and the y-axis as the radial direction. As a uniform temperature was applied across the channel, the Brownian motion in the x and y directions should be uniform along the radial direction. Since the velocity gradient affects only the standard deviation in the x direction (σ_x), σ_y is a measure of the Brownian motion alone and should be uniform across the channel. The value of σ_x contains both Brownian-motion and velocity-gradient information and varies according to the gradients present in each window.

The temperature values obtained from the mean increase of the peak width in the y direction are plotted against the expected values in Fig. 5. The average difference between the measured and expected temperatures was found to be ±2.6 °C.

Brownian-Motion-Based Biosensor

Brownian motion of suspended particles can be used as a means for the detection of biological agents. If the tem-

perature of the fluid is known, the diffusion is a function only of the viscous drag acting on a particle. In this method, fluorescent particles are functionalized with antibodies against a specific analyte and are introduced into a sample containing that analyte. As the analytes bind to the particles the hydrodynamic drag is increased, causing a decrease in the diffusion coefficient, which can be measured using μPIV techniques.

The common methods for biological-agent detection measure binding events using fluorescence, bioluminescence, surface plasmon resonance, changes in impedance, changes in the resonance of a microbalance, and changes in the conductance of nanowires. Typically, such biosensors use "sandwich" assays for detection and measurement. The disadvantage of using sandwich assays is that it is difficult to produce two antibodies that each bind to different sites of an antigen. Also, the probability of two binding events occurring on a single antigen is much less than that of a single binding event.

The advantage of a diffusion-based biosensor is that it avoids the need for a sandwich assay by directly measuring the reduction in the diffusion coefficient of antibody-functionalized submicron particles caused by the binding of complementary antigens. This technique should be useful for bioanalytical techniques for drug discovery, and for pathogen detection in complex media.

Microrheology Using Brownian Motion

Studying rheological properties within cells and complex fluids is an important step in understanding biological motility. Cell biologists have discovered that many aspects of a cell's gene expression, such as locomotion, differentiation, and apoptosis, are also governed by the stress and elasticity of its surroundings. However, standard mechanical and optical rheological techniques cannot be applied at such small length scales.

Recently, Brownian-motion-based techniques have been developed to measure local rheological properties and resolve microheterogenities inside such complex fluids. Particle-tracking techniques have been used to measure the displacements of individual particles and calculate their diffusion using Eq. (2). The disadvantage of single-particle tracking is that a large volume of data needs to be taken to obtain a statistically averaged result. Moreover, the probability of a particle diffusing out of the region of interest increases as the measurement time increases. A large number particles can be used in PIV-based methods, so that the measurement time can be reduced. Also, the loss of a few particles due to diffusion out the region of interest does not severely affect the measurement.

Future Directions for Research

The PIV-based diffusometry method is still in its infancy and has the potential to be developed into a powerful tool that can be used across several different disciplines. The sensitivity of the technique can be increased by increasing the magnification, decreasing the size of the pixels in the camera, and increasing the number of images obtained. The particle size and the time between a pair of images need to be chosen such that the particles diffuse by more than the linear dimensions of a pixel. The technique is especially sensitive to particle clumps present in the measurement region. An efficient, easy-to-use algorithm for diffusometry techniques needs to be developed in order to increase the usage of the technique.

Microrockets

KENNETH S. BREUER
Division of Engineering, Brown University, Providence, RI, USA
kbreuer@brown.edu

Synonyms

Microthrusters; Microjets

Definition

Microrockets are microfluidic systems that generate a high speed (supersonic) jet of gas, used either for propulsion, materials processing or other applications.

Overview

Microrockets generate high speed gas jets by expanding a gas (or vapor) through a converging-diverging nozzle to generate high speed supersonic jet at the exit. The appeal of microrockets derives from the *cube-square* law. In general, the thrust of a rocket is determined by the plenum pressure, P_c, and the nozzle throat area of the rocket, while the mass of propellant used is proportional to the plenum pressure and the *volume* of the system. Thus the thrust-to-weight ratio of a rocket will increase as the characteristic scale decreases:

$$\frac{F}{m} \propto \frac{P_c L^2}{P_c L^3} = \frac{1}{L}\,.$$

However, at the microscale, the performance of the microrocket is limited by viscous losses due to the low Reynolds number of the expanding flow. These losses are characterized by the thrust efficiency which compares the observed momentum flux to the momentum flux predicted for an ideal (zero viscosity) fluid. Computations and experiments (for example, Bayt and Breuer 2000 [1]) confirmed supersonic exit flow and have found efficiencies ranging from 10% - 80%, depending on the Reynolds number of the system, which in turn depends directly on the size of the throat and the fluid temperature and pressure as it passes through the nozzle, prior to supersonic expansion. The performance of the system can be improved by raising the temperature of the gas. Examples include using an electrical heater in the plenum upstream of the throat (Bayt and Breuer 2001 [2]), and using a chemical reaction, such as combustion (London et al. 2001 [3]).

Microrotorcraft

LAURA SCHAEFER
Mechanical Engineering and Materials Science Department, University of Pittsburgh, Pittsburgh, PA, USA
las149@pitt.edu

Synonyms

Microair vehicle (MAV); Unmanned rotorcraft; Miniature unmanned air vehicle (UAV); Mesicopter; Microdrone

Definition

Microrotorcraft are small scale vehicles for which both the thrust and the directional control are provided using rotors. Although the rotorcraft themselves do not fall within the traditional length scales of microsystems, micromanufacturing techniques must be applied to create the rotors and motors, and microscale effects dominate the aerodynamic behavior.

Overview

Specifications and Aerodynamics

Microrotorcrafts are a subcategory of microair vehicles (MAVs), other permutations of which include fixed-wing MAVs, flapping-wing MAVs, and microrockets. In 1996, the Defense Advanced Research Projects Agency (DARPA) defined the principal characteristics of MAVs to be that they must not exceed 15 – 20 cm in length, width, or depth and have a flight speed of 10 – 20 m/s. Additionally, MAVs must weigh less than 100 g and be capable of carrying a payload of up to 20 g for 20 – 60 min over a distance of up to 10 km. Each unit should also cost less than $ 1000 to produce. In addition to satisfying these requirements for MAVs, microrotorcrafts must rely solely on two or more rotors to supply both the thrust and directional control for their flight. Although there is currently no microrotorcraft (or any other MAV) that satisfies all of these requirements, progress has been made over the past ten years toward achieving some of these goals.

Microrotorcrafts could be used for a variety of missions. Their portability and hovering capabilities make them well-suited for military surveillance missions (also categorized as hover-and-stare missions), as well as for other data gathering activities. Furthermore, clusters of microrotorcrafts could be used to provide insight into weather phenomena, pollution dispersal, wave patterns, etc. Finally, because microrotorcrafts are unmanned, they could also be used in hazardous environments (whether due to biological, chemical, or other causes) or for extra-planetary or low-gravity missions, such as exploration of Mars.

The dimensions of microrotorcrafts (as with other MAVs) mean that these vehicles operate in a relatively low Reynolds number regime, on the order of 10^4 (in comparison to large aircraft, which may have Re values in excesses of 10^9). At low Re, viscous effects become dominant. In this regime, the aerodynamic efficiency of microrotors is significantly smaller than is seen for conventional rotorcraft on the macroscale [1]. Other aerodynamic consequences of low Re flow are that the thermal boundary layer thickness is large compared to the airfoil chord size, and can affect the potential flow region, and that the pressure will not necessarily be constant throughout the boundary layer.

There are limited theoretical or numerical analysis tools available for low-Re aerodynamic effects and many of the predicted phenomena must be verified experimentally. For example, in the design of his mesicopter, Kroo evaluated two potential codes that might be able to apply to microrotorcraft modeling [2]. Both codes are Navier–Stokes solvers: the FLO103 (which is a Reynolds-averaged Navier–Stokes solver) and the INS2D (which solves the incompressible Navier–Stokes formulation). He also studied the applicability of the MSES program, which divides the flow field into an outer and an inner flow region. Other researchers (such as [1]) have relied on commercially-available codes such as FLUENT, despite some of that solver's limitations at low Reynolds numbers.

Comparison of Microrotorcrafts and Fixed-Wing MAVs

Some of the advantages of microrotorcrafts over fixed-wing MAVs are their potential agility, hovering capabil-

ity, and vertical take-off. The largest disadvantage is their lower endurance. Green and Oh showed this mathematically as a simple function of thrust for two different configurations, as outlined below [3].

For both a fixed-wing MAV and a microrotorcraft, the endurance (or active flight time) of the craft can be characterized as the capacity of the power source divided by the current draw of the motor. For a rotorcraft, the thrust (T) generated by the propeller is:

$$T_{\text{rotor}} = C_{\text{T}} \rho A (\omega R)^2 , \tag{1}$$

where C_{T} is the thrust coefficient, ρ is the density, and ω is the angular velocity. It is clear that T is directly proportional to the square of ω. The propeller is powered by the motor, and the motor's shaft speed is directly proportional to its current draw, so that:

$$E \propto \frac{1}{\sqrt{T}} , \tag{2}$$

where E is endurance.

For a fixed-wing craft, the thrust is equal to the drag on the craft:

$$T_{\text{fixed}} = D = \frac{1}{2} \rho V_{\infty}^2 S C_{\text{D}} , \tag{3}$$

where V_{∞} is the free-stream velocity, S is the wing area, and C_{D} is the coefficient of drag. Therefore, combining Eqs. (1)–(3), the resulting ratio of the fixed-wing and rotorcraft endurance is:

$$\frac{E_{\text{fixed}}}{E_{\text{rotor}}} = \sqrt{\frac{T_{\text{rotor}}}{T_{\text{fixed}}}} . \tag{4}$$

The thrust required for a rotorcraft will be equal to its weight, while the thrust required for a fixed-wing craft will be significantly less than the weight, even given a poor span efficiency. Therefore, from Eq. (4), the endurance of the fixed-wing craft will be greater than the endurance of the rotorcraft.

Another simpler way of considering this issue is the familiar comparison of thrust to the lift-to-drag ratio:

$$T = \frac{W}{\text{Ratio}_{\text{LD}}} , \tag{5}$$

where W is the weight. Since typical fixed-wing vehicles can achieve lift-to-drag ratios of $20-100$, their required thrust is much less than that of rotorcrafts. However, since the lift-to-drag ratio will decrease with the scale of a MAV, it has been theorized that the endurance characteristics of microrotorcrafts may at some scales become competitive with fixed-wing MAVs.

Example Microrotorcraft Configurations

Proposed microrotorcraft designs can generally be grouped into categories depending on the number of rotors that are utilized. These include single rotor configurations (such as tip-jets), ducted or unducted twin rotors (for example, the Cypher and Cypher II), and crafts with four or more rotors (the Gyronsaucer, Roswell Flyer, Stanford's Mesicopter, etc.) [4].

There have been a variety of microrotorcraft designs hypothesized and prototyped. These include the Kolibri model, which had a ducted fan design. Although the diameter of the Kolibri rotor fell within the aforementioned DARPA specifications, it could only hover for a maximum of 20 min, and its weight was 320 g. The ISTAR configuration also uses a ducted fan, but weighs over 1.8 kg [1].

Kunz proposed two potential microrotorcraft designs. The first had a gross take-off mass of only 17 g. It utilized four four-blade ducted rotors, each with its own rotor, and arrayed around a control circuit. Each rotor unit was only 2.5 cm in diameter. This device was not self-powered, however, an issue that would add considerable weight to the final design, given that the hover power was calculated to be 16 W. Kunz also developed a 65 g microrotorcraft. Again, this craft used 4 rotors around a central control circuit. However, the rotors were not ducted, and consisted of 2 blades apiece, with a total rotor diameter of 6.35 cm. The hover power requirement was 15 W, which could be maintained for one minute, given the on-board power supply. Finally, Kunz also developed a much larger prototype that weighed 150 g, utilized four unducted two-blade rotors (10 in diameter), and could carry a 20 g payload for 5 to 20 min [5].

Oh et al. designed and built a two-blade, backpackable microrotorcraft specifically designed for hover-and-stare operations [6]. Their device was longer (17" × 8" × 4") and heavier (450 g) than the DARPA guidelines, but was capable of hovering for up to 90 s using standard lithium poly batteries while delivering image data from an on-board camera.

Young et al. have provided a review of a number of their proposed microrotorcraft designs [7]. These include a quad-rotor tail sitter, which uses rotor speed control for vehicle trim, and can engage in hovering or forward flight; a mini-morpher, which can change shape to operate as either a ducted-fan flier or a hybrid rotorcraft/fixed-wing vehicle; a tandem twin-fuselage tiltrotor, which employs two rotors mounted between two joined fuselages; and a coaxial helicopter, where two two-blade rotors are mounted coaxially are controlled by two coupled drive trains.

Bohorquez et al. designed, built, and tested both single rotor and coaxial dual-rotor vehicles they dubbed MICOR [4]. The single rotor device had a takeoff weight off 100 g, and was able to hover for 3 m using its on-board power supply.

Improving Microrotorcrafts

Some of the primary obstacles to meeting the original DARPA guidelines are a satisfactory level of power for the microrotorcraft motor(s), device durability, flight control technologies and strategies, sensor weight and secure and reliable communication, and not just understanding, but also capitalizing on low-Re aerodynamic phenomena. More details on the methodology for addressing these areas, current research findings, and future challenges are provided in the following sections.

Basic Methodology

Figure of Merit

The figure of merit for a rotor is a simple ratio of the ideal power to the actual power required to hover. While the ideal power is simply a function of thrust and velocity, the actual power accounts for both the ideal power and the profile power. Neglecting induced power (the power needed to overcome the drag that results from changes in the flow caused by the lift), the figure of merit for a hovering rotorcraft then becomes:

$$FM \approx \frac{P_{\text{ideal}}}{P_{\text{ideal}} + P_{\text{profile}}} . \tag{6}$$

The ideal power is simply:

$$P_{\text{ideal}} = T v_{\text{hover}} = T\sqrt{\frac{T}{2\rho A}} = \frac{T^{3/2}}{\sqrt{2\rho A}} , \tag{7}$$

while the profile power (the power required to overcome form drag and skin friction) is:

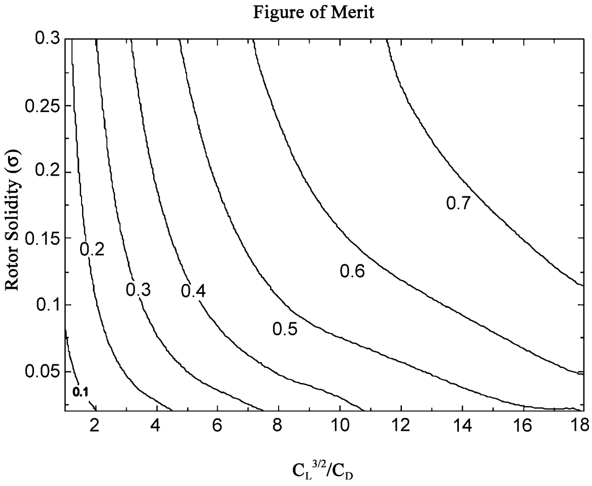
$$P_{\text{profile}} = N_{\text{b}}\Omega \int_0^R \frac{1}{2} C_{\text{D}} \rho V_d^2 c y \, \text{d}y , \tag{8}$$

which can be approximated as [5]:

$$P_{\text{profile}} \approx \frac{\rho \sigma C_{\text{D}} (\omega R)^3 A}{8} , \tag{9}$$

where σ is the rotor solidity:

$$\sigma = \frac{N_{\text{b}} c}{\pi R} . \tag{10}$$



Microrotorcraft, Figure 1 The figure of merit for a microrotorcraft plotted as a function of rotor solidity (σ) and $C_{\text{L}}^{(3/2)}/C_{\text{D}}$ for a coefficient of lift of 0.5

The thrust (see Eq. (1)) can also be approximated as a function of these variables:

$$T \approx \frac{\rho \sigma \pi C_{\text{L}} (\omega R)^2 R^2}{6} . \tag{11}$$

Combining Eqs. (6), (7), (9) and (11) yields [5]:

$$FM \cong \frac{1}{1 + \left(\frac{3}{2}\frac{C_{\text{D}}}{C_{\text{L}}}\sqrt{\frac{3}{\sigma C_{\text{L}}}}\right)} . \tag{12}$$

It should be noted from Eq. (12) that for rotorcraft, although the general trend is the same, the maximum of the ratio of $C_{\text{L}}^{(3/2)}/C_{\text{D}}$ is more important to the figure of merit than the L/D ratio [1]. For a coefficient of lift of 0.5 (which is reasonable for microrotorcraft), it can be seen in Fig. 1 that the figure of merit increases with increasing $C_{\text{L}}^{(3/2)}/C_{\text{D}}$.
If the induced power is accounted for, the figure of merit can instead be expressed as [4]:

$$FM = \frac{\sqrt{\frac{C_{\text{T}}^3}{2}}}{\kappa\sqrt{\frac{C_{\text{T}}^3}{2}} + \frac{\sigma \bar{C}_{\text{D}}}{8}} . \tag{13}$$

Where C_{T} is the thrust coefficient, $\bar{C}_{\text{D}}$ is the mean drag coefficient, and κ is the induced power factor.
In addition to this rigorous statement of the figure of merit, there are also other criteria that can be used to quantify the effectiveness of a microrotorcraft [8]. These include how well the inherent properties of a microrotorcraft can be utilized by the operator, whether the performance fits

M

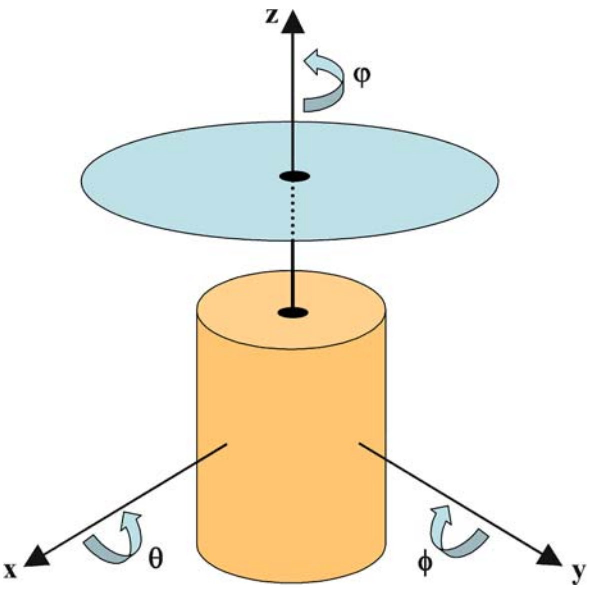
the needs of a particular task, what is the short term performance (or bandwidth), the speed at which the microrotorcraft can make moderate attitude changes, and what is the achievable attitude rate. Further considerations include the simplicity of the vehicle, the ease of payload packaging, and the compactness of folding [4].

Control Methods

Development of control methodologies for microrotorcrafts is complicated on a number of levels. The rotors provide both the thrust and the directional control for the vehicles, and the resulting microrotorcraft motion is affected by the user's inputs, by interactions between the rotors, and by external/environmental factors. For a microrotorcraft, controls must be designed and implemented for the vertical, longitudinal, and lateral directions, as well as for the yaw (the rotation about a craft's vertical axis). While yaw and thrust can be changed by varying the speed of the rotor motors, more sophisticated techniques are required for lateral control. Three potential methods for accomplishing this are flaps, a gimbaled drive train, and reaction jets [4]. Although microrotorcraft controls are still in the development stage, there are well-established linear control laws for macroscale rotorcrafts that could potentially be adapted to microrotorcraft design and operation. It is likely that the most effective control laws for microrotorcrafts will come from the intersection of first principle modeling and system identification. In both hover and flight modes, the operative degrees of freedom for microrotorcrafts results in a large number of interrelated states and design parameters. Mettler [8] has enumerated microrotorcraft control issues as falling into six main categories: the changing flight dynamics, multivariable (six degrees of freedom and four control variable) and unstable (the attitude dynamics) vehicle behavior, rotor-fuselage coupling, and sensitivity to disturbances. The six degrees of freedom of a microrotorcraft (a simplified version of which is shown in Fig. 2) can be expressed using the standard Newton–Euler equations of motion for a body-fixed frame of reference:

$$\begin{aligned} \boldsymbol{F} &= m\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} + m(\boldsymbol{\omega}\times\boldsymbol{v}) \\ \boldsymbol{M} &= \mathbf{I}\frac{\mathrm{d}\boldsymbol{\omega}}{\mathrm{d}t} + (\boldsymbol{\omega}\times\mathbf{I}\boldsymbol{\omega})\,, \end{aligned} \tag{14}$$

where $\boldsymbol{F}$ is the external force vector, m is the mass, $\boldsymbol{v}$ is the velocity vector, $\boldsymbol{\omega}$ is the angular velocity vector, $\boldsymbol{M}$ is the external moment vector, and $\mathbf{I}$ is the inertial tensor. These relations can be used to develop three interrelated differential equations for the translational motion and three equations for the angular motions. Finding a closed-form solution for these equations is problematic, however, so the system identification method instead develops simplified forms of these expressions.



Microrotorcraft, Figure 2 Six degrees of freedom for a basic microrotorcraft

Small Scale Effects

Heat Transfer

Given the importance of low-Re, viscous flow on microscale aerodynamics, it is possible to take advantage of the dominant heat transfer effects to enhance microrotorcraft flight. These heat effects can be characterized using the standard transport equations and a Navier–Stokes solver. In order to accurately apply the physical properties, it is important to include the effect of temperature on the viscosity (using, for example, Sutherland's, Wilke's, or Keyes' laws), thermal conductivity, and specific heat of the surrounding fluid (air).
Heat transfer effects can be used to improve microrotorcraft performance through the introduction of a temperature gradient over the airfoil. Both the temperature and velocity boundary layers are relatively thicker for small-scale airfoils, and a lower temperature on the upper surface will accelerate the flow, while a higher temperature on the lower surface will decelerate the flow. The resulting changes to the pressure distribution on the airfoil can increase the lift and reduce the drag. From the standard governing equations and asymptotic matching, Kim [1] developed an approximation for the pressure coefficient

along a microrotorcraft's airfoil as:

$$\begin{aligned}&Cp\left(\frac{x}{c}; \mathrm{M}, \alpha, \delta, \mathrm{Re}, \mathrm{Pr}, \frac{T_{\mathrm{wu}}}{T_\infty}, \frac{T_{\mathrm{wl}}}{T_\infty}\right)\\&= Cp^*\left(x^*; \mathrm{M}, \alpha_{\mathrm{M}}, \mathrm{Re}_{\mathrm{M}}, \mathrm{Pr}, \frac{T_{\mathrm{wu}}}{T_\infty}, \frac{T_{\mathrm{wl}}}{T_\infty}\right)\\&+\left[Cp_{\mathrm{u,l}}\left(\frac{x}{c}\right) - Cp_{\mathrm{cp}}\left(\frac{x}{c}; \mathrm{M}, \delta, A\right)\right] V^*(x^*)\rho^*(x^*)\,, \end{aligned} \tag{15}$$

where Cp_{cp} is the pressure coefficient in the overlap region, and is equal to:

$$Cp_{\mathrm{cp}} = (-1)^m \frac{2\alpha w_0 \sqrt{\frac{c}{x}}}{\beta}\,, \tag{16}$$

while $Cp_{\mathrm{u,l}}$ is derived from classical subsonic linear airfoil theory:

$$\begin{aligned}Cp_{\mathrm{u,l}} = &-2\frac{\delta}{\beta}\Bigg\{h(1+2\cos\theta)\\&+2\sum_{k=2}^{\infty} A_{2k-1}\left[\frac{\sin(2k-1)\theta - \sin\theta}{\sin\theta}\right]\\&+2\sum_{k=2}^{\infty} A_{2k}\left[\frac{\sin 2k\theta - \sin 2\theta}{\sin\theta}\right]\\&+(-1)^m\left[w_0\frac{1+\cos\theta}{\sin\theta} - \sum_{n=1}^{\infty}(-1)^n w_n \sin n\theta\right]\Bigg\}\,.\end{aligned} \tag{17}$$

Cp^* cannot be expressed in closed form, but is derived from a computational solution of the dimensionless equations for mass, momentum, and energy, where the fluid properties are governed by the ideal gas equation of state. In Eqs. (15)–(17), x is the location; c is the chord length; M is the Mach number; α is the angle of attack; δ is the airfoil thickness ratio; T is the temperature, where wu is the upper wall, wl is the lower wall, and ∞ is the free stream; $*$ represents a dimensionless variable; A is the thickness function; m is a surface determinant, and equals $+1$ for the upper surface and -1 for the lower surface; w is the camber line; β is a function of the Mach number such that $\beta^2 = \mathrm{M}^2 - 1$; and h is a function of the nose radius of curvature R_c, such that $h^2 = R_c/2\delta^2 c$. The thickness function can be expressed as its coefficients of the Fourier series expansion:

$$A_n = \frac{2n}{\pi}\int_0^{\pi} t\frac{x}{c}\sin(n\theta)\,\mathrm{d}\theta\,, \tag{18}$$

as can the airfoil's camber line:

$$\begin{aligned}w_0 &= 1 - \frac{1}{\pi A}\int_0^{\pi} \mathrm{Ca}'\frac{\xi}{c}\,\mathrm{d}\theta\,,\\ w_n &= \frac{2n}{\pi A}\int_0^{\pi} \mathrm{Ca}'\frac{\xi}{c}\cos(n\theta)\,\mathrm{d}\theta\,.\end{aligned} \tag{19}$$

Finally, the dimensionless velocity and density in Eq. (15) are at the edge of the thin boundary layers in the inner region, and are given by:

$$\begin{aligned}V^* &= \sqrt{1 - 2\frac{\left(1 + \frac{\gamma \mathrm{M}_\infty^2}{2} - Cp^*\right)^{\gamma-1/\gamma} - 1}{(\gamma-1)\mathrm{M}_\infty^2}}\\ \rho^* &= \left(1 + \frac{\gamma \mathrm{M}_\infty^2}{2} Cp^*\right)^{1/\gamma}\,.\end{aligned} \tag{20}$$

The solution of these equations, and the resulting effect on microrotorcraft lift, drag, and endurance, is discussed in the Key Research Findings section.

Viscous Swirl Effects

In addition to amplified heat transfer effects, understanding microrotorcraft operation at low Reynolds numbers also requires better modeling of viscous swirl effects. There are numerous enhanced viscous swirl models that could be utilized, a review of some of which has been provided by Kunz [5]. The average wake deficit viscous swirl model is based on using a power-law fit of computationally-modeled airfoil wake profiles at low Re (using INS2d data):

$$\begin{aligned}v_{\mathrm{v}} &= v_{\mathrm{v1}}\,\mathrm{arclength}^{v_{\mathrm{v2}}}\,,\\ v_{\mathrm{v1}} &= -3\,\mathrm{e}^{-10}\mathrm{Re}_{\Omega\mathrm{r}}^2 - 3\,\mathrm{e}^{-6}\mathrm{Re}_{\Omega\mathrm{r}} + 0.241\,,\\ v_{\mathrm{v2}} &= 3\,\mathrm{e}^{-9}\mathrm{Re}_{\Omega\mathrm{r}}^2 - 7\,\mathrm{e}^{-5}\mathrm{Re}_{\Omega\mathrm{r}} - 0.372\,,\end{aligned} \tag{21}$$

where v_{v} is rotor viscous tangential induced velocity and $\mathrm{Re}_{\Omega\mathrm{r}}$ is the Reynolds number calculated using the rotor angular velocity multiplied by the local section radius. This model is simple and straightforward, but it has been found that it overestimates the viscous swirl effects.

A second viscous swirl model that accounts for downstream rotor effects is the Gaussian wake viscous swirl model:

$$\frac{u}{U_\infty} = \frac{u_{\mathrm{mid}}}{U_\infty}\exp\left(-\frac{(\bar{y}-\mu)^2}{2\sigma}\right)\,, \tag{22}$$

where U_∞ is the free-stream velocity, σ is the wake deficit standard deviation, and μ is the mean of u/U_∞.

Finally, there is also the simple and familiar conservation of angular momentum viscous swirl model:

$$v_{\mathrm{V}} = 2u\left(\frac{C_{\mathrm{D}}}{C_{\mathrm{L}}}\right). \tag{23}$$

Kunz found that this model has reasonable extensions to low-Re flows.

Key Research Findings

Heat Transfer and Fluid Flow Effects

As predicted by both low-Re theory and computational modeling of Eq. (15), experimental testing of microrotorcrafts with an induced temperature difference over the blade thickness verified that heat transfer effects can significantly affect aerodynamic performance. Kim [1] constructed a microrotorcraft that utilized a thermoelectric alloy material for the rotor blades. By applying a voltage at the centerline of the airfoil section, he was able to utilize the ►peltier effect to create a temperature difference of 65.5 K across each blade. He tested the blades at a range of angles of attack, and found that there was decent agreement with the numerical predictions. For example, at an angle of attack of 4.5°, upper surface temperature of 290.5 K, and lower surface temperature of 356 K, Eq. (15) predicted an increase in the lift coefficient of 5.5%, and experimental testing found an increase in the lift coefficient of 7.7%.

While the magnitude of this error shows the need for more refined computational predictions, the qualitative result remains that heat transfer effects can be important to the efficiency of microrotorcraft in their highly viscous, low-Re operating regime. However, when there is an induced temperature difference over the rotor blades, Kim also found computationally that increasing either the Mach number or the Reynolds number decreased the improvement in the lift coefficient. Furthermore, an additional complication remains in evaluating the magnitude by which the increase in the aerodynamic efficiency is offset by the increased power needed to activate the Peltier effect in a thermoelectric rotor blade.

Blade Geometry and Configuration

To evaluate the effects of blade geometry and configuration, Kim [1] performed a number of microrotorcraft spin tests on a single-rotor device using a load cell to measure thrust and a laser to measure rotor speed. The motor was driven using an external power supply. Kim tested blades with varying aspect ratios, cambers (the asymmetry of an airfoil's top and bottom shape), and thicknesses, tapers, pitches, and configurations.

In terms of the overall aerodynamic efficiency of the device, he found that it was desirable to employ a moderate camber (4 – 6%), low thickness (5 – 6%), high aspect ratio, and pitch setting in the range of 12 – 15 degrees. He also concluded that changing the blade tapering had only minor consequences for the efficiency. (Young et al. [7] also found that changes in tapering had a minimal effect on the aerodynamic performance.) Finally, increasing the number of rotor blades did increase the thrust, but it also increased the power consumption, which is a critical issue for microrotorcrafts, and is discussed in more detail in the next subsection. Kim's optimal configuration resulted in a lifting capacity (C_T/σ) of 0.16, a figure of merit of approximately 0.5 (which represents a poor hovering efficiency), and a lift-to-drag ratio of around 10.

Kunz [5] also tested a number of blade configurations. He examined a five-blade 2.2 cm diameter rotor, a four-blade 2.5 cm diameter rotor, and two-blade 10 in diameter rotor. These designs were based on an optimization methodology that Kunz developed for microrotorcraft design. He found that the errors between the predicted and tabulated values were less 10% for all of the rotor designs except the five-blade rotor. One reason for this, as well as for some of the errors found in the other rotor predictions, was the role of structural deformation. All of the rotors exhibited some degree of static deflection from manufacturing and/or handling, and also torsional deflection due to rotational mass effects during operation. While, theoretically, a reduced airfoil thickness can increase the aerodynamic efficiency of a microrotorcraft, a thinner airfoil is also subject to greater torsional deflections, and this must be accurately accounted for in any numerical model to optimize the rotor design.

Power

One of the largest challenges in designing microrotorcrafts has been providing adequate power for both the lift-off and hover modes of operation. Bohorquez et al. [4] calculated that a two-rotor vehicle that meets the DARPA requirements for size and weight would require a power draw of 15 W to ascend, hover, and maneuver. This power could be provided by fuel cells, batteries, IC engines, chemomechanical engines, compressed gas, etc., with the first two options proving to be the most likely choices.

Thomas et al. [9] further quantified the flight endurance time (t_{E}) as a function of available energy as:

$$t_{\mathrm{E}} = \eta_{\mathrm{P}}\left(\frac{E_{\mathrm{Avail}}}{W^{3/2}}\right) \times \left(\frac{\rho S C_{\mathrm{L}}^3}{2C_{\mathrm{D}}^2}\right)^{1/2}, \tag{24}$$

where η_P is the propeller efficiency, E_{Avail} is the available energy (from a battery or other source), and W is the weight of the microrotorcraft and its payload. Note the familiar ratio of $C_L^{(3/2)}/C_D$ from the figure of merit (Eq. (12)). They proposed to provide the required power through the use of laminated polymer lithium ion bicell materials with barrier-layer packaging. The bicell is 0.5 mm thick with a mass density of 0.14 g/cm^2. It demonstrates a 3.7 V discharge and 7.2 mAh/cm^2 charge storage capacity. Furthermore, the packaging is only 0.1 mm thick with a mass density of 0.013 g/cm^2. By building the payload or packaging systems out of this material, it may be possible to greatly increase microrotorcraft endurance times. Thomas et al. tested this type of battery on a fixed-wing MAV rather than a microrotorcraft, and were able to achieve endurance times of up to 107 min for a 171 g vehicle (which included 98 g of battery weight).

Controls and Sensors

In evaluating control systems for microrotorcrafts, Mettler [8] found that frequency domain identification served as a better method than time domain identification. This is because in frequency domain identification, the output measurement noise does not affect the results, it is possible to focus on a precise frequency range (which minimizes the disparity between the modes of motion), and frequency responses can completely describe the system's linear dynamics. Mettler also determined that the rigid body equations of motion needed to be expanded through use of the hybrid formulation to generate a more accurate control system. This method models the rotor motion using a tip-path plane model, and expresses the rotor forces and moments in terms of the rotor states. The rotor and fuselage motions are then dynamically coupled.

Oh et al. have proposed the use of two optic flow sensors to provide real-time feedback on both obstacles and altitude [10]. The sensor model that they tested weighed just 4.8 g, had an optic flow rate of 20 rad/s, and was approximately the size of a U.S. quarter. One sensor should be placed on a gimbal so that it is always facing directly toward the ground, and the other should be forward facing. For the sensors, the rate of optic flow (rad/s) is equal to:

$$\mathrm{OF} = \frac{V}{D}\sin\theta - \omega\,, \tag{25}$$

where V is the forward velocity, D is the distance from an obstacle, θ is the angle between the obstacle and the microrotorcraft's direction of travel, and ω is the angular velocity. Since it is likely that changes in the vehicle's pitch will be much smaller than changes in its forward motion, ω can be neglected, further simplifying Eq. (25).

Coupling the optic flow sensors with control loops allows a microrotorcraft to perform both autonomous landing and autonomous collision avoidance. For example, when providing feedback to the ground-facing sensor, Eq. (25) reduces to $\mathrm{OF} = V/D$. In order to keep a constant rate of optic flow, the velocity of the microrotorcraft must decrease as its distance from the ground decreases, which results in a smooth landing.

Future Directions for Research

In order to create a durable, flexible, and autonomous microrotorcraft that can be used in a variety of applications, more work is needed on a number of fronts. Additional experimental data should be gathered on the effects of blade design, and these data should be used to both improve existing 2-D microrotorcraft representations and to generate more detailed 3-D Navier–Stokes computational models. These data could be created using actual small rotor systems, or through the use of scale models.

Improvements are also needed in the endurance time of microrotorcrafts. Further energy sources should be investigated, and the trade-offs of materials that improve aerodynamic efficiency but require power (such as thermoelectric or piezoelectric rotors) should be quantified. Endurance time could also be increased by improving the efficiency or lowering the weight of auxiliary systems such as the micromotor, control circuits, and sensors. Hybrid configurations, such as the prop-hanging vehicle proposed by Green and Oh [3], could also be developed.

Finally, improved communications and control mechanisms are needed. For example, ▶ neural networks could be used to train optic flow sensor controls to react appropriately to changes in light intensity, diffuse objects (such as fog), and low contrast obstacles (such as a white wall) [10]. Beyond the control of single microrotorcrafts, strategies should also be developed to control communications and reactions for groups of these vehicles.

Miniature heat-removal devices; Micro-heat exchangers; Microchannel heat sinks (MCHS); Flow of coolants in micro-conduits; Nanofluid flow in microchannels

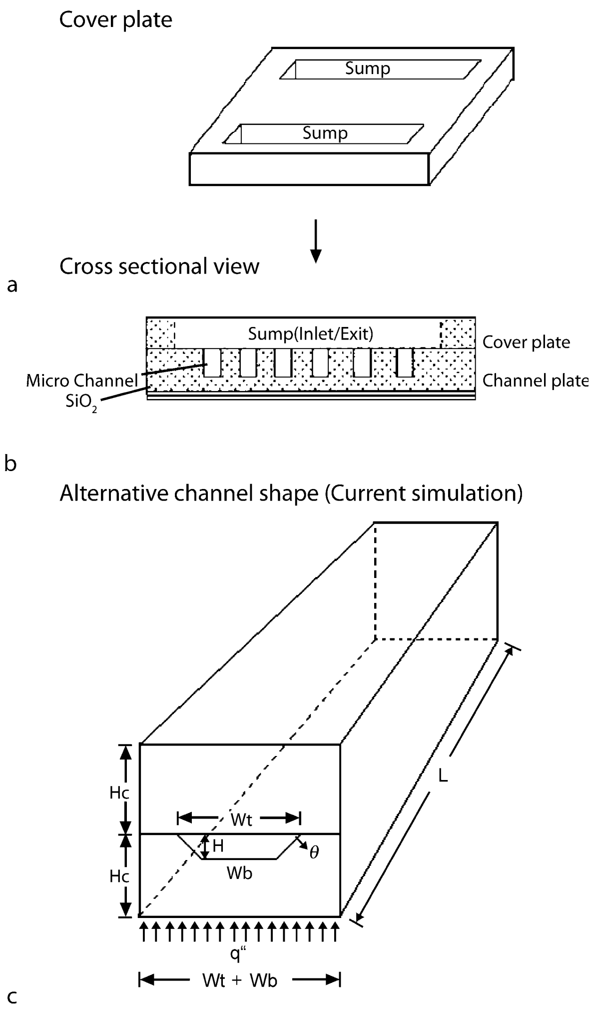
Definitions

A microscale cooling device consists of a coolant flowing through a large number of parallel, micromachined or etched conduits to remove heat from and generate uniform temperature distributions in microelectromechanical systems, integrated circuits boards, laser-diode arrays, high-energy mirrors and other compact products with high transient thermal loads. Key is the very large heat transfer surface-to-volume ratio of the device. The coolant can be a pure fluid or a very dilute mixture of distilled water (or ethylene glycol, engine oil, etc.) and nanoparticles, such as metals, metal-oxides, and carbon-based materials. Heat transfer occurs via forced convection, which includes impinging jets of the coolant and liquid-to-vapor phase change due to boiling or condensation. The microchannels are typically silicon-, metal-, or plastic-based and often feature circular, rectangular or trapezoidal cross sections, ranging in terms of the hydraulic diameter from 100 nm to 1000 μm. Alternatively, porous media, such as foam, has been employed as micro-conduits with pure fluids.

Overview

Fundamental to the understanding of the dynamics of microscale cooling devices is the description of convection heat transfer in these micro-conduits. The most rigorous approach would be to analyze the behavior of each coolant molecule in terms of simultaneous mass, momentum and heat transfer. Even for microchannels this would imply tracking billions of *particles*; hence, for most engineering applications the coolant is treated as a continuum. The continuum mechanics assumption is valid as long as the size and mean-free-path of the molecules (or particles) are small enough compared to the device dimensions, e. g., channel height or tube diameter. This is basically assured when the Knudsen number, defined for gas flow as the ratio of mean-free-path distance to characteristic system length, is less than 0.1 and then macro-level modeling equations can be used (see, for example, review chapter 12 by Zohar [1] in The MEMS Handbook). Nevertheless, a number of phenomena unique to micro-conduits still prevail, causing pressure drops, flow rates and/or friction factors to differ from results obtained for macro-channels [2]. Examples include dominant entrance effects because the conduits are very short, significant surface roughness effects due to the closeness of the channel walls, earlier onset of turbulence because of induced instabilities, measurable viscous dissipation effects resulting from steep velocity gradients, possible fluid-slip on channel walls depending upon the physical-chemical characteristics of the (coated) surfaces, and significant effects of low-level forces usually not relevant in macro-devices, such as surface tension and electrostatics.

Already in 1981, Tuckerman and Pease [3] achieved heat transfer rates of about $10^5\ \mathrm{W/m^2K}$ for water flow in small cooling channels etched in a silicon substrate. A representative microchannel heat sink (MCHS) is shown in Fig. 1. Typically, a coolant is forced through a large number of parallel channels, which are in contact with a hot surface, to convect evolving heat away and provide a near-uniform temperature field in the device to be cooled. An MCHS can generate such elevated heat transfer rates because of its high surface-to-volume ratio and enhanced



Microscale Cooling Devices, Figure 1 Typical microchannel heat sink elements and the current computational trapezoidal microchannel unit

thermal conductivity of the coolant (i. e., when using a nanofluid), while being very small in size and having relatively low coolant-volume and pumping-power requirements. Clearly, channel geometry/configuration, type of coolant with associated flow regime (or thermodynamics) and required pumping power are some of the more important system parameters determining MCHS performance. The underlying microfluidics for flow in microchannels is outlined in [4] and [5] while MCHS performance has been discussed by Kandlikar and Grande [6], Li et al. [7], and Koo and Kleinstreuer [8], among others. Li and Peterson [9] focused on MCHS performance improvements considering nanofluids vs. pure water as well as geometric parameters, especially the channel aspect ratio, H/W (see Fig. 1). Nanofluids are very dilute suspensions of metal, metal-oxide or carbon-based nanoparticles (0.01 to 4% by volume) in liquids, such as water, ethylene glycol, etc. These mixtures exhibit thermal conductivities which are 30 to 300% higher than the one of the carrier fluid [10].

Basic Methodology

In order to provide some physical insight into the dynamics of microchannel heat sinks (MCHS), steady laminar water flow in a smooth single trapezoidal microchannel is discussed and compared with measured data sets. Then the effects of nanofluids on augmented MCHS heat transfer are introduced, employing very simple correlations for the enhanced thermal conductivities of the mixtures. The fluid flow and heat transfer simulations have been carried out with the commercial software CFX-10 (Ansys, Inc., Canonsburg, PA) and user-supplied pre- and post-processing software.

Theory

Figure 1c depicts the representative microchannel under consideration. The top width W_t, bottom width W_b and depth of the channel H are 500 μm, 358.4 μm and 100 μm, respectively. The base angle, which is the angle between the channel side wall and bottom wall, is 54.7°. The length of the channel L is 27 mm. The heights of the cover and base substrate are both $H_c = 500\,\mu\text{m}$. A constant heat flux, i. e., $q'' = 431{,}466\ \text{W/m}^2$, from below and adiabatic conditions at the other boundaries were assumed. First, a smooth channel with pure de-ionized water as the working fluid is considered. The hydraulic diameter for the present case is:

$$D_h = \frac{4 \times 0.5 \times (W_t + W_b) \times H}{W_t + W_b + 2 \times H/\sin\theta} = \frac{2 \times 858.4 \times 100}{858.4 + 245.1} = 155.6\,\mu\text{m}\,. \tag{1}$$

Other important geometric channel parameters are the aspect ratio as well as the aspect factor, defined respectively as (see Fig. 1c):

$$A = W_b/W_t \tag{2}$$

and

$$\alpha = H/W_b\,. \tag{3}$$

Assuming steady laminar 3D flow and heat transfer with constant material properties, the continuum mechanics equations are:

$$\nabla \cdot \boldsymbol{u} = 0\,, \tag{4}$$

$$\rho_f(\boldsymbol{u}\cdot\nabla\boldsymbol{u}) = -\nabla p + \nabla\cdot(\mu_f\nabla\boldsymbol{u}) \tag{5}$$

and

$$\rho_f c_{p,f}(\boldsymbol{u}\cdot\nabla T) = k_f\nabla^2 T + \mu_f\Phi\,, \tag{6}$$

where

$$\Phi = \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\frac{\partial u_i}{\partial x_j}\,. \tag{7}$$

In the solid region:

$$k_s\nabla^2 T = 0\,. \tag{8}$$

Here, ρ is the density; k is the thermal conductivity; μ_f is the fluid dynamic viscosity; p is the pressure; T is the temperature; $\boldsymbol{u}$ is the velocity vector; c_p is the specific heat capacity, and Φ is the viscous dissipation; the subscripts f and s represent fluid and solid, respectively. For nanofluids, the corresponding effective thermal conductivities and effective fluid dynamic viscosities will be introduced.

When using CFX-10, the solid and fluid are treated as a unitary computational domain. The interface between the solid and fluid is automatically connected by equal temperature magnitudes and heat flux values; thus, only the boundaries for the unit cell are needed. Specifically, for the hydraulic boundary conditions, a uniform velocity is applied at the channel inlet:

$$u = 0,\quad v = 0,\quad w = U_{in}\quad \text{for}\quad x = 0\,,\quad (y, z) \in \text{channel region}\,. \tag{9}$$

The outlet pressure is the static pressure, i. e.,

$$p_{out} = 0\,. \tag{10}$$

The no-slip boundary condition was enforced at all solid walls.

The thermal boundary condition at the bottom is:

$$q'' = C\,. \tag{11}$$

Adiabatic boundary conditions are applied at all other sides of the walls:

$$\frac{\partial T}{\partial n} = 0\,. \tag{12}$$

In the fluid region:

$$T = T_{in}\quad \text{for}\quad x = 0,\quad (y, z) \in \text{channel region}\,. \tag{13}$$

Results

Pure Water Flow

For comparison purposes, a steady global energy balance based on the temperature difference between the channel inlet and outlet was performed, i. e.,

$$\rho_f u_m c_p A_c (T_{out} - T_{in}) = q'' A_{bottom}\,. \tag{14}$$

Here, u_m is the mean velocity, A_c is the area of the channel cross section, and A_{bottom} is the area of the heated substrate wall.

Figure 2a depicts the simulated water temperature rise between the channel inlet and outlet as a function of inlet Reynolds number and the theoretical values predicted by Eq. (14), where $\text{Re} = u_m D_h/\nu_{fluid}$. Figure 2b shows the dimensionless entrance length at different Reynolds numbers in comparison with the experimental result of Hao et al. [11]. When the Reynolds number is less than 1000, the entrance length dependence can be expressed as a linear correlation of the form:

$$L_{e,d} = L_e/D_h = (0.08 \sim 0.09)\text{Re}\,. \tag{15}$$

For noncircular conduits the channel aspect ratio or aspect factor (see Eqs. (2) and (3)) have a profound influence on the friction factor $C_f = f\text{Re} = \Delta p D_h^2/2\mu_f uL$, which has a constant value of 16 for circular conduits. For example, Fig. 2c provides a comparison of the simulation results with an empirical correlation of Wu and Cheng [12], i. e.,

$$f\text{Re} = 11.43 + 0.80\exp(2.67 W_b/W_t)\,. \tag{16}$$

The bar-height of the numerical data represents the range of the friction factor for different hydraulic diameters and different Reynolds numbers, which are clearly less important than the aspect ratio.

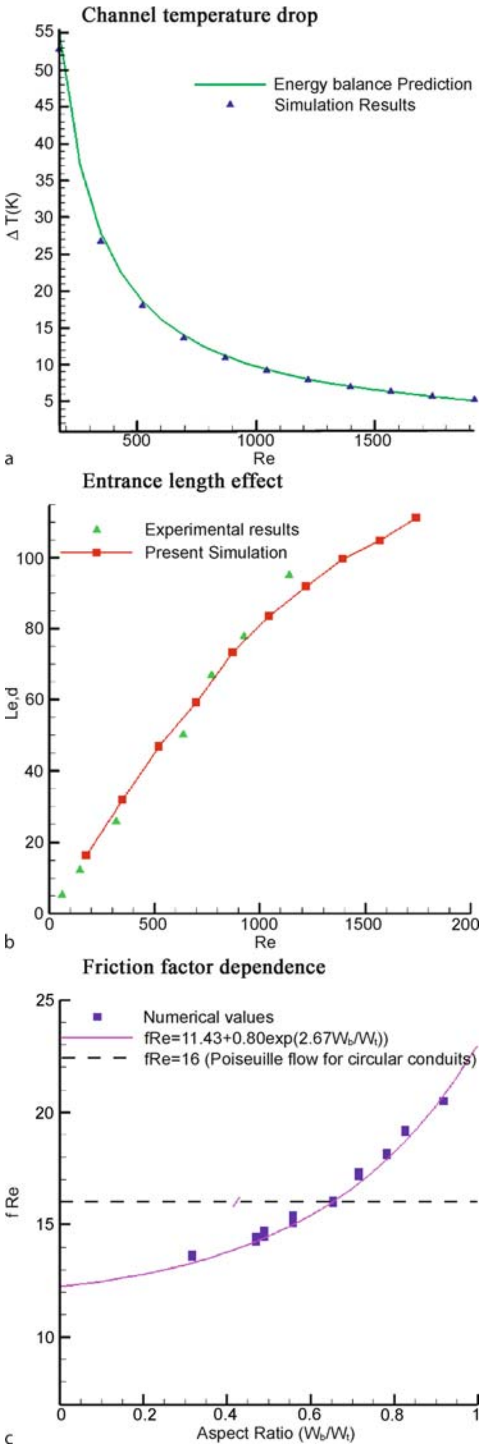
Nanofluid Flow With Heat Transfer

In order to investigate the heat transfer characteristics of a nanofluid in the trapezoidal microchannel, we employed a CuO-water combination as the working fluid. Clearly, the thermal fluid properties of the nanofluid have to be updated. Thus, in the governing Eqs. (5) and (6), the following expressions were introduced, replacing the previous μ_f and k_f parameters. Typically, for a very dilute suspension, the effective viscosity, density and specific heat capacity have the following forms:

$$\mu_{nf} = \mu_f\frac{1}{(1-\varphi)^{2.5}} \tag{17}$$

$$\rho_{nf} = \varphi\rho_p + (1-\varphi)\rho_f \tag{18}$$

$$c_{p,nf} = c_{p,p}\varphi + c_{p,f}(1-\varphi) \tag{19}$$



Microscale Cooling Devices, Figure 2 Model validations: (**a**) temperature rise from heat sink inlet to outlet; (**b**) dimensionless entrance length as a function of inlet Reynolds number [11]; (**c**) comparison of the numerical friction coefficient with an experimental correlation [11]

here, ρ_{nf} is the nanofluid density, μ_{nf} is the nanofluid viscosity, $c_{p,nf}$ is the specific heat capacity, φ is the volume fraction, $c_{p,p}$ is the particle specific heat capacity and $c_{p,f}$ is the specific heat capacity of the base fluid.

The most elusive parameter is the effective thermal conductivity. At present, there is no single expression for k_{eff} representing all nanofluids. Thus, in order to be somewhat realistic and computationally efficient, we chose the correlations based on experimental results of Das et al. [13] as our effective thermal conductivities:

$$k_{eff} = 1.19 k_f \quad \text{for} \quad \varphi = 1\% \tag{20}$$

$$k_{eff} = 1.27 k_f \quad \text{for} \quad \varphi = 4\%\,. \tag{21}$$

The base fluid temperature was set to 36 °C.

The calculated pressure gradient results for the CuO-water mixture at different volume fractions and two experimental data sets of Qu et al. [14] for trapezoidal microchannels as a function of inlet Reynolds number are given in Fig. 3a. The measured data points for pure water flow in two trapezoidal silicon channels with hydraulic diameters $D_h = 142.0\,\mu m$ and $168.9\,\mu m$ envelope the result for the present channel geometry which falls right between the two sets of measured data points. When adding nanoparticles at three different volume fractions, it clearly shows that the pressure gradient increases slightly with volume fraction, which is in line to the results of Chein and Huang [15].

In order to investigate heat transfer enhancement for nanofluids, the average Nusselt numbers for different volume fractions are compared. The average Nusselt number is defined as:

$$Nu_{ave} = \frac{q'' D_h}{(T_{w,ave} - T_{f,ave}) k_f} \tag{22}$$

where

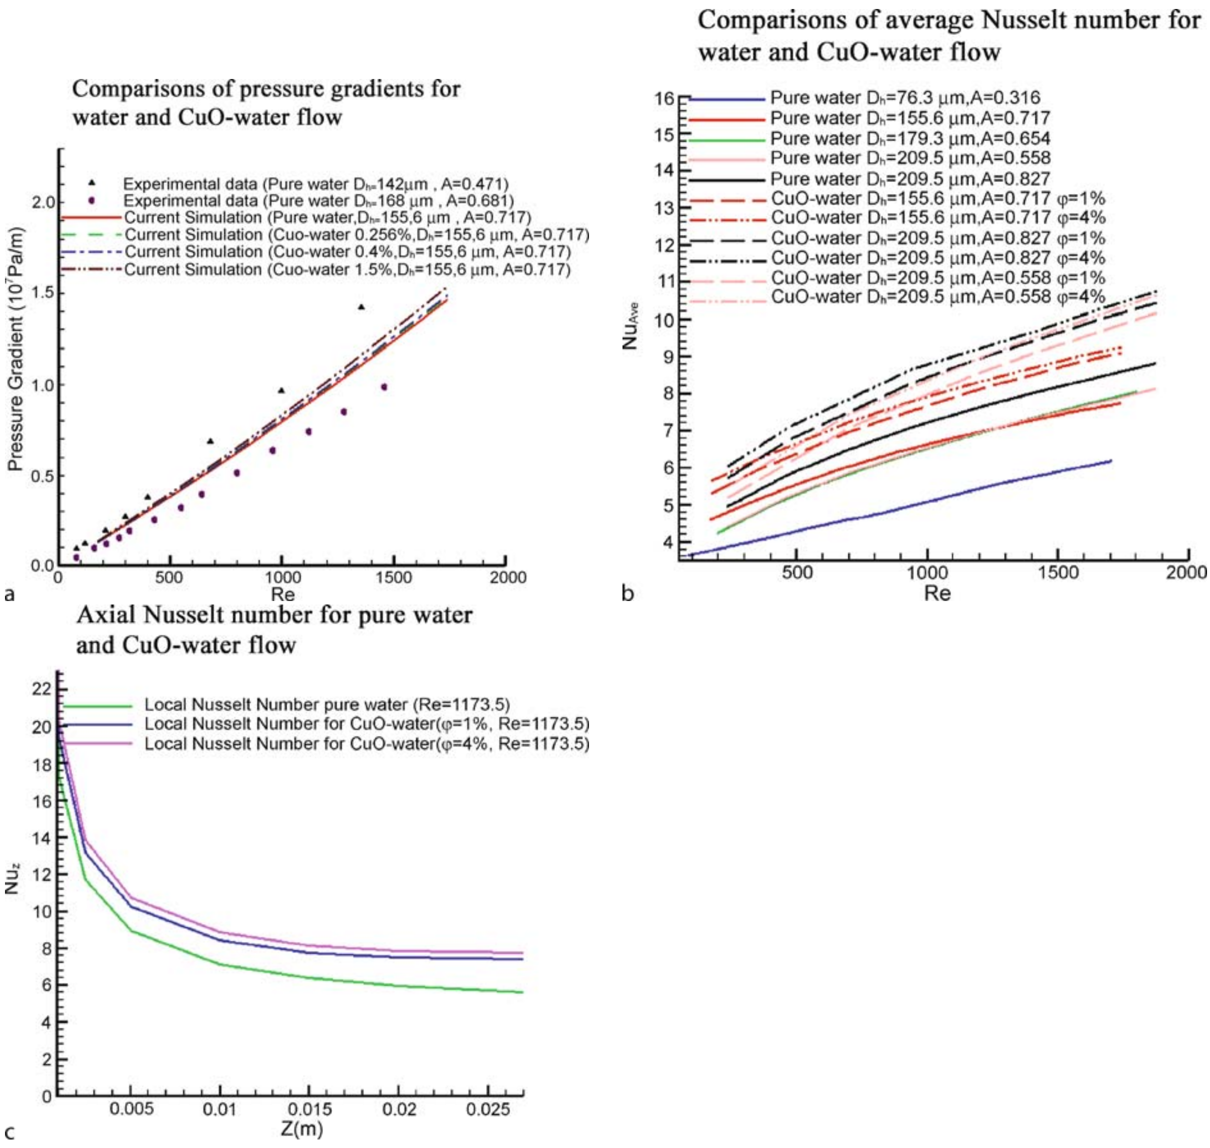
$$T_{w,ave} = \frac{1}{A_{int}} \iint_A T \mathrm{d}A \tag{23}$$

and

$$T_{f,ave} = \frac{1}{V} \iiint_{V_f} T \mathrm{d}V \tag{24}$$

$T_{w,ave}$ is the surface-averaged temperature at the fluid–solid interface of area A_{int}, $T_{f,ave}$ is the volume-averaged temperature of the fluid field and k_f is the thermal conductivity of the pure water.

Figure 3b compares the average Nusselt numbers for different channels with different nanoparticle volume fractions and different Reynolds numbers. It shows that



Microscale Cooling Devices, Figure 3 Computational results: (**a**) pressure gradient vs. Reynolds number; (**b**) thermal properties for different channels with different fluids; (**c**) local Nusselt number in the axial microchannel direction for different fluids

nanofluids can improve the thermal performance of microchannels:

- the larger the volume fraction of nanoparticles, the higher is the thermal performance;
- the channel shape has a strong influence on thermal performance; and
- a large aspect ration appears to be beneficial for low Reynolds number flows.

Considering the same hydraulic diameter ($D_\mathrm{h} = 209.5\ \mu\mathrm{m}$), the smaller aspect ratio case ($A = 0.558$) Nu_ave increases more rapidly when compared to the larger aspect ratio case ($A = 0.827$). There is a $20-30\%$ heat transfer enhancement in microchannels when employing nanofluids. The aspect ratio (or hydraulic diameter) measurably influences thermal enhancement when using nanofluids.

The axial Nusselt number, based on the local surface temperature and fluid temperature cross-sectionally averaged were investigated as well. The use of nanofluids greatly decreases both the channel wall temperature and fluid temperature for the same wall heat flux. Thus, it can improve the thermal dissolve capability of microchannels. In Fig. 3c, the local Nusselt numbers along the microchannel are displayed. The local Nusselt number is defined as:

$$\mathrm{Nu}_z = \frac{q'' \cdot D_\mathrm{h}}{(T_{\mathrm{w},z} - T_{\mathrm{f},z})k_\mathrm{f}} \tag{25}$$

Here $T_{w,z}$ and $T_{f,z}$ are the average wall temperature and fluid temperature as a function of axial coordinate z. Again, the local Nussels numbers are enhanced when nanofluids are employed. Figure 3c also indicates the higher thermal performance in the entrance region, especially near the inlet. As the fluid flow develops, the local Nusselt number approaches a constant value for each case. Because the entrance range of microchannels can be quite substantial, a strong entrance influence on thermal performance of microchannels can not be neglected.

Key Research Findings

Microchannel Heat Sinks

Heat removal and control has become a challenging task with the application of various high power, high speed Micro-Electro-Mechanical Systems (MEMS) in electronics or mechanical equipment. As discussed, most solutions are based on microchannel heat sinks which commonly consist of an array of microchannels.

Colgan et al. [16] described a practical implementation of single-phase Si-microchannel devices designed for cooling very high power chips. The 3D rendering of their assembled microchannel cooler is shown in Fig. 4, where the manifold chip is on top and shown semi-transparent. The test results indicated Nusselt numbers as high as 25 for reasonable flow velocities ($\sim 2.52\,\text{m/s}$). The staggered fin arrangements were at a pitch of $100\,\mu\text{m}$, channel width of 65 or $75\,\mu\text{m}$, and fin lengths of 210 to $250\,\mu\text{m}$. The strong entrance effect of the microchannel was considered to be one important factor to support the elevated average Nusselt number, which is in line with corresponding to the laminar convective heat transfer theory. The resulting heat transfer coefficients were as high as $130\,\text{kW/m}^2\cdot{}^\circ\text{C}$. The resulting pressure drop was less than 35 kPa.

Kandlikar et al. [17] presented an optimization scheme for designing microchannel heat exchangers for cooling high-heat flux silicon chips with water. An offset strip-fin construction was analyzed for dissipating heat fluxes above $3\,\text{MW/m}^2$. The continuous fin in the microchannels was broken down into several smaller fins that were placed offset to each other in the flow direction. In this arrangement, a higher heat transfer coefficient was obtained; but, with an increase in pressure as well because of the stronger fluid-development effect. In order to reduce the pressure drop of the system, a split-flow arrangement was employed to replace the single-pass arrangement, which is shown in Figs. 5a, 5b. The fluid was introduced at the center and exited on the two sides. The reduction of the flow length through the channel passages resulted in a lower pressure drop, as displayed in Fig. 5c. The heat dissipation capacity for a specified pres-

Microscale Cooling Devices, Figure 6 Map of general performance trends for a typical two-phase microchannel heat sink: (**a**) fixed total volume flow rate and (**b**) fixed pressure drop [19]

sure drop was significantly enhanced. The improvement can be attributed to the increased heat transfer coefficient leading to a reduced mass flow rate, and the reduced fluid flow length for each fluid stream. This offset strip-fin configuration in a split-flow arrangement provides an interesting option for extending the heat flux limit in direct chip cooling applications. More recently, Kandlikar [18] presented a system for cooling a high-power density processor chip which included two coolant loops. The actual heat generating device is cooled by the primary microchannel heat sink and the primary coolant was cooled by the second cooling system. In their solution, the building HVAC system was connected to the secondary cooling loop. With the current single-phase enhanced microchannel technology, a heat dissipation rate as high as $10\,\text{MW/m}^2$ was predicted. The microchannel fluid flow boiling heat transfer was also considered in the study, but the author thought that the operational instability and the resulting low critical heat flux levels had prevented their implementation in practical devices. Single-phase cooling should be more promising because of its reliable operation and ability to handle different imposed heat fluxes.

Qu and Mudawar [19] discussed a comprehensive methodology for optimizing the design of a two-phase microchannel heat sink. In their study, flow rate or pressure drop were key constraints in the design of microchannel heat sinks which often demanded specialized micro-pumps with performances dictated by either flow rate or pressure drop. For a fixed flow rate of $Q = 60\,\text{ml/min}$ and a device heat flux of $q''_{\text{eff}} = 500\,\text{W/cm}^2$, the acceptable range of two-phase operation was confined so that the dissipative heat flux will not exceed the maximum dissipative heat flux of the microchannel heat sink. For two-phase microchannel heat sinks, the minimum dissipative heat and maximum dissipative heat are defined as:

$$q''_{\text{min}} = \frac{\rho Q c_{\text{p,f}}(T_{\text{sat}} - T_{\text{in}})}{WL} \quad (26)$$

$$q''_{\text{max}} = \frac{\rho Q \left[c_{\text{p,f}}(T_{\text{sat}} - T_{\text{in}}) + h_{\text{fg}}\right]}{WL}\,. \quad (27)$$

Here T_{sat} and T_{in} are the fluid saturation temperature and inlet temperature, respectively; W and L are the width and length of the microchannel heat sink, respectively; h_{fg} is the latent heat of vaporization. Finally, they provided the numerical procedure for the optimal design of two-phase microchannel heat sink either by fixing flow rate or fixing pressure drop. The general performance map trends for fixed total volume flow rate and fixed pressure drop are shown in Figs. 6a and 6b. It provides a reference for optimizing two-phase microchannel heat sink.

Jang and Kim [20] investigated experimentally fluid-flow and heat-transfer characteristics of a microchannel heat sink, again subject to an impinging jet. This type of heat sink retains the high heat transfer coefficient asso-

ciated with a typical microchannel heat sink and experiences a low pressure drop compared to the microchannel heat sink with parallel flow. The authors modeled the microchannel heat sink, subject to an impinging jet, as a porous medium. Based on their experimental results, they suggested correlations for the pressure drop across a microchannel heat sink subject to an impinging jet as well as its thermal resistance as follows:

$$\Delta p = \rho \left(\frac{V_0}{H}\right)^2 \left(\frac{L^2}{8}\right) \left(1 + \frac{12}{\mathrm{Re}_{\mathrm{wc}}}\frac{H}{Wc} + \frac{C_{\mathrm{E},x}\varepsilon^2 L}{3K^{1/2}}\right) - \rho \left(\frac{V_0}{H}\right)^2 \left(2 - \frac{24}{\mathrm{Re}_{\mathrm{wc}}}\frac{H}{Wc} - \frac{4C_{\mathrm{E},x}\varepsilon^2 L}{3K^{1/2}}\right) \quad (28)$$

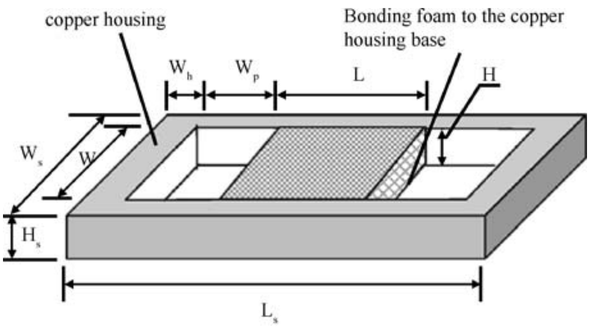
$$\theta = \frac{1}{\dot{m}C_{\mathrm{p}}} + 0.028\frac{1}{k_{\mathrm{f}}L}\left(\frac{w}{L}\right)^{0.332}\left(\mathrm{Re}_{\mathrm{dp}} \times Ar\right)^{-0.324} \quad (29)$$

for $3 \leq Ar \leq 11$ and $0 < \mathrm{Re}_{\mathrm{dp}} < 500$, where

$$Ar = \frac{H}{Wc}\,. \quad (30)$$

Here, Δp is the pressure drop across a microchannel heat sink subject to an impinging jet, ρ, V_0, ε, K, C_{E}, H, Re, Wc, Ar are density, impinging velocity at the inlet of the microchannel heat sink, fluid dynamic viscosity, porosity, permeability, Ergun coefficient, and channel height, Reynolds number, channel width and aspect ratio, respectively. The correlations for the pressure drop, the thermal resistance were compared with experimental results, and both match with experimental results within ±10%.

Zhang et al. [21] experimentally investigated the fluid flow and heat transfer of liquid-cooled foam heat sinks (FHS). As indicated in Fig. 7, eight open-cell copper foam materials with two pore densities of 60 and 100 PPI (pores per inch) and four porosities varying from 0.6 to 0.9 were bonded onto copper base plates, which formed the FHS. The authors focused on the characterization of a foam heat sink with high pore density and heat exchange area for cooling high-performance electronic chips in comparison with a microchannel heat sink. The thermal resistances and pressure drops were measured for the FHS subject to fixed heating power of 60 W and maximum pressure drop around 0.5 bar. As expected, the thermal resistance in each case decreased with the increase of the flowrate. This porosity effect on the thermal resistance can be attributed to characteristics inherent in the foam structure. Porous foams with lower porosities have a higher interstitial velocity and thus a higher local heat transfer coefficient. For the four 60 PPI FHS, the one with the lowest porosity of 0.6 was found to possess the lowest thermal resistance level accompanied by the largest pressure drop. Plotting the thermal resistance against the pressure drop and pumping power (see Fig. 8) revealed that 0.8 is the optimal porosity for the FHS at 60 PPI with a minimal thermal resistance 0.31 °C/W. For the 100 PPI case, the porosity of 0.9 was identified to be the optimal porosity with a minimum thermal resistance of 0.34 °C/W, due to the bypassing through the gap on the foam, which partially offsets the high pressure drop related to the high pore density.

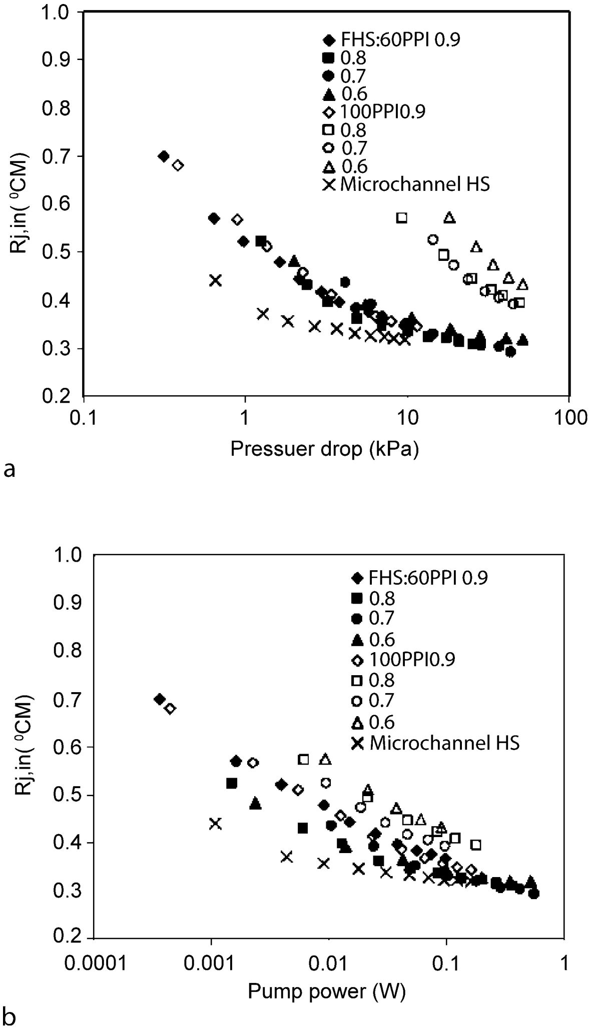


Dimensional details for the Foam Heat Sink (FHS) and the microchannel Heat Sink (HS) (Unit: mm)

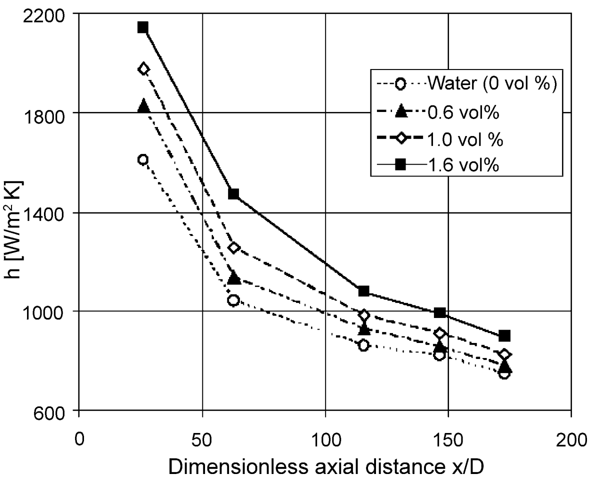
Parameters	FHS 60/100PPI	Microchannel HS
Foam or finned array width W	12.2	12.2
Foam or fin length L	13	15
Faom or fin height H	2	2
Heat sink width W_s	26	24
Heat sink length L_s	52	52
Heat sink height H_s	3.5	2.8
Housing width W_h	10.5	11
Plenum width W_p	9	7.5
Unit cell scale	0.42/0.25	0.6

Microscale Cooling Devices, Figure 7 Schematic of a metallic foam heat sink (FHS) design compatible with geometric data table [21]

Peles et al. [22] investigated heat transfer and pressure drop phenomena over a bank of micro-pin fins in a micro-heat sink. The dimensionless total thermal resistance was expressed as a function of Reynolds number, Prandtl number and the geometrical configuration of the pin-fin micro-heat sink. They compared their theoretical model with their experimental results and concluded that very high heat fluxes can be dissipated at a low wall temperature rise using a microscale pin-fin heat sink. Thus, forced convection over shrouded pin-fin arrays is a very effective cooling device. In many cases, the primary cause for the rise in wall temperature is the increase of the fluid tempera-



Microscale Cooling Devices, Figure 8 Thermal resistances for FHS of both 60 and 100 PPI and the microchannel heat sink with respect to: (**a**) the pressure drop and (**b**) the pumping power [21]



Microscale Cooling Devices, Figure 9 Nanofluid flow application in microchannel heat sink: axial profile of local heat transfer coefficient ($Re = 1050 \pm 50$) [23]

ture as it flows through microchannels. To suppress the convective thermal resistance at high Reynolds numbers, dense pin-fin configurations are preferable, while for low Reynolds numbers more sparse arrangements are advisable. The thermal resistance is less sensitive to changes in the tube diameter at larger diameters, so very low tube diameters (below $\sim 50\,\mu$m) should be avoided. To increase efficiencies, pins should be relatively short. However, correlations for heat transfer coefficients at low Reynolds numbers, as applicable to microscale systems, using intermediate pin lengths are not available.

Li and Peterson [9] investigated numerically the thermal performance of silicon-based microchannel heat sinks using a simplified heat transfer model, i. e., 2D fluid flow and 3D heat transfer analysis. The tested rectangular microchannels had widths ranging from 20 μm to 220 μm and depths ranging from 100 μm to 400 μm. The effect of microchannel geometry on the temperature distribution was discussed, assuming constant pumping power. Their model was validated with previously published experimental results and theoretical analyses. It was found that both the physical geometry of the microchannel and the thermo-physical properties of the substrate are important parameters in the design of these microchannel heat sinks. The optimal number of channels was found to be N=120 per cm with an aspect ratio as large as possible (i. e., very deep grooves), while still meeting the constraints imposed by

- the strength of the microchannel heat sinks and
- a ratio of $W_{\text{channel}}/W_{\text{pitch}} \approx 0.7$ for deep grooves.

Nanofluid Flow in Microchannel Heat Sinks

As mentioned, nanofluids exhibit unusual thermal and fluid properties, which in conjunction with microchannel systems provide enhanced heat transfer performance in heat transfer and fluid flow. For example, Wen and Ding [23] reported a considerable convective heat transfer augmentation when employing γ-Al_2O_3 nanoparticles in water flow in a copper tube based on their experimental results. The test γ-Al_2O_3 nanoparticles had a size range of 27 – 56 nm. Figure 9 depicts the local heat transfer coefficient vs. axial distance from the entrance of the test section, which clearly shows that the enhancement of the local heat transfer coefficient is much more dramatic than the enhancement of the effective thermal conductivity in the

main section of the test tube. The classical theory fails to predict the peculiar heat transfer behavior of nanofluids, mainly because of the migration of nanoparticles as well as particle-induced disturbance of the boundary layer in the entrance region.

Chein and Huang [15] analyzed the silicon microchannel heat sink performance using $Cu-H_2O$ nanofluid. Two specific geometries, one with $W_{ch} = W_{fin} = 100\,\mu m$ and $L_{ch} = 300\,\mu m$, the other with $W_{ch} = W_{fin} = 57\,\mu m$ and $L_{ch} = 365\,\mu m$ were examined. The particle volume fraction φ of the nanofluid was in the range of $0.3-2\%$. They postulated for laminar nanofluid flow in microchannels:

$$\mathrm{Nu_{nf}} = \mathrm{Nu_{CNF}} + c_3\varphi^{n_1}\,\mathrm{Pe_d^{n_2}}\,\mathrm{Re_{nf}^{n_3}}\,\mathrm{Pr_{nf}^{n_4}}\,, \tag{31}$$

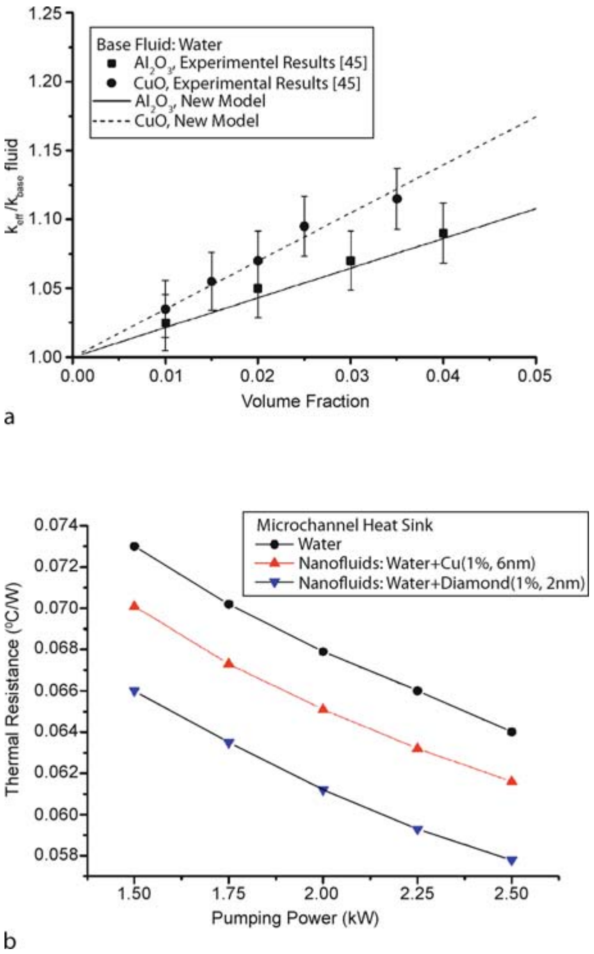
where $\mathrm{Nu_{CNF}} = D_h h/k_{nf}$ and $c_3, n_1 - n_4$ are constants that were determined from experimental data, i. e., c_3, n_1, n_2, n_3 and n_4 are 4.884, 0.754, 0.218, 0.333 and 0.4, respectively. They showed that Nu increases significantly with the increase in Re and φ when compared with pure water. The enhancement of the nanofluid thermal conductivity was contributed to the increase in thermal conductivity of the coolant and the nanoparticle thermal dispersion effect. The experimental results also showed that there is almost no extra pressure drop occurring when using nanofluids as coolants.

Koo and Kleinstreuer [8] investigated laminar nanofluid flow in microheat-sinks using the effective nanofluid thermal conductivity model they had established [24]. For the effective viscosity due to micromixing in suspensions, they proposed:

$$\begin{aligned}\mu_{\text{effective}} &= \mu_{\text{static}} + \mu_{\text{Brownian}}\\ &= \mu_{\text{static}} + \frac{k_{\text{Brownian}}}{k_f} \times \frac{\mu_f}{\mathrm{Pr}_f}\,.\end{aligned} \tag{32}$$

The impact of volume fraction in laminar flow of water and ethylene glycol with CuO-nanoparticles on the microchannel pressure gradient, temperature profile and Nusselt number was analyzed. Based on their experimentally validated results, the following was recommended: Use of high Prandtl number carrier fluids, high aspect ratio channels, high thermal conductivity nanopaticles, and treatment of channel surface to avoid nanoparticle accumulation.

Yang et al. [25] experimentally measured convective heat transfer coefficients of several nanoparticle-in-liquid dispersions for laminar flow in a horizontal tube heat exchanger. Graphite nanoparticles with an aspect ratio of 0.02 (l/d) were selected, with an average diameter of about $1-2\,\mu m$ and lengths of $20-40$ nm. The test tube had an inside diameter of 0.457 cm and 45.7 cm in



Microscale Cooling Devices, Figure 10 Nanofluid flow applications in microchannel heat sinks: (**a**) comparison of model predictions with experimental thermal conductivity data for copper oxide-in-water and aluminum-in-water nanofluids [27]; (**b**) thermal resistances of microchannel heat sinks with water-based nanofluids containing copper and diamond particles [26]

length. Although the graphite nanoparticles increased the static thermal conductivity of the mixture significantly at low weight fraction loadings, the authors found that the experimental heat transfer coefficients showed lower increases than predicted by either conventional correlations for homogeneous fluids or correlations developed for particle suspensions with aspect ratios close to one. The type of nanoparticles, particle loading, base fluid chemistry, and the process temperature are all important factors influencing the thermal performance of nanofluids.

Jang and Choi [26] numerically investigated the cooling performance of a microchannel heat sink with nanofluids. Two kinds of nanofluids were investigated in this study, i. e., $d_p = 6$ nm nanoparticles in a copper-water mixture and $d_p = 2$ nm diamond-in-water nanofluid. A the-

oretical model was employed for the thermal conductivity of nanofluids that accounts for four modes of energy transport: the thermal diffusion in the base fluid, the thermal diffusion of nanoparticles, the collision between the nanoparticles, and the nanoconvection due to Brownian motion. Specifically,

$$k_{\text{nanofluids}} = k_{\text{f}}(1-\phi) + \beta k_{\text{p}}\phi + 3C\frac{d_{\text{f}}}{d_{\text{p}}}k_{\text{f}}\text{Re}_{d_{\text{p}}}^{2}\,\text{Pr}\,, \quad (33)$$

where β is a constant related to the Kapitza resistance, being in the order of 0.01; d_{f} and d_{p} are the equivalent diameters of a base fluid molecule and a nanoparticle, respectively; $\text{Re}_{d_{\text{p}}}$ and Pr are the Reynolds number and the Prandtl number, and $C = 6 \times 10^{6}$.

Figure 10a compares the previous experimental findings [27] with the results of the new model. With the new effective thermal conductivity model, the cooling performance of the microchannel heat sink with nanofluids was considered. The cooling performance of a microchannel heat sink with nanofluids was evaluated in terms of the thermal resistance θ, which is defined as:

$$\theta = \frac{T_{\max} - T_{\text{in}}}{q''}\,, \quad (34)$$

where q'', T_{in}, and $T_{\max}$, are the heat flux generated, temperature of the inlet coolant and the maximum temperature at the bottom surface of the microchannel heat sink, respectively. Figure 10b shows the thermal resistance of microchannel heat sinks with water-based nanofluids containing copper and diamond particles. Clearly, the cooling performance of a microchannel heat sink with water-based nanofluids containing diamond (1 vol.%, 2 nm) at the fixed pumping power of 2.25 W is enhanced by about 10% when compared to that of a microchannel heat sink with water. The numerical results show that the nanofluids reduce both the thermal resistance and the temperature difference between the heated microchannel wall and the coolant.

Microchannel heat sink (MCHS) performance using copper-water and carbon nanotube-water nanofluids as coolants was analyzed by Tsai and Chein [28]. The microchannel heat sink was modeled as a porous medium. The MCHS performance was characterized by the thermal resistance which was divided into the conductive thermal resistance and convective thermal resistance. When employing a nanofluid as the coolant, the convective thermal resistance was found to increase due to the increase in viscosity and decrease in thermal capacity. The reduction of the total thermal resistance was contributed to the reduced temperature difference between the MCHS bottom wall and bulk pure fluid or nanofluids which produced a reduction in conductive thermal resistance. For the pure fluid, it was found that the higher aspect ratio decreased the thermal resistance which confirmed the results of Li and Peterson [9]. However, the nanofluid has a significant effect on MCHS performance only when the channel aspect ratio and porosity are low. For the MCHS with high channel aspect ratio and porosity, it was found that using the nanofluid does not produce significant MCHS performance enhancement. Under the condition of a given pressure drop, an optimum MCHS design was investigated. It was found that using nanofluid can enhance the MCHS performance when the porosity and aspect ratio are less than the optimal porosity and aspect ratio. The optimal aspect ratio had a value of 5–6 for different pressure drops, i.e., 50 kPa and 200 kPa. The authors compared the performance of the pure fluid cooled and nanofluid cooled MCHS with the optimized channel geometry of Tuckerman and Pease [3]. It was found that a 23% and 25% reduction of thermal resistance was achieved by using the nanofluids of Cu-water and CNT-water with a 4% volume fraction, respectively.

Future Directions for Research

Nanofluids are one of the most promising candidates for optimal microscale cooling devices. Thus, ongoing research is focusing on the thermal and fluid properties of nanofluids as well as such mixture flow in microchannels. How to optimize the cooling capabilities of nanofluids in microchannel heat sinks will be a challenging task. Alternative approaches include fluid-jet impingement and two-phase, i.e., liquid–vapor, flow with boiling heat transfer.

Microfluidic flow visualization; Microfluidic imaging

Definition

Flow visualization is a branch of fluid mechanics that provides visual perception of the dynamic behavior of fluids flows. The fundamental principle of any flow visualization technique lies in the detection of fluid transport by altering the fluid properties while leaving the fluid motion unaltered. *Microscale flow visualization* focuses on imaging microscale flows microfluidic flows, with the most common techniques broadly classified into particle-based and scalar-based methods.

Overview

The concept of Lab-on-a-Chip (LOC) has triggered an avalanche of developments and discoveries leading to an exponential growth of the microfluidics field in both industry and academia [1]. The reduction in dimensions that accompanies miniaturization results in flows through microchannels which are drastically different from macroscale flows and theory. Fluid motion at these small scales, integrated with nonlinear interaction between macromolecules can create complex phenomena which are difficult to predict and simulate theoretically. Rapid development of microfluidic technologies has been augmented by parallel progress of various visualization techniques for assessing the transport phenomena occurring at these scales. Although flow visualization on the macroscale was pioneered in the late 19th century, microscale flow visualization techniques were not demonstrated until the early 1990's. Since then, a number of methods have been developed, which are reviewed in detail in several recent publications [1–3].

Microscale flow visualization has played a key role in the development of the microfluidics and LOC fields. It is central to fundamental understanding of microflows, developing novel microfluidic processes, investigating non-ideal and non-linear behaviors, and providing data for numerical simulations. Many microfluidic applications such as mixing, pumping, and filtering require flow visualization to characterize device efficiency. To date, most microscale flow visualization techniques have focused on determination of flow velocity in liquids (or velocimetry). The most common microscale flow visualization techniques can be broadly classified into particle-based and scalar-based methods.

Particle Based Techniques

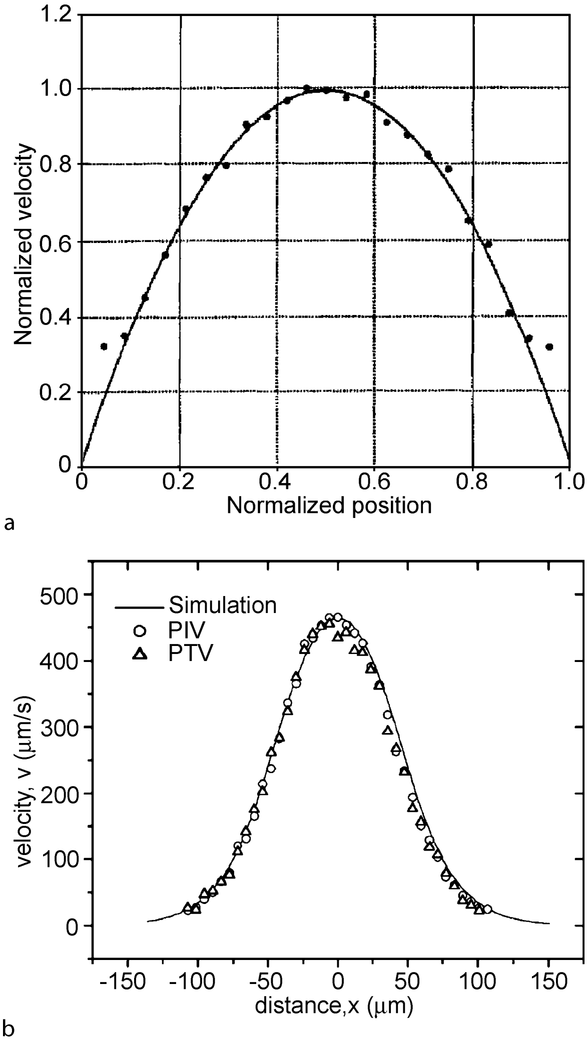
Particle based flow visualization techniques introduce marker particles into the flow field to study the motion of the bulk by determining the velocity vectors associated with these particles. Laser Doppler velocimetry (LDV), optical Doppler tomography (ODT) and particle image velocimetry (PIV) are the different methods that have been developed in this regard. However, of these methods microscale PIV (μ-PIV) is the most well-developed and popular microscale flow visualization technique.

Laser Doppler Velocimetry (LDV)

LDV relies on detection of light reflected from particles within a flow. Two cross-collimated laser beams creating an interference pattern pass through a small sampling volume. A microscopic pattern of bright and dark stripes forms in this intersection volume. Particles in the flow passing through this pattern reflect light towards a detector with a characteristic frequency indicative of the particle velocity, based on the Doppler effect. One of the drawbacks of this technique is the dependence on the size of the probe volume. As the volume decreases, the probability of a particle passing through the volume decreases, thus limiting the accuracy of the velocity measurements. Also, stray reflections near microchannel walls may corrupt the signal at the detector. LDV was successfully used by Tieu et al. [4] to measure laminar flows in 175 μm thick channels using diode lasers (Fig. 1a). The system offered a wall resolution of 18 μm, while higher resolution could be achieved by correcting the astigmatism of the laser diode using cylindrical lens.

Optical Doppler Tomography

ODT has been developed to accurately resolve the location and velocity of particles in highly scattering medium, especially useful in medical diagnosis. For example, knowledge of in vivo blood flow under the skin allows clinicians to determine depth of burns [5]. ODT combines single beam Doppler velocimetry with optical coherence tomography using a low-coherence Michelson interferometer. Light in an ODT system is broken into a target arm (containing the sample) and a reference arm (usually a mirror). The combination of backscattered light from the target arm and reference light from the reference arm gives rise to an interference pattern only when optical path lengths of light in the target and reference arms match to within the laser coherence length. Particle velocity is determined by measuring the frequency shift of the backscattered interference pattern at the detector. The ODT system developed by Chen et al.[6] exhibited a lat-



Microscale Flow Visualization, Figure 1 (**a**) Velocity profile across 175 μm wide glass microchannel obtained by LDV [4]. (**b**) Velocity field across a 120 μm wide acrylic microchannel, obtained experimentally with both PIV and PTV and compared with simulation data [18]

eral and axial resolution of 5 μm and 15 μm limited by the beam spot size.

Particle Image Velocimetry (PIV)

PIV is an optical whole-field, non-intrusive measurement technique to measure fluid velocity by recording the displacement of small tracer particles added to the fluid. PIV has been extensively reviewed in past [5], and can be divided into pattern matching velocimetry (PMV) and particle tracking velocimetry (PTV). PIV offers more flow information per interrogation, and thus substantially more work has been done in this field compared to LDV and ODT.

In PMV, the velocity vectors are estimated by tracking patterns of particles in a small interrogation area. PMV measures the velocity field from images obtained at two different times with a know time delay governed by the delay between the pulses of the laser. The two images are then cross-correlated to extract information about flow. In PTV, the velocity vectors are estimated by tracking individual particles in a small interrogation area. In comparison to the PMV technique, the PTV technique offers better resolution as individual particles are tracked and not the overall pattern. Figure 1b shows typical velocity filed obtained using PIV and PTV techniques.

Application of PIV to microflows, or microscale PIV (μ-PIV), was first successful demonstrated by Santiago et al. [7] in 1998. Today, it is rapidly becoming the preeminent technique for visualizing velocity in liquid flows in microfluidic devices. However, there are three fundamental aspects differentiating macroscale and microscale PIV (discussed in detail by Wereley et al. [8]). First, as the particles become small compared to the wavelength of the illuminating light (i. e. $d \ll \lambda$), the amount of light scattered by such a particle (which varies as d^6 due to Rayleigh scattering [9]) places significant constraints on the imaging optics. To overcome this problem, fluorescently-tagged microspheres are commonly used for better imaging. Second, when the seed particle size becomes very small, the effects of particle-particle and particle-fluid molecule interactions become significant, preventing the particles from following the flow to some degree. This error in the resulting velocity vector is substantially reduced by averaging multiple image interrogations. The third significant difference is that the flow is volume illuminated due to use of high numerical aperture microscope objectives that have a narrow depth of focus.

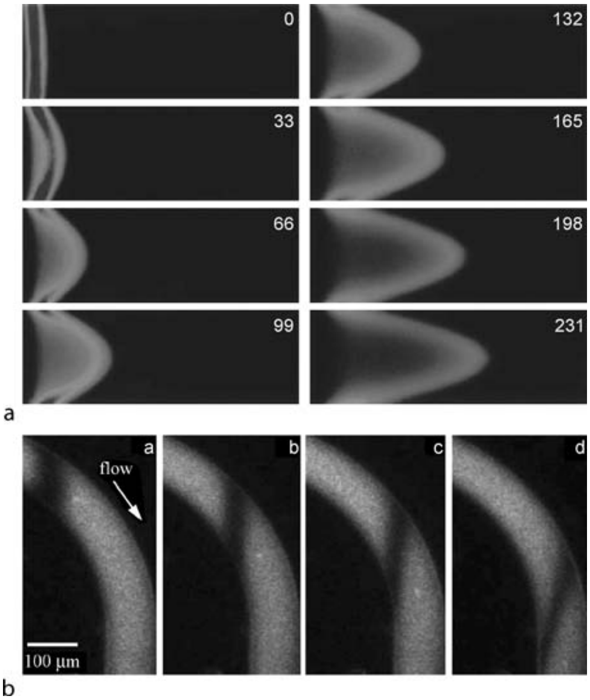
Scalar Based Techniques

Scalar based techniques using molecular tracers (fluorescence or phosphorescence) have been widely employed for visualization of microflows. To obtain velocity information, images at two instances in time are obtained and correlated to determine the displacement. Perhaps the most common visualization technique is using conventional food dye visualization. Food dyes are preferred over other molecular tracers as they are safe, cheap and available in most supermarkets. Most food dyes are sold as concentrated solution with a specific gravity greater than one. To make the dye buoyant such that it follows the flow field, they are generally mixed with a small quantity of alcohol. Another common indicator which is often used to visualize flows is milk. Milk is frequently preferred over dye solutions due to good reflective properties which improve image contrast. When using milk as a flow indicator, it is essential to flush the injection system after the experiment as any milk left in the system may curdle and can cause flow blockage.

Scalar image velocimetry (SIV) is the technique used to determine the vector velocity fields by recording images of a passive scalar quantity and inverting the equation of motion for a passive, conserved scalar. The technique was originally developed by Dahm et al. [10] to measure the velocity field in a turbulent jet. Later, Tokumaru and Dimotakis [11] developed image correlation velocimetry (ICV), which uses correlation of two successive scalar images to measure fluid velocity vectors. Since then, a variety of methods for tracking scalar tracers have been developed including laser-induced fluorescence (LIF), flow-tagging velocimetry (FTV), molecular tagging velocimetry (MTV), laser-induced molecular tagging (LIMT), laser induced photochemical anemometry (LIPA), photobleached fluorescence (PF), microbubble lensing induced photobleaching (μBLIP), IR thermal velocimetry (ITV) and photo-activated nonintrusive tracking of molecular motion (PHANTOMM). However, the basic mechanisms employed in these techniques are fluorescence, photobleached fluorescence, phosphorescence, caged fluorescence, and IR heating [2].

Fluorescence

Fluorescence techniques have been widely used to determine the velocity of flows by imaging the elapsed displacement in a given time interval. Fluorescence is the phenomenon by which electromagnetic excitation of a molecule results in the emission of a photon. The emitted light has a wavelength longer than the light absorbed. This shift in the wavelengths, called the Stoke's shift, was first observed by Stokes in 1852 and forms the basis of fluorescence microscopy. The typical lifetime of a fluorophore in the excited state is 1 – 10 ns. This inhibits the use of fluorescence as a flow visualization tech-



Microscale Flow Visualization, Figure 2 (**a**) Images of pressure-driven flow through an open 100 µm i.d. fused-silica capillary using a caged fluorescein dextran dye. Pressure differential of 5 cm of H_2O per 60 cm of column length. Viewed region 100 µm × 200 µm. The frames are numbered in ms as measured from the uncaging event [13]. (**b**) Electroosmotic flow profile from top to bottom in a curved acrylic microchannel at time a) $t = 0$ s, b) $t = 1.2$ s, c) $t = 1.8$ s, and d) $t = 3.2$ s, studied by Mosier et al. [14]. The electric field is 30 Vcm^{-1}. The photobleached region helps to study the stretching and tilting of the flow profile due to the 'racetrack' effect

nique on its own. Instead, fluorophores are used along with caging molecules to facilitate tagging, or are permanently tagged by overexposure (photobleaching). For example, the absorption maxima of fluorescein molecule is 490 nm and the emission maxima is 513 nm. Similarly, the absorption maxima of another popular fluorophore, Rhodamine 6G, is 530 nm and the emission maxima is 566 nm.

Caged Fluorescence

Caged-fluorescent or photoactivated fluorescent (PAF) dye molecules are fluorophores with additional chemical groups that quench the fluorescence of the dye. Upon exposure to electromagnetic radiation, the chemical group is cleaved (photolysis) and fluorescence is recovered, known as an uncaging event. The first demonstration of measuring flow velocity in macrochannels ~ 1 cm in diameter using caged-fluorescent dyes was shown by Lempert et al. [12] in 1995. He named his scheme as "PHoto-Activated Nonintrusive Tracing Of Molecular Motion" (PHANTOMM). However, it was Paul et al. [13] in 1998 who applied caged fluorescence to visualize and characterize microscale flows. The technique was demonstrated for pressure- and electrokinetically driven flows in capillaries. Light from a 355 nm tripled Nd:YAG laser was used to un-cage the caged fluorophores. The resulting sheet of uncaged fluorescein was then excited using a second laser (Argon ion laser, and later doubled Nd : YVO_4 laser). Fluorescent images indicating dye transport were then captured using an attached CCD camera. Representative images are shown in Fig. 2a.

Photobleaching

Photobleaching is the permanent destruction of fluorescence by over exposure to a high-intensity light. Photobleaching is a common problem in time-lapse microscopy. However, it can be employed to visualize microscale flows using the fluorescence recovery after photobleaching (FRAP) technique. Mosier et al. [14] employed photobleaching of fluorescein to visualize electroosmotic and pressure driven fluid flow fields (Fig. 2b). A brief exposure to a laser sheet photobleaches a fraction of the fluorophores present in the diluted fluorescein solution flowing in the microfluidic device. The development of this photobleached region is then used to determine flow field conditions and transport coefficients such as velocity vectors and electro-osmotic mobility. A distinct advantage of this technique is the ability to use visible light and standard dyes as opposed to caged-dyes that typically require ultraviolet light to activate the dye molecules. However, the signal-to-noise ratio that defines image contrast of this technique is almost an order of magnitude inferior when compared to caged-fluorescence imaging.

Phosphorescence

Phosphorescence is a process, similar to fluorescence, by which electromagnetic excitation of a molecule results in the emission of a photon. However, unlike fluorophores, which have a lifetime of about 1 – 10 ns, a phosphorescent molecule does not immediately discharge the absorbed radiation. Typically, the emission lifetimes of phosphorescence emission can be as long as several milliseconds. Although a variety of phosphorescence techniques are available, analogous to fluorescence, they are not as popular as their fluorescence counterparts due to the much longer tracer lifetimes. These longer tracer lifetimes also limit their applicability to relatively fast flows ($Re > 10$),

which are not very characteristic of microscale flows (typically Re < 1).

IR Heating

IR-based velocimetry technique involves measurement of small volume flows using a non-invasive, simple design. A small volume of flow is heated by repeated exposures to IR radiation and detected at a short distance downstream using heat indexing, thermal imaging or laser induced interferometric backscatter. IR heating based flow monitoring was demonstrated by StClaire and Hayes [15] in a 184 μm diameter capillary over a velocity range of 2 – 25 cm/s (500 nl/s to 7 ml/s). A small volume of fluid was heated using a NiCr heating coil driven by a variable AC controller. By heating, one can change the refractive index of the fluid and thus determine the flow velocity by measuring the laser light backscattered from the capillary at a fixed length downstream. Markov and Bornhop [16] employed similar technique to measure linear flow velocity within filled capillaries. In their case, an infrared laser diode was used to repeated heat a small volume of fluid and measuring the thermally induced change of refractive index using a micro-interferometric back-scatter detector (MIBD).

Summary

Selection of an appropriate microscale visualization technique depends primarily on the application of interest. Both particle-based and scalar-based measurement techniques can be applied to most microscale flows. However, one advantage of scalar-based techniques is that the molecular tracer will not be trapped in even the smallest passages, thus avoiding issues arising from channel blockage. Also, with an increasing trend towards soft polymeric microfluidic devices, particle based techniques could probably be difficult to implement due to the problem of particles sticking to the walls of the device which can possibly decrease the resolution of the measurement. Another limitation of particle based methods, typically PIV, is that while characterizing electroosmotic flows the particles can acquire substantial charge (due to their larger size as compared with molecular tracers) and become influenced by both the hydrodynamic and the electrical forces. However, one major limitation of scalar-based techniques is that the diffusivity of the molecular tracers can be typically much higher than individual particles, thereby lowering the spatial and velocity resolution of the measurements. The following section will discuss in detail experimental methodologies of two most commonly used methods for microscale visualization: μ-PIV and fluorescence. We will limit our discussion to pressure driven flows.

Basic Methodology

Microscale Particle Image Velocimetry (μ-PIV)

The principle of μ-PIV lies in recording of images of the flow field with a well-defined time-delay with the help of small fluorescently-tagged particles as illustrated in Fig. 3. Unlike traditional tracking schemes where individual particles are tracked, in μ-PIV sets of particle images are tracked with a high particle density. The particles are assumed to have densities similar to the surrounding fluid and are small enough so that they follow the flow faithfully without influencing it. By recording the position of a particle at two separate time instants the local fluid velocity can be determined using following equitation:

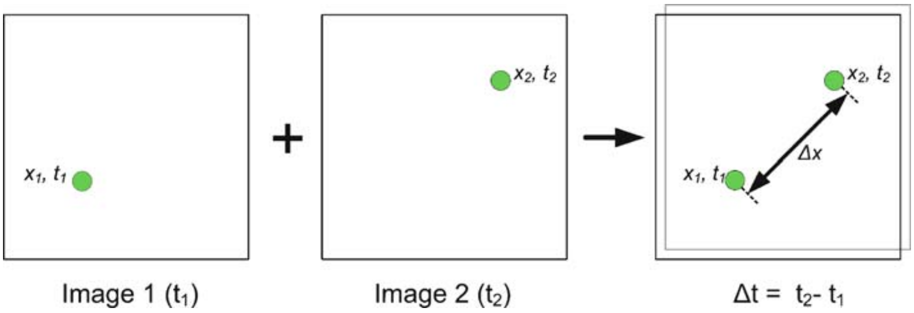
$$u = \frac{x_2 - x_1}{t_2 - t_1} = \frac{\Delta x}{\Delta t} \tag{1}$$

where x_1 is particle position at time t_1, and x_2 is particle position at time t_2. By extending this concept to the entire flow field, high spatial resolution and accuracy can be obtained. As a single image pair may contain hundreds of particles, the images are typically divided into smaller sub-areas called interrogation regions.

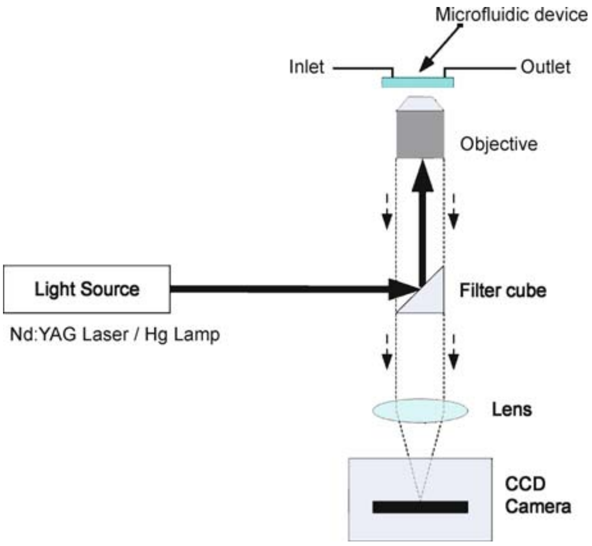
The first successful μ-PIV system was demonstration by Santiago et al. [7] in 1998, who recorded the velocity vector in a Hele-Shaw flow around a 30 μm cylindrical obstruction. The system utilized an inverted epi-fluorescent microscope (e. g., Nikon TE2000 or Olympus IX71), a Hg arc lamp for continuous illumination, and a intensified CCD camera to image 100 – 500 nm diameter fluorescently-tagged polystyrene particles. Flow was injected into the microfluidic device using a conventional syringe pump (e. g., Harvard Apparatus). Meinhart et al. [17] demonstrated an improved μ-PIV system consisting of the same general components with the exception that the continuous light source was replaced by dual 5 ns pulsed Nd:YAG lasers (e. g., New Wave, Minilase System) along with beam expanding optics. High accuracy and spatial resolution (~ 1 μm) using this technique were reported.

Figure 4 shows a typical experimental setup to conduct μ-PIV measurements in microfluidic devices. Imaging is typically performed using 60× water or oil immersion objectives. For microchannels incorporating 3-D structures, a microscope with z-translation is commonly used to capture images at varying height within the channel. The microscope must be equipped with a high-speed camera capable of capturing thousands of images per second. A computer with large processing power is then used to analyze these images and extract flow information.

Characteristics of the particle imaging system largely determine the achievable resolution in a μ-PIV system. Two critical parameters here are the total magnification



Microscale Flow Visualization, Figure 3 Schematic illustrating the principle of flow characterization using PIV technique. By calculating the displacement of a particle in a known time delay, the flow velocity vectors can be calculated



Microscale Flow Visualization, Figure 4 Schematic of the experimental set-up used to carry out μ-PIV measurements. A pulsed Nd:YAG laser or a continuous Hg arc lamp is used to excite fluorescently tagged polystyrene particles on an inverted epi-fluorescent microscope. A CCD camera is used to capture the particle images at regular well-defined time intervals. A filter cube is selected based on the fluorophore used (i. e. FITC for fluorescein or TRITC for rhodamine)

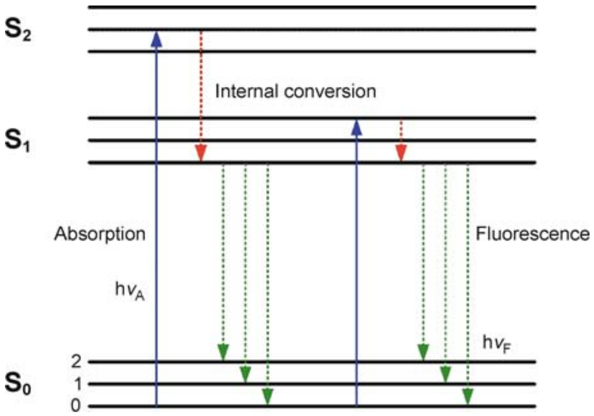
and the numerical aperture of the objective lens. For a 60 × objective lens with a numerical aperture of 1.4, the image diameter of 500 nm diameter spherical particles is 700 nm in the object plane [7]. By resolving the particle image over an area in the detector that is 3 to 4 px across, the uncertainty associated with determining the center of the cross-correlation peak is approximately 10% of the particle image diameter, which translates to approximately 70 nm in the object plane [18].

Particle size is an important consideration in any particle tracking method. Particles should be small compared to the dimensions of the microfluidic channels, and should be much smaller in size (less than 1% of the hydraulic diameter of the microchannel) than the distance over which spatial velocity gradients are to be measured. Another important consideration is the optical signal produced by the particles. The particles should be large enough to be visible above background noise without producing unnecessarily large images which may limit the spatial resolution of the measurements. Inertial particle effects are typically not important in μ-PIV (500-nm diameter polystyrene spheres have a response time of 10^{-8} s).

Since the probe area in μ-PIV is volume illuminated rather than sheet illuminated, it limits the number density of particles that can be traced to characterize the flow. If the particle density is too low, then cross-correlation techniques fail to provide an adequate signal, making the measurements noisy and inaccurate. On the other hand, if the particle density is too high, then out-of-focus particles can reduce the visibility of in-focus particles making the signal noisy. One of the possibilities to overcome this limitation is by averaging the correlation function over a large number of PIV recording pairs. This concept of averaging correlation functions can also be applied to other evaluation algorithms such as Minimum Quadratic Difference method. Wereley and Meinhart [19] developed a second-order accurate PIV technique based on adaptive central difference interrogation (CDI) algorithm. The adaptive CDI algorithm provides better accuracy compared to traditional adaptive forward difference interrogation (FDI) algorithms, especially at large time delays between camera exposures. The technique was used to study pressure driven flow around a red blood cell. An excellent review by Wereley et al. [8] highlights the various advanced algorithms developed to obtain maximum spatial resolution with the μ-PIV technique.

Fluorescence-Based Flow Visualization

The fluorescence process is a three-stage process involving excitation of a fluorophore from ground state S_0 to



Microscale Flow Visualization, Figure 5 Jablonski diagram illustrating the principle of fluorescence excitation. The diagram shows the possible routes by which an excited molecule can return to its ground state via unstable triplet states

any one of the excited states S_1, S_2, or S_n (Fig. 5) by the absorption of a photon depending on the wavelength of the radiation. At each of these electronic energy levels the fluorophores can exist in a number of vibrational states denoted by 0, 1, 2 etc. The fluorophore stays in the excited state for a finite time, typically $1-10$ ns and then returns to its ground state by the emission of a photon of lower energy. Because of their short lifetime, the measurement of time-resolved emission requires sophisticated optics and electronics.

As mentioned earlier, most microscale flow visualization techniques have focused on determination of flow velocity in liquids (or velocimetry). Fluorescence based techniques, e. g. LIF and PF, have been extensively used for this application. However, in this section, we will look at another microfluidic application for which the development of microscale flow visualization techniques has been critical—micromixing.

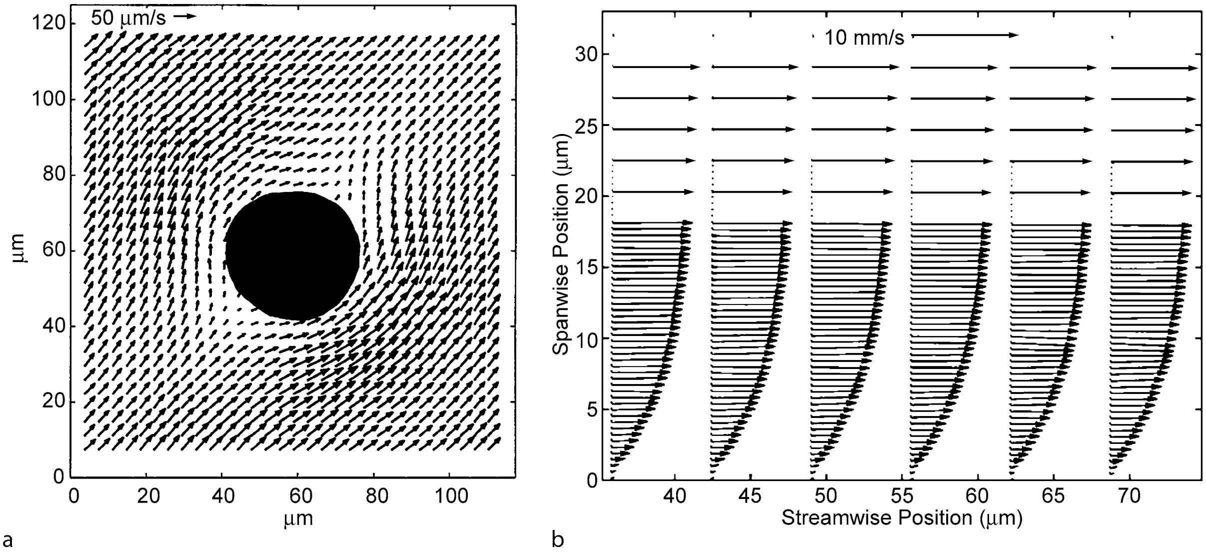
In many miniaturized biological systems (e. g., LOCs) mixing is needed in microchannels for blending, emulsification and suspensions of two or more fluids, or mixing of reactants for process initiation. For example, biochemical sensing techniques such as immunoassays and hybridization analysis require rapid and homogeneous mixing of macromolecular solutions such as DNA or globular proteins. Many investigators have used reactions between acids and bases to observe mixing (via change in pH and thus color of the indicator such as phenolphthalein). Although this technique is rather simple and inexpensive, fluorescence offers an efficient and more accurate method that is not influenced by reaction kinetics and reaction types (endothermic or exothermic). Further, the size of the fluorophores is comparable with most protein molecules that are commonly used in biological analysis.

The experimental set-up to capture real-time images of the two-fluid mixing is similar to that used for μ-PIV (Fig. 4). It also consists of an inverted microscope, but a continuous light source, such as Hg arc lamp is used. The microscope filter cube, color filter assembly, is selected for the specific dye to be used as tracer. Fluorescein is the most common and inexpensive fluorescent dye with the absorption maxima of 490 nm and the emission maxima of 513 nm. For fluorescein, a FITC filter cube must be used. The standard FITC filter set from Chroma Technology consists of a 480 nm bandpass exciter filter, a 505 nm dichoric beam splitter, and a 535 nm bandpass emission filter. For another popular fluorophore, rhodomine 6G (absorption maxima of 530 nm and emission maxima of 566 nm), a TRITC filter cube must be used. The standard TRITC filter set from Chroma Technology consists of a 540 nm bandpass exciter filter, a 565 nm dichoric beam splitter, and a 605 nm bandpass emission filter. Higher quality filters improve fluorescence imaging since these filters offer wider excitation and emission with steeper passbands. Such filters provide more excitation and capture more fluorescence, resulting in greater signal to noise ratio, and allow for the cube assembly to be placed closer together for those dyes with a very short Stoke's shift.

To measure mixing characteristics, 1 μM dye solution is injected in one of the inlets of the microfluidic micromixer using a syringe pump while water is pumped into the other. The dye solution is prepared using deionized water. Higher concentration dye solutions can be used, but are not desirable due to CCD camera saturation and higher exposure times which reduce response time. To quantify mixing by visualizing fluorescence intensity, images of the channel with the two fluids are acquired using an automated image acquisition system at various positions along the channel. Typically, the images are captured with a ~ 1 μm resolution in z direction and $1-2$ μm resolution in the $x-y$ plane.

Following image capture, the images are analyzed to extract the intensity value at each pixel. The two most common commercial image processing software packages are Metamorph® (Universal Imaging) and Image Pro Plus (Media Cybernetics). Alternatively, a public domain Java image processing program ImageJ (developed by the National Institutes of Health, USA) can be used. From the captured images, grey-scale line scans indicating pixel intensity across the microchannel width are recorded. The intensity values must be normalized to 1 using the highest intensity value. The extent of mixing is determined based on the standard deviation of the pixel intensity distribution across the microchannel. To calculate standard deviation, the following equation is used:

M



Microscale Flow Visualization, Figure 6 (**a**) μ-PIV velocity map of a Hele-Shaw flow [7]. The velocity vector field shown contains over 900 velocity vectors, with a spatial resolution of 6.9 × 6.9 × 1.5 μm for each vector measured using an eight image ensemble-average. (**b**) Ensemble-averaged near-wall velocity vector field measured using μPIV technique in a 30 μm (high) × 300 μm (wide) × 25 mm (long) channel by Meinhart et al. [17]. The spatial resolution is 13.6 μm × 4.4 μm away from the wall and 13.6 μm × 0.9 μm near the wall. A velocity vector spacing of 450 nm in the wall-normal direction is obtained due to a 50% overlap between interrogation spots

$$\sigma = \left[(I_{\text{low}} - I_{\text{ave}})^2\right]^{\frac{1}{2}} \tag{2}$$

where I_{low} is the lowest grey scale pixel intensity, I_{ave} is the average overall the pixels in the image and σ is the standard deviation [20]. Using this definition, standard deviation is 0.5 for completely separated flow streams at mixer entrance and 0 for perfect mixing.

Although a fully mixed channel should have a standard deviation of 0, in practice however even fully mixed channels exhibit some noise in the pixel intensity. Thus, the background noise for each image is based on the variation in fluorescence intensity for a fully mixed channel. Noise values of ~ 0.1 are typical. Thus a fully mixed channel can exhibit a standard deviation of ~ 0.1.

Standard deviation can be related to percent mixing efficiency E by the following equation:

$$E = (1 - 2\sigma) \times 100\% \tag{3}$$

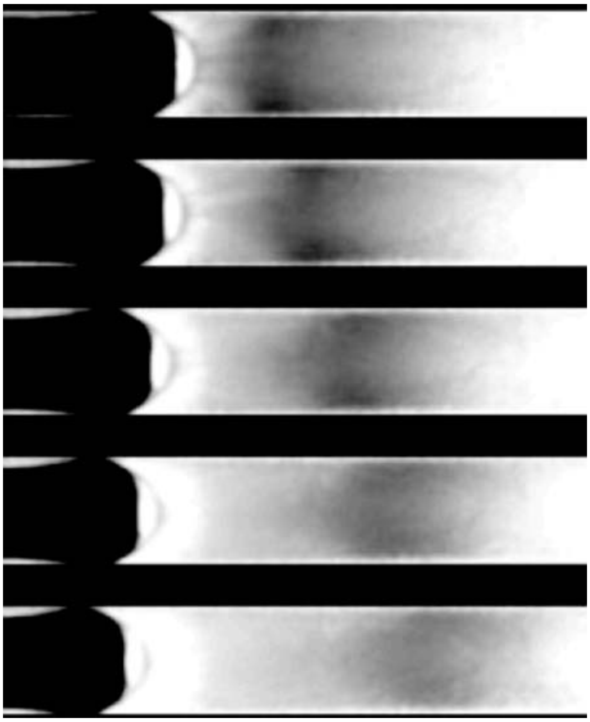
Complete mixing of two flow streams is characterized by a mixing efficiency of 100%. Thus, $\sigma = 0.2$ implies 60% mixing.

Key Research Findings

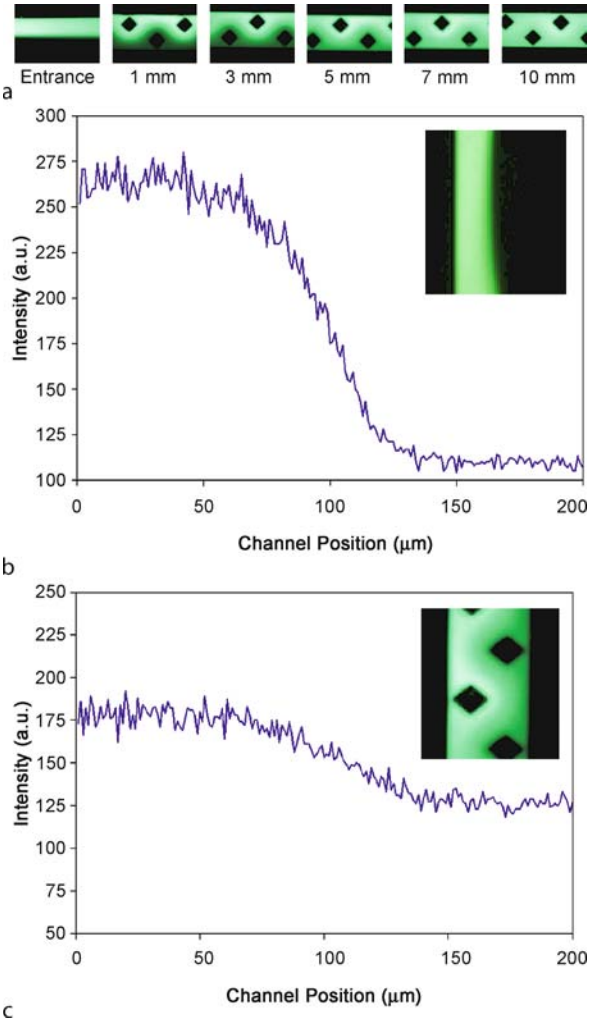
The field of microscale flow visualization has been receiving wide attention in the recent years due to developments in microfluidics and LOCs. Most of the developed techniques are capable of high spatial and velocity resolution, with μ-PIV and fluorescence imaging being the most widely used.

Figure 6a illustrates a typical result obtained with the μ-PIV technique—an instantaneous velocity field of a Hele-Shaw cell [7]. The velocity field vectors were measured by averaging an eight image ensemble recorded using a CCD array exposed for 2 ms with a 68.5 ms time delay between successive images and 300 nm polystyrene particles. Spatial resolution was 6.9 μm × 6.9 μm × 1.5 μm. Figure 6b shows an ensemble-averaged near-wall velocity vector field measured using μ-PIV technique in a 30 μm (high) × 300 μm (wide) × 25 mm (long) channel [17]. Using a Nd:YAG pulsed laser to illuminate fluorescently tagged particles and camera capable of capturing images within a 500 ns time interval, high spatial resolution of 13.6 μm × 4.4 μm away from the wall and 13.6 μm × 0.9 μm near the wall was obtained. By overlapping the interrogation regions 50%, a velocity vector spacing of 450 nm in the wall-normal direction is obtained.

Recently Sinton et al. [21] developed a technique based on photobleached fluorescence microflow visualization. Their technique, called micro bubble lensing-induced photobleaching (μ-BLIP), takes advantage of the change in properties of a gas bubble – liquid interface creating an optical arrangement in which light incident on the bubble is focused into the surrounding liquid, resulting in locally



Microscale Flow Visualization, Figure 7 A μ-BLIP generated flow marker indicating electroosmotic transport inside a 100 μm fused silica capillary. The five image sequence is captured using a CCD camera running at 15 Hz with individual exposures times of 1/60 s [21]



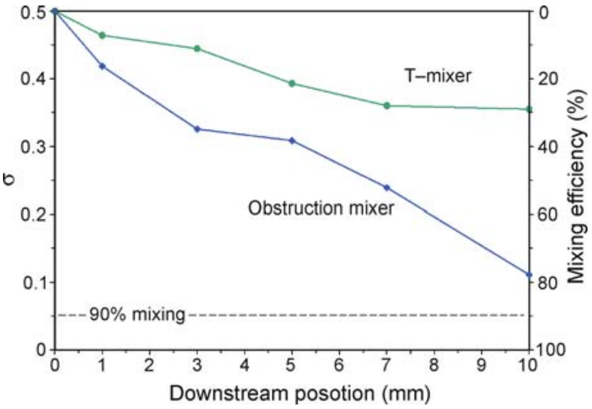
Microscale Flow Visualization, Figure 8 (**a**) Mixing visualization using 1 μM fluorescein solution in mixer with break-up obstructions at increasing distances downstream. Fluorescein solution is flowing in the upper portion of the images (pseudo colored green) and water in the lower portion. Pixel intensity line-scans across the microchannel cross-section at (**b**) the entrance and (**c**) 5 mm downstream [22]

increased total light exposure. The technique was used to analyze the electrokinetic transport of a photobleached marker by measuring the cross-channel velocity profile. A five image sequence showing the transport of a μ-BLIP generated flow marker is shown in Fig. 7.

Figure 8a illustrates typical fluorescent images of a micromixer, indicating the mixing behavior at increasing distance downstream at $Re = 0.1$. The obstruction micromixer is a planar passive microfluidic mixer with diamond-shaped obstructions within the mixing channel to break-up and recombine (i. e., laminate) the flow [22]. The images were captured using an inverted microscope (Nikon TE2000) equipped with a 12-bit CCD camera (CoolSNAP ES). Figures 8b and 8c show representative cross-sectional scans indicating the pixel intensities of the two fluids at entrance and 5 mm along the channel. At the channel entrance, since no mixing occurs, the fluorescent intensity curve is similar to a step function with half the channel filled with a 1 μM fluorescein solution (Sigma-Aldrich) and the other half with water. At 5 mm downstream, the fluorescence intensity curve tends to flatten out indicating mixing. Figure 9 shows mixing intensity of a typical T-mixer and an obstruction mixer calculated using Eq. (2). A T-mixer is a basic passive micromixer with two inputs opposite to each other and orthogonal to the straight mixing channel with no obstructions. In a T-mixer, two liquids flow next to each other and mix by diffusion across their interface. T-mixer is a commonly used benchmark when comparing micromixer performance.

Future Directions for Research

The discussed microscale flow visualization methods discussed here were divided into particle- and scalar-based approaches. However, as hybrid techniques are developed



Microscale Flow Visualization, Figure 9 Mixing intensity of a typical T-mixer and an obstruction mixer calculated using Eq. (2) for increasing distance downstream

and marker sizes begin approach single molecule dimensions (e. g., quantum dots), these distinctions will become progressively blurred and no longer meaningful. Although the developed techniques help us understand the nature of flows on the microscale, they cannot be readily applied to nanoscale. Resolving nanoscale features with visible light presents a fundamental challenge. Integrating optical detectors on-chip, such as a high-speed high-resolution CCD array, may minimize coupling losses and maximize signal intensity permitting to resolve nanoscale flow features. Current monitoring techniques could be used to characterize bulk velocity in nanochannels for electroosmotic flows. Reducing wavelength of tracer emission (e. g., deep UV or radioactive traces) may also offer a way to image flows on the nanoscale.

Definition

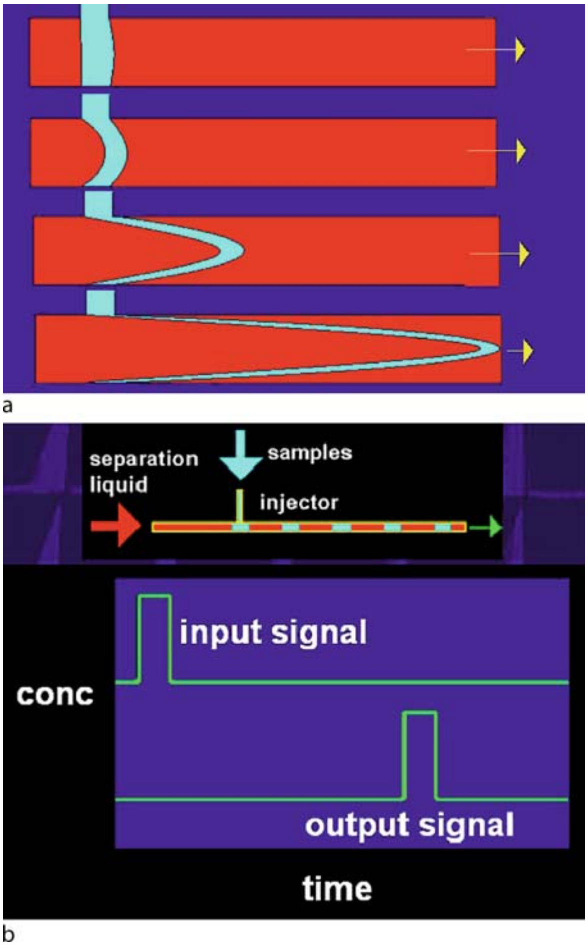
Microsegmented flow is the formation of a series of small moving liquid volumes of one phase embedded in a linear order in a liquid forming a second phase due to the immiscibility with the first one. Segmented flow is applied in microtubes, capillaries and microchannels for the definition of small process volumes to be operated serially or in parallel.

Overview

Microsegmented flow describes the phenomenon of the formation of fragments of a liquid column inside a microchannel or capillary, if the liquid is injected into an immiscible liquid. The formed sections of the liquid are called slugs or segments. For many applications – namely in synthetic chemistry – the slug formation itself is of interest, for example in order to realize local mixing and plug-flow transport characteristics. Beside these aspects, the formed segments of a liquid embedded in a linear order in a second immiscible inert liquid can also be applied for the definition of separate reaction volumes. In this case, the segments can be addressed and, therefore, generated and manipulated individually. Microslugs, which are addressable inside a sequence of slugs, are understood as microfluid segments in the narrow sense. Microsegmented flow is based on the principle of spontaneous separation of phases between immiscible liquids. This effect is well known from the separation of oil and water. Such combinations of liquids form separated droplets or segments in capillaries and microchannels. This formation of certain small volumes of one liquid separated from each other by segments of the second liquid occurs spontaneously and with high reproducibility. The specific of liquid separation in microfluidics consists in the phenomenon that the diameter of formed segments or droplets corresponds to the diameters of the applied channel. This effect results in each process of segment or droplet generation in a linear order of small liquid volumes.



Microsegmented Flow, Figure 1 Flow behaviour in homogenous and heterogeneous liquid systems: (**a**) fluidic dispersion of a concentration pulse after injection into a homogeneous laminar flow in a microchannel (schematic); (**b**) plug-like transport of a concentration pulse in the case of a segmented flow

The formation of segments is accompanied by several crucial advantages for microfluidics. The first is that microfluid segments result from a regular subdivision of larger volumes into small partial volumes. This represents the simplest way for technical compartmentation. The second is the addressability. The microfluid segments in a capillary or microchannel are in a linear order and each segment can be identified by its number in this order. The third is the stability. Microfluid segments possess a size-dependent stability against pressure and shear forces. Thus, they can be transported and manipulated in different ways. The fourth is the suppression of fluidic dispersion in case of slug flow behaviour during transport of segments in capillaries (Fig. 1).
The microfluid segments are always handled in capillaries and microchannels. In consequence, they are sepa-

rated from the environment. Problems caused by contact to air like undesired evaporation of solvent and complete drying out are avoided. Undesired influences of humidity and oxygen from air on oxidation-sensitive compounds of anaerobic cells can be excluded or strongly suppressed. Also, undesired effects of contact between the components of handled samples and the wall surfaces can be significantly reduced or suppressed by the separation of samples inside segments from the walls due to the carrier liquid.

The completely new quality of microfluid segments in comparison with microtiterplates (MTPs) and nanotiterplates (NTPs) is marked by their operability in fluidic systems and networks. Microfluid segments are the best adapted form of sample handling in microflow-through systems. And in contrast to NTPs, the stability of segments increases with decreasing sample volume. So, it is to expect that microfluid segments will be particularly important for future applications with sample handling in the lower nanolitre and in the picolitre range. Probably, microfluid segments will be a very promising technique for future picolitre and femtolitre fluidics.

Basic Methodology

In mixtures of miscible liquids, the free energy of mixing results from an overcompensation of a decrease of interaction energy between the molecules of both liquids by the mixing entropy. Such an overcompensation of interaction energy reduction by entropy gain does not take place if the interaction between molecules of two different species is much lower than the interaction energy of molecules of the single types. This is exactly the case if protic liquids with high dipole moments and a strong tendency of forming of hydrogen bridges come together with molecules interacting exclusively by van der Waals forces (lipophilic interactions). The miscibility increases in general with increasing temperature because the entropic energy gain increases with increasing temperature.

$$\mathrm{d}G(\mathrm{mix}) = \mathrm{d}H(\mathrm{mix}) - T\mathrm{d}S(\mathrm{mix}) \tag{1}$$

The stability of fluid segments is due to the interface tension in the system. Each increase of interface area leads to an increase of energy inside the system.

$$E(\mathrm{interface}) = A(\mathrm{interface}) \times \sigma(l1,\ l2) \tag{2}$$

Microfluid segments always have a tendency to minimize their surface to volume ratio. The effect can be defined by a density of interface energy $D(\mathrm{interface})$:

$$D(\mathrm{interface}) = \frac{E(\mathrm{surface})}{V(\mathrm{segment})} = \frac{\sigma(l1,\ l2)}{d} \tag{3}$$

where $d = V(\mathrm{segment})/A(\mathrm{surface})$. The ratio d of segment volume to liquid interface (segment surface) is a shape-dependent characteristic length parameter of the fluid segment.

The tendency of minimization of the interface energy corresponds to the maximization of the curvature of segment surface. As a result, the behaviour of microfluid segments can be controlled by tuning their geometry and applying appropriate shear forces on them.

Laminar homogenous flow causes a large fluidic dispersion of concentration signals in microchannels. In contrast, microfluid segments show a nearly ideal slug-flow behaviour.

If the volume of the segments embedded in a carrier liquid is small enough in comparison with the diameter of the fluid channel, the best relaxed shape is a sphere. Deviations in shape of segments from a sphere indicate larger volumes, wall contact or deformations by shear forces. The deformation of a segment during the transport from a channel of larger diameter to a smaller one or the passage of any kind of fluid resistance or barrier is always connected with an increase in interface energy. An enhancement of interface energy is a precondition for the initiation of interface-changing processes like splitting of segments.

The fluidic dispersion can be completely suppressed if the wetting tendency against the wall surfaces is reduced. Such a reduction of wetting can easily be achieved by using appropriate wall materials or by surface modification. So, the covering of silicon or glass surfaces by alkylsilane residues (silanization) leads to a large increase of contact angle of aqueous phases and can suppress wetting and cross-talk between fluidic segments completely, if the aqueous fluid segments are embedded in a non-polar organic phase.

Microfluid segments can be generated simply by merging two streams of two immiscible liquids. In this case, a resulting liquid column containing alternating segments of both liquids is formed automatically. Segments can be produced with high frequencies. They can be fused, split and shifted in their position. Different concentrations inside segments can be realized by double- or multi-injector arrangements, by fusion of two or more segments or by coupling micromixing with segment generation. The motion of segments can induce very efficient mixing inside the segments. Sequences of segments can be merged in order to generate complex microsegment patterns.

The shape and transport behaviour of segments are strongly dependent on the wetting behaviour of the segment liquid on the walls. Wall segment-induced internal convection takes place at high wetting tendency (low contact angles). The wetting of the walls always causes an induction of segment-internal fluid motion. Vortices are

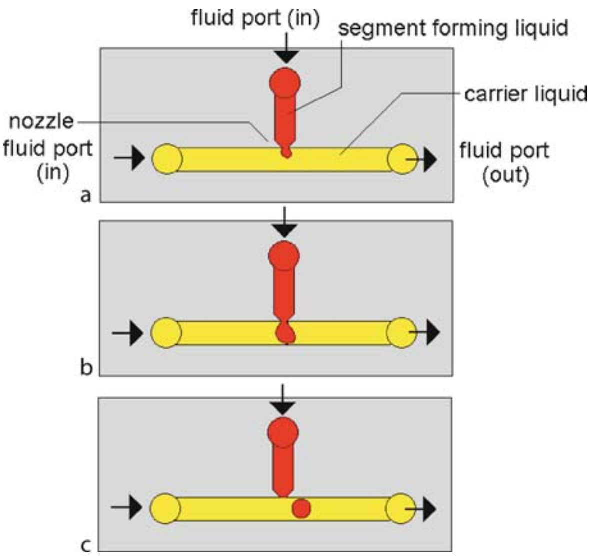
formed. A back streaming occurs in the centre of the segment. The segment can be completely separated from the wall if no wetting takes place (contact angle 180°). In this case, interactions between components inside the segment and the wall surface can suppressed completely. The existence of segment-internal convection depends on the shear forces and on the viscosity ratio of the segment liquid and the embedding liquid outside the segment.

Cross-talk between fluid segments of the same phase can take place if the contact area of the separating phase with the wall does not form a closed ring. This is always the case for the embedding phase (carrier phase) if the embedded phase is without wall contact.

Key Research Findings

The Size of Segments

The size of segments is mainly determined by the geometry of the channel in the segment-forming region and the applied shear forces. At low shear forces, the liquid injected through a T-injector or through a nozzle into the carrier liquid tends to fill the complete diameter of the main channel. A regular formation of microsegments of a volume corresponding to a sphere with the diameter of the main channel is observed (Fig. 2). The volume of generated segments can be significantly larger than the volume of a sphere with the diameter of the channel in the case of large nozzle diameters and low viscosity of carrier liquid. The segments become the shape of a slug.



Microsegmented Flow, Figure 2 Formation of a fluid segment during injection at a T-junction with aperture

The volume of the formed droplets injected into a carrier liquid can be lower than the volume of a sphere with a diameter of the main channel, if high shear forces (high flow rate of carrier liquid) and a small diameter of the nozzle are applied. Small droplets relaxing into a nearly ideal spherical shape are delivered in this case. They can be small and move through the channel like solid particles. The size of these particles increases with increasing diameter of the nozzle aperture and decreasing flow rate of the carrier liquid.

Beside the flow rate of the carrier liquid, the viscosity of the carrier also affects the size of segments. In general, an increase in viscosity results in a decreased size of generated segments. The size of generated segments can be well reproduced if the segments are released from the wall of the main channel. However, the behaviour of segment-forming liquids can become very complex and unpredictable, if local or partial wetting takes place.

Formation of Series of Segments

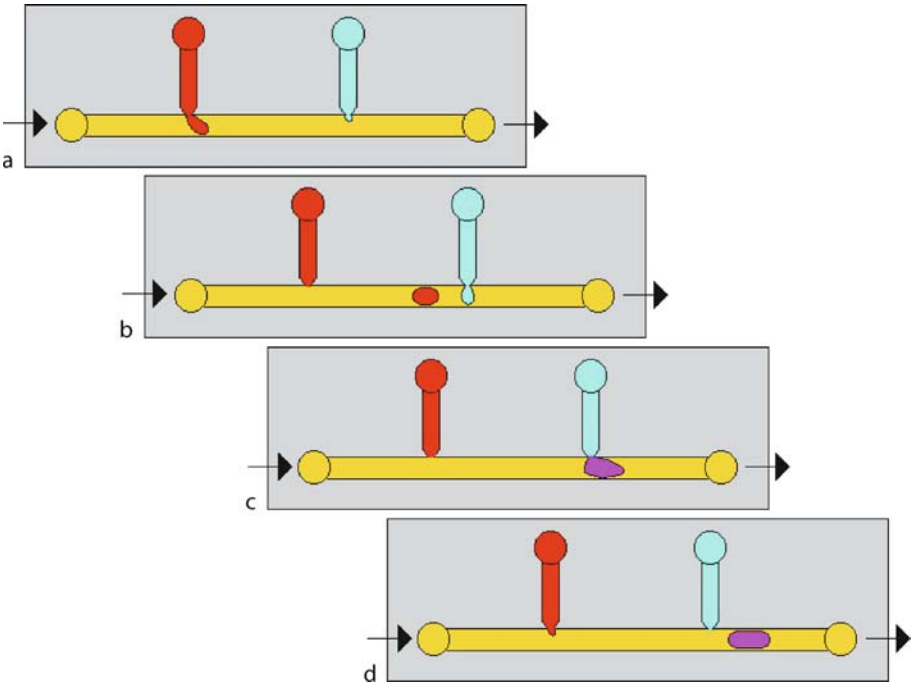
A regular formation of fluid segments takes place if the segment-forming liquid is non-wetting and is brought together with the wetting carrier liquid with constant volume flow rates. Such a regular segmentation is marked by a constant size of segments as well as a by a constant frequency. Fluctuations in segment size and distance observed in real experiments can be smaller than 1% and are mainly due to shifting or fluctuating flow rates, small pressure fluctuations or particles passing the injector.

Characterization of Segments

Size and distance of segments can be characterized by the relative distance of alternating phase boundaries (liquid–liquid interfaces). These positions can be determined by photographic imaging. Electrical or optical methods can much easier be applied for automated recording of the quality of segment sequences. The measurements can use the differences in physical properties of segment liquid and carrier liquid.

In case of coloured liquids, photometry represents a very simple method for the determination of the alternating liquids. Microphotometric arrangements easily allow measurement frequencies up to 5 kHz. This means that the size of segments passing the detector with a frequency of 25 Hz can be measured with an accuracy of about 1%.

Carrier liquid and segment liquid consist normally of substances or mixtures with very different electrical properties. For example, the dielectric constants of an oil or a perfluorinated alkane (typical carrier liquids for aqueous segments) are much smaller than those of water. Electrical measurements can use differences in specific resistances



Microsegmented Flow, Figure 3 Mixing of two miscible liquids inside a segment formed and transported in a carrier stream of a third immiscible liquid

of direct or alternating current. In principle, changes in electrochemical properties like media-dependent electrode potentials or Faraday currents can also be used for the detection of the interfaces.

For practical purposes, the characterization of the components of segments is of interest beside the size and distance between segments. Optical methods are preferred due to their easy applicability. Other sensoric functions like electrochemical methods can only be used if there is a contact between segment and wall. This contact is often suppressed by a film of carrier liquid between the segment and the wall.

Dosing to Preformed Segments

The addressability of segments can be used for the formation of segment sequence pattern. Pattern can be expressed by changing size, distance or compositions. Alternating size or alternating colour represent, for example, two simple forms of patterns.

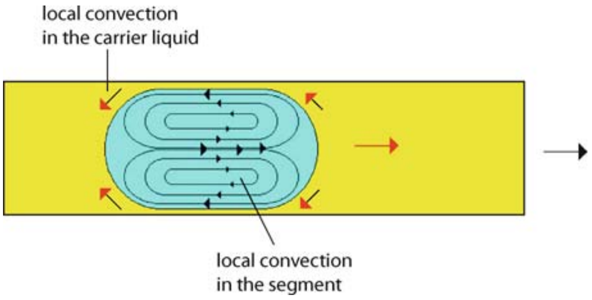
Changes in composition can be achieved either by changing concentrations in the injected liquid or by changing the concentration of a component inside a segment by injecting additional solution of another composition to a preformed segment. This dosing is preferably realized by using a second injector with an injection nozzle.

Double-injector devices are well suited for the generation of patterned segment sequences. They are particularly suited for making segment series with stepwise varied volumes and concentration ratios. Dosing can also be used for the unification of two different educt solutions in order to start chemical reactions inside segments (Fig. 3).

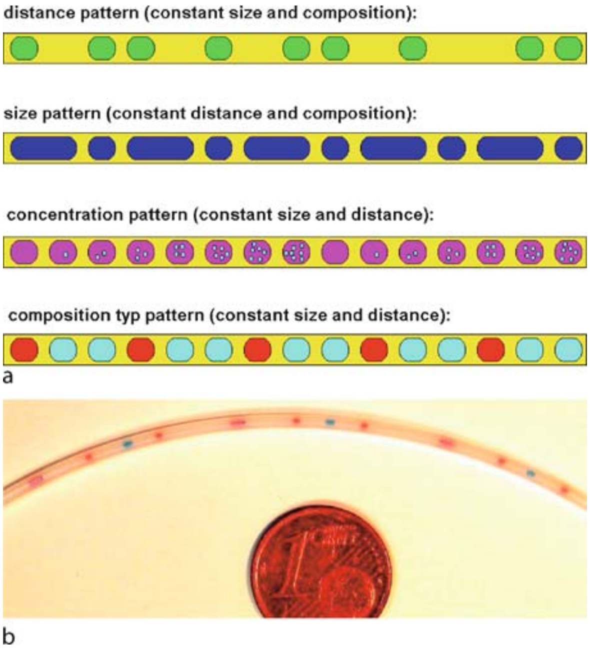
Segment sequences with larger stepwise varied concentrations or concentration ratios can easily be realized by including mixer structures in the inlet channels before the segment generating injector. Changing the composition, but with constant size of segments formed, is achieved if the two inlets of the injector are conducting fluid streams of different concentration and complementary changed flow rates.

Mixing by Induction of Segment-Internal Convection

The mixing of the original segment liquid with an added liquid is a precondition for the initiation of chemical reactions inside segments and for other operations with segments with homogenous distributed substances. In the case of particle-like transport behaviour of spherical segments, the mixing inside segments is only driven by diffusion if no external forces are inducing segment-internal convection. This process can be slow, in particular in the case of dissolved macromolecules, nanoparticles and cells. Such a convection can be caused by fields generated outside



Microsegmented Flow, Figure 4 Internal convection inside a moving fluid segment



Microsegmented Flow, Figure 5 Pattern formation in microfluid segment sequences: (**a**) pattern types (schematic); (**b**) periodic pattern of segments with different size and composition after merging of two simple segment sequences with different period and composition

the segmented fluids, for example by magnetic fields or mechanic oscillations like surface acoustic waves (SAWs), if the liquid is sensitive to these forces (magnetic properties, local density differences).

A simple induction method for internal convection is the transfer of shear stress from the embedding carrier liquid into the embedded liquid of the segments (Fig. 4). This is always the case if the viscosity of the liquid inside the segments is not much greater than the viscosity of the carrier liquid. A particularly intense segment-internal convection is induced if segments pass curved channels or capillaries. Series of loops lead regularly to good internal mixing after dosing to segments. Loop or meander structures are often used as mixer elements for segment-internal mixing in microfluidic devices for segment operations.

Segment Merging (Fusion) and Segment Sequence Patterns

The generation of composition and size patterns in fluid segment sequences can also be realized by fusion of segments of different original composition. In the absence of surfactants, the contact of two segments of the same solvent leads to an immediate coalescence. Molecular layers formed by surfactant molecules at the fluid interfaces can suppress or delay the coalescence and, therefore, segment fusion.

The fusion of segments can be initiated by the joining of two or more segment streams, for example in a Y- or T-element. The regularity of fusion is often disturbed by fluctuations in segment distances in the original sequences. Then, devices with hydrodynamic self-controlling of segment transport can support a synchronization of segment pairs arriving from both input streams at the junction structure.

Segment fusion can also be realized in inline structures, if one segment stops at a fluid resistance or in a stopping chamber, so that it is united with a following segment. The larger segment so formed can move on in the case of appropriate stopping structures. A regular pairwise fusion in a linear chain of segments demands good adaptation of flow rate, viscosity and stopping structure. A regular mixing of segments from two original segment streams can be achieved in an alternative to the one-step fusion at a T- or V-junction by a two-step process consisting of segment stacking by a branched structure (T- or V-shaped) and a subsequent linear fusion structure.

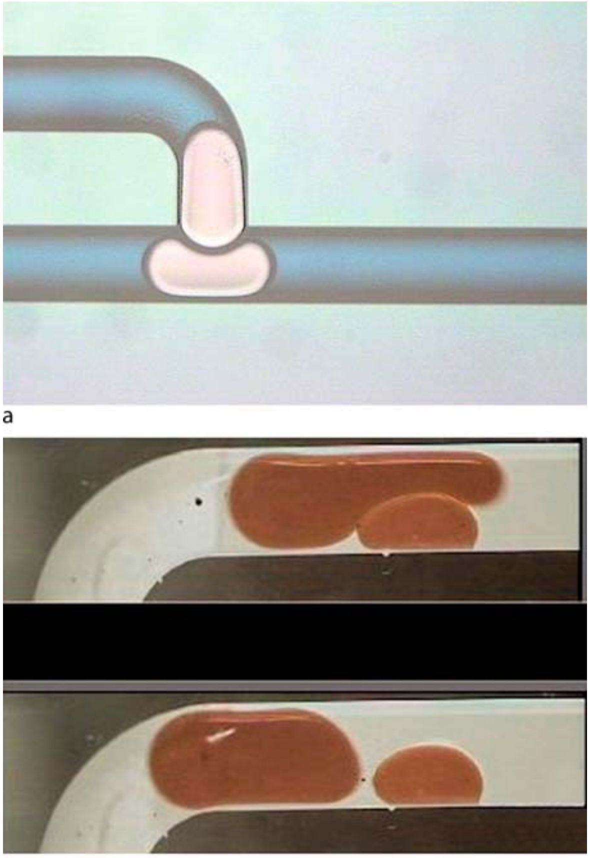
Fusion and splitting of segments can result in complex, but regular patterns. In principle different types of sequence pattern can be realized (Fig. 5a):

- distance patterns;
- size patterns;
- concentration patterns;
- segment type patterns; and
- mixed variants of these types.

An example of a nearly periodic, but complex pattern with segments varying in distance, size and composition is shown in Fig. 5b.

Surfactants affect the transport behaviour and the fusion behaviour of fluid segments. The contact between microfluid segments leads regularly to an immediate coalescence. This coalescence can be delayed or completely suppressed if surfactants are involved (Fig. 6). Segments can be pressed against each other in a T-junction without coalescence, for example (Fig. 6a). In some cases, a strong deformation occurs without coalescence or destruction of

M



a

b

Microsegmented Flow, Figure 6 Influence of surfactants on segment transport behaviour: (**a**) deformation of a segment under contact with another segment without fusion; (**b**) separation, contact without coalescence and deformation of two fluid compartments of the same phase type (dark) in the surrounding of an immiscible carrier liquid (bright) in the presence of surfactants

segments, as is observed in an example where one fluid segment is adsorbed at the wall, whereas a second segment passes under strong deformation (Fig. 6b). It is assumed that in these cases the presence of surfactants leads to membrane-like molecular double layers in the contact region of segments.

Applications

Microfluid segments are applied both in microchemistry and in biotechnology. They are used, for example, in chemical synthesis in liquid phase, for the preparation of nanoparticles, for analytical chemistry, for cell cultivation and screening and for DNA amplification by polymerase chain reaction. Cell technology, molecular biotechnology, medical and environmental diagnostics as well as the development of new materials and active agents demand new methods for the characterization and optimization of substances and microscopic biological objects like cells, cell organelles, viruses and biomacromolecules. This demand can be regarded as a need for read-out and optimization of information incorporated in molecules, solids and biosystems. Laboratory techniques and equipment get more and more the character of an information interface between chemical and biological objects on the one side and measurement devices and computers on the other. No large amounts of substances are needed for this information exchange and optimization. The applied number of biological or chemical objects involved in the information exchange processes can be reduced to the minimal value which is necessary for initiation of processes, detection of interactions or read-out of data. In contrast, instead of single samples, large sets of samples must be operated in order to maximize the information throughput. Therefore, several miniaturization and parallelization strategies have been developed during the last few decades.

Series of microfluid segments represent an important alternative to the microchamber arrays like MTP and NTP technology. MTPs and NTPs were introduced for highly parallelized handling of liquid samples. However, there are several disadvantages in the application of such microchamber arrays. First, the filling of the chambers demands a liquid dispensing or pipetting system. So, the generation of larger sample sets is always connected with a complex mechanical system and more or less sophisticated handling. Second, the application, processing and characterization of liquids inside the microchambers of MTPs and NTPs become increasing difficult and less reproducible in the case of decreasing liquid volumes. Third, the further manipulation after application of liquids into the chambers is difficult. MTPs and NTPs do not support complex operations with liquids. So, automation of processes with several process steps is connected with much effort in roboting and micropipetting or completely impossible. All these problems can be overcome by the application of microfluid segments. The constant volume and composition and the comparatively high stability of a certain segment make these fluid elements well suited for massive serial or highly parallel processing.

Future Directions of Research

Recent research is focussed on understanding the transport behaviour and the phenomena of induced convection inside the segments and in the carrier liquid. The understanding of different influences on the convection pattern is important for mixing control, minimization of mixing time inside segments and understanding the role of material and process parameters like viscosity and flow rate on

internal mixing. Particular attention is paid for the incorporation of particles and cells, which can influence the internal convection on one side, but can be damaged or destroyed by shear stress due to the internal convection.

Particular importance attaches to the wetting behaviour of the segments. This is responsible for the transport behaviour and influences strongly the deformation behaviour in the case of geometry change as well as fusion and splitting processes. Therefore, the control of changes in interface tensions is very important. Considerable changes can be induced by addition of surfactants or other amphiphilic chemicals, chemical reaction and also by biological activity.

There is much research concerned with different applications of the segmented flow principle. It reaches from chemical synthesis to analytical procedures in inorganic and organic chemistry and molecular biology to miniaturized screenings with bacteria, eucaryotic cells and multicellular organisms. The investigations deal with the formation and transport behaviour of the fluid segments under the particular application conditions, with the behaviour of treated objects like cells, particles and biomolecules inside the segments and with the improvement of different conventional methods by transferring them into microfluid segments. Therefore, improvements of yield and selectivity in chemical reactions, efficiency and reproducibility in analytical procedures and the efficiency of highly parallelized screenings are under investigation.

The development of (1) new handling tools for fluidic segments, (2) the improvement of the characterization of segment contents, (3) the control of segment operations in complex networks, (4) the use of microfluid segments as models for biological compartmentation and (5) the ultraminiaturization of the segmented flow principle will be the main challenges for further research besides the recent basic investigations on segment formation, microfluidic behaviour and applications.

It is comparatively easy to generate and process larger series of fluid segments. However, there is an urgent need for segment-on-demand techniques in order to realize well-controlled automated processes for the generation of segment patterns and for dosing and fusion processes with different treatment of single segments. The individually addressed stopping, switching and other manipulation of well-selected single segments from larger segment sequences are a second demand on the development of new microfluidic actuators. The development of microstructured actuators for addressing single segments must be accompanied by the development of appropriate miniaturized sensors. In principle, several sensor developments during the last few decades for other purposes can be applicable, but they are not adapted for microfluid segment control and operations and must be adapted and integrated in functional modules or microfluidic networks for microsegmented flow applications.

Sensors relevant to the above discussion are mainly necessary for identifying segments and measuring the position, size and speed of them. Additional information can be supplied by measuring pressure drops, pressure fluctuations, electrical conductivity, dielectric properties, temperature, thermal capacity and heat conductivity. In addition to this sensing, more detailed information from microfluid segments must be extracted in order to characterize the content and the change of content of segments during chemical and biological processes inside the segments. Therefore, different spectroscopic and other analytical techniques have to be adapted to microfluid segment systems. Optical techniques are favoured for this purpose, because they work without direct mechanical or chemical contact with the segment liquids. Unfortunately, spectrophotometry and fluorimetry in the UV and visible range of light supply only raw information about chemical and biological changes. More information could be gained by mid-infrared and Raman spectrometry. Possibly, turbidimetric measurements, light scattering, microscopic techniques and relaxation measurements using thermal pulses and laser-impulse techniques would probably be suited for gaining supplementary information about changes inside fluid segments.

It is expected that more interest will be focused on the segment behaviour in complex networks of segment elements if control of transport and manipulation of individual elements is improved. Particular processes including several steps of splitting and fusion will be of interest. However, the development of such complex systems, which could be applied for analytical or screening procedures, must be strictly founded on strong control of the previous history of the content of single segments (segment process reports) and is therefore dependent not only on the architecture of networks but also on the successes of the development of integrated sensors and actuators for segment addressing.

A particularly interesting field is the ultra-miniaturization of fluid segments. The further decrease of segment volumes into the picolitre and sub-picolitre range leads to segments which are much more robust than larger ones due to the high surface to volume ratios. Also, interface properties and interface changes will become increasingly important in such systems. It is expected that a lot of exciting new effects will be discovered during this ultraminiaturization process. Future developments will probably include the treatment of high numbers of robust spherical picolitre and femtolitre droplets dependent on changing physical and chemical parameters and gradients of them in embedding liquids. They will involve a drastic

enhancement of mobility of medium and higher viscosity liquids in very small channels by transporting them in the form of segments or droplets in embedding liquids of very low viscosity (for example by pressure-liquified inert gases), switching of segment properties and segment interactions by radiation-induced switching of molecular interface layers, "tunnelling" of liquid phases through other phases and many other effects. Of particular importance could be studying segment behaviour in small environments like nanocapillary slits and inside nanotubes. Besides simply structured fluidic segments, the embedding of micelles, vesicles, colloidal phases and nanoemulsions as well as the generation, handling and manipulation of complex hierarchically structured segments (nested phases) will be of particular importance for this research direction.

The application of different types of amphiphilic substances in connection with a variety of segment manipulations opens the possibility to construct microfluidic segments as models for spontaneously formed vesicles, biological cells, cell organelles, viruses and other particles and compartments. This gives the possibility of preparing cell-like microcompartments with selected groups of cellular functions and to make different functional models of living cells. In this way, addressable populations of "artificial cells" equipped with different sets of functions could be operated. Fluidic networks for the handling of these compartments will probably be particularly suited for studying cellular interactions and chemical communications, and also the interactions between the artificial cell-like compartments and cells. Processes like endocytosis and exocytosis, cell division and penetration through membranes could be statistically studied in populations of well-designed nanofluidic objects embedded in fluidic segments which allow all required manipulations. It is imaginable that the technique of segmented flow will not only be able to contribute to a lot of new cell-oriented techniques, but also could contribute to the understanding and future technical reproduction of the mystery of life.

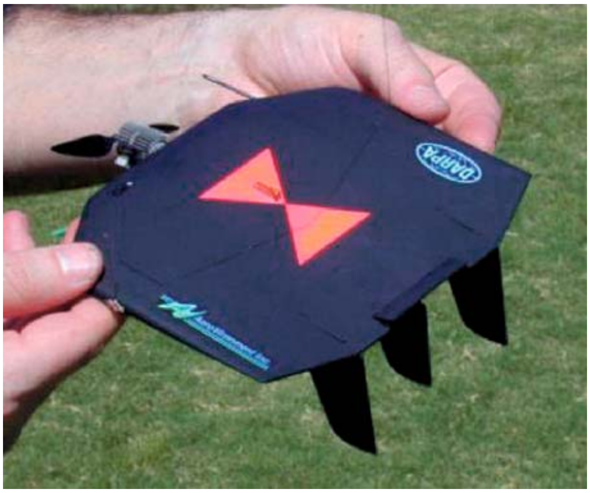
Stereolithography

Definition

► Stereolithography (SL) is a special type of additive fabrication process, in the general class of techniques known

as solid freeform fabrication (SFF), that is used to produce solid objects directly from computer design data. Solid freeform fabrication refers to techniques in which a solid object is manufactured by the sequential delivery of energy and/or material to specific points in space to produce that solid part. SFF is also sometimes referred to as solid freeform manufacturing (SFM), rapid prototyping (RP), rapid manufacturing (RM), additive fabrication (AF), or layered manufacturing (LM). In stereolithography, manufacturing of the desired part is accomplished by using a vat of liquid photocurable resin and a light source that can produce pattern-wise exposure in the vat to build up the solid polymer object via localized polymerization of the photocurable resin. ►Microsterolithography (MSL) simply refers to SL processes which possess feature resolutions that are significantly higher than the tens of micron accuracies that are typically possible with conventional SL tools.



Microsterolithography, Figure 1 Schematic of a scanning-based stereolithography apparatus

Overview

►Stereolithography (SL) is one type of layer-by-layer manufacturing process, based on photopolymerization of a photocurable resin, that was first reported in 1981 by teams from the United States [1], Europe [2], and Japan [3]. It is a 3D manufacturing technique that can directly build a solid 3-dimensional part directly from a computer data file containing the information on the part size and shape in electronic format. Such electronic data can be generated either directly from computer aided design (CAD) software when an object is designed, or can be generated from existing solid objects through imaging techniques that can measure and record the shape and size of an object in a three dimensional data format such as magnetic resonance imaging (MRI).

The SL process begins with the generation of the 3D data file containing a model of the shape and size of the object that is to be built. This model of the object is then sliced into a series of closely spaced planes that represent two-dimensional (2D) cross-sections of the 3D object, each at a slightly different coordinate along one axis of the object. These 2D slices are then translated into numerical control codes and combined together to generate a data file that can control the stereolithography apparatus (SLA) that is used to build the part. Most commonly, this data file is used to control elevator position and laser beam scanning path in a scanning laser SLA tool. A simple schematic of how such a scanning laser SLA tool works is shown in Fig. 1. First, an elevator platform that will support the part that is being built is brought within some close distance to the surface in a vat of a photocurable resin. A laser is scanned over the surface of the vat and initiates polymerization where the resin is exposed to the light. Two main types of polymerization reactions are used in SL processes:

- radical induced chain propagation polymerizations (often of acrylic monomers) and
- ionic chain propagation polymerization (often with epoxy or urethane monomers).

Examples of the basic chemistry involved in such polymerizations is shown in Fig. 2. In conventional SLA tools, the laser beam diameter is typically on the order of 100 μ in size and the focused beam has a large depth of focus such that a relatively consistent beam diameter can be maintained as the beam is scanned across large areas of the vat. After the first layer of the object is polymerized, the elevator is lowered down by some small incremental distance into the vat, the liquid resin is allowed to flow over the top of the first layer, and the laser is scanned over the surface to initiate polymerization of the second layer of the part in this new resin layer. This process is repeated over-and-over for each layer of the part until the object is completed. Once the object has been made, the part is raised from the resin vat on the elevator, drained and washed of the unreacted photocurable resin, and subjected to various treatments to finish hardening the object. The first commercially available SLA system was produced by 3D Systems in 1987 and SL is now a widely used technique in industries such as automotive and aerospace. In these industries, SL was originally used to fabricate an array of objects from basic design verification parts to "show and tell" objects at low cost before significant more expense was invested to mass produce or make any actual application-ready mechani-

Microsterolithography, Figure 2 Examples of the basic chemistry involved in the photopolymerization processes used in stereolithography

cal parts. Instead of waiting the days, weeks, or months that were common at the time for production of a complex mechanical part using milling or other machining and molding techniques, SL allowed for the direct production of such parts on the time scale of hours. For this reason, it was termed a *rapid prototyping* method. The first SL materials consisted of mixtures of monomers, oligomers, and photoinitiators that could be cured into high moleular weight polymers by exposure to ultraviolet light, and these compounds were used to make purely polymeric solid objects. However, to meet the demands of various applications, especially in terms of transitioning the method from a rapid prototyping technique to a true *rapid manufacturing* method, new photocurable resins that could be used to produce ceramic or metallic parts were developed [4]. Such new resin developments allowed the parts produced by SL to be directly used in applications such as rapid tooling.

Microstereolithography (MSL) is a more recent augmentation to conventional SL techniques that allows for parts with much higher spatial part resolution and surface finish to be produced. In MSL techniques, much more tightly focused light (i. e. exposure sources with a much smaller effective pixel size are used, generally with pixel or spot sizes on the order of 1 μ or better) is used to initiate polymerization and cure the part. There have been two basic types of MSL techniques reported:

- scanning-based MSL methods and
- projection-based MSL methods.

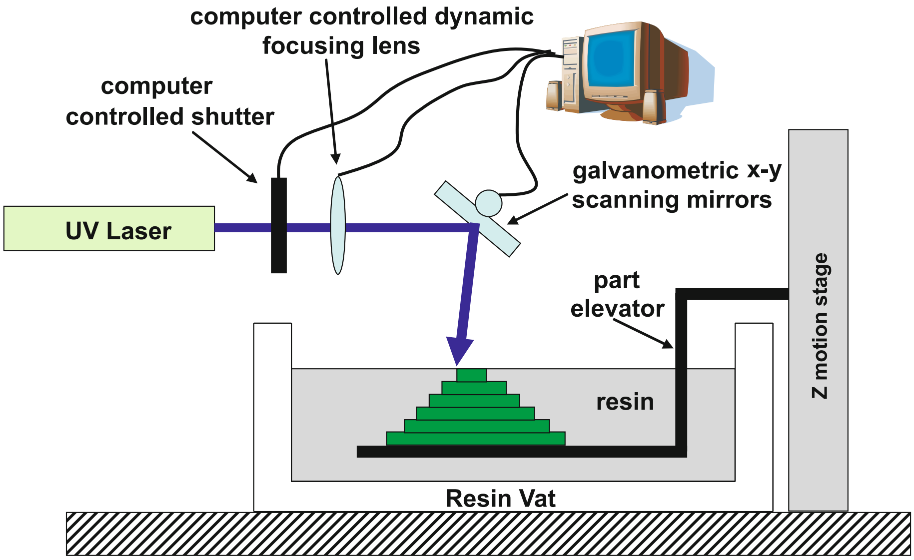
Additional details of these methods are provided in the next section.

Basic Methodology

As mentioned previously, microstereolithography systems can be divided into two general categories:

- scanning-based systems and
- projection-based systems.

Scanning-based MSL systems are basically modified versions of the classical SLA tools originally developed for SL. They generally involve scannning a very tightly focused laser beam over or within a vat of liquid photocurable resin to produce a solid 3D object. A schematic example of a possible configuration for an MSL tool that is analogous to the SLA apparatus described earlier is shown in Fig. 3. Such a tool and technique are also referred to as a vector-by-vector MSL apparatus or method. The main difference between the MSL tool in Fig. 2 and the original SLA tool shown earlier in Fig. 1 is that a dynamic lens is shown in the MSL tool to maintain a very tightly focused beam. The disadvantage in such an MSL tool is that the plane of best focus for such a tightly focused beam being moved by means of a series of rotating mirror is a spherical surface whereas the liquid monomer surface to be cured is planar in nature. This requires the use of such a dynamic focusing lens that can be used to adjust the focal length of the beam as the beam is scanned so as to maintain the desired small beam diameter on the resin vat surface as each layer of the object is drawn. Even though it is in principle possible, published reports show that this issue of dynamic focusing is critical to producing a high resolution process using such a tool and that it is in fact quite difficult to achieve the desired resolutions using such a configura-



Microsterolithography, Figure 3 Schematic of a basic microstereolithography apparatus

tion. Due to these difficulties, a series of other types of scanning MSL tools have been reported in the literature as described in the following sections.

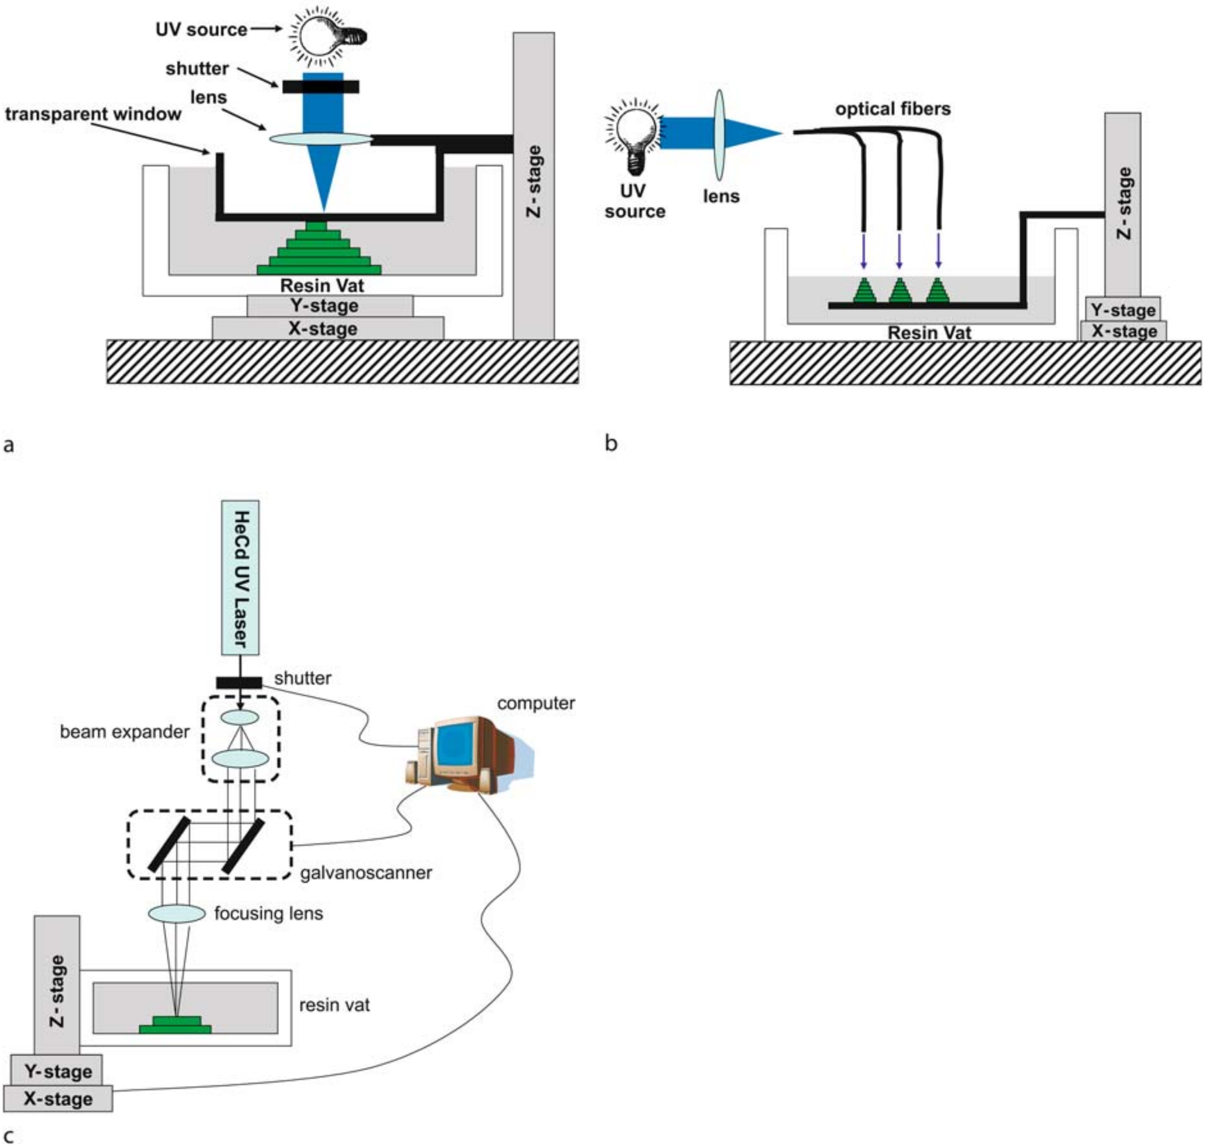
The Integrate Harden (IH) Polymer Stereolithography Process

The first reported MSL technique was in fact introduced by Professo Ikuta and coworkers in 1993 and was used for making microelectromechanical system (MEMS) parts [5]. In their Integrated Harden Polymer Stereolithography process (IH process), a tightly focused beam was scanned over a resin vat. In their case, a window was placed on the surface of the vat and exposure occurred through the window. The position of the window was translated in the *Z*-direction to change the location of the surface at which polymerization occured. Due to the focusing problem mentioned earlier and the fact that commercial galvanometric scanning mirrors did not possess the scanning resolutions needed, a different *X*-*Y* scanning and *Z*-scanning approach was used in the original IH method. The focal point of the apparatus remained fixed in space relative to the window by directly attaching the exposure source, lens, and optical window that defined the resin surface to a motorized *Z*-stage so as to achieve the tightest possible focus. To produce the object, the vat was translated in the *X*-*Y* plane and the window and focused spot was translated in the *Z*-direction to cause local polymerization and solidify the object being manufactured (see Fig. 4). The main disadvantage of this technique is that the scanning speeds possible when moving the entire resin vat are significantly lower than the scanning speed possible when simply moving the beam around using galvanometric mirrors. However, high aspect ratio, 3D parts were made using this type of method. Another disadvantage of this technique is that it is possible for the part being polymerized can stick to the optical window in such a constrained surface configuration, and thus free surface versions of this type of system have also been produced and used, whereby the resin vat is translated in all three directions (*X*-*Y*-*Z*) while the exposure source and focal spot remain fixed in space. Feature resolutions on the order of 1 μ have been demonstrated using such systems.

The Mass-IH Process

In order to address the speed issue with the original IH process, Prof. Ikuta developed and reported the so-called Mass-IH process in 1996 [6]. In this new version of the IH technique, the exposure source was tightly focused onto a fiber optic bundle, and each of the fiber ends was placed into a ordered array that was used to generate a series of exposure point sources in the resin vat that were scanned by again moving the entire object and resin vat (see Fig. 4). The advantage in the Mass-IH process is that it can be made reasonably parallel in nature using this multi-exposure source approach to offset the slow scanning speed of the resin vat. Both the IH and Mass-IH processes suffered from a number of problems though including:

- the depth of resolution of the object is determined by the thickness of the layer slices stacked together to build the object and



Microsterolithography, Figure 4 Schematic of the apparatus used for the (**a**) IH process, (**b**) Mass-IH process, and (**c**) Super-IH process developed by [3]

- surface tension effects and other phenomena can lead to deformation or destruction of small microscale parts during fabrication and processing.

The Super-IH Process

Due to the limitations of the IH and Mass-IH processes, Professor Ikuta and coworkers developed and reported the so-called Super-IH process in 1998 in which a broad beam is tightly focused into the volume of the resin vat and is used to cause local polymerization at the focal spot of the beam (see Fig. 4). A 3D object is produced by translating the focal spot of the beam inside the vat to draw out the desired shape. This movement away from surface polymerization in the resin vat in favor of polymerization in the volume can allow one to eliminate the need for support or sacrificial structures that are common in conventional SL processes that rely on surface polymerization. Furthermore, since the polymerization of material does not occur at a free resin surface in the super IH process, surface tension effects and other problematic phenomena associated with polymerization at the resin surface can be minimized or eliminated. However, there are a number of challenges associated with such a technique. First, the beam used for

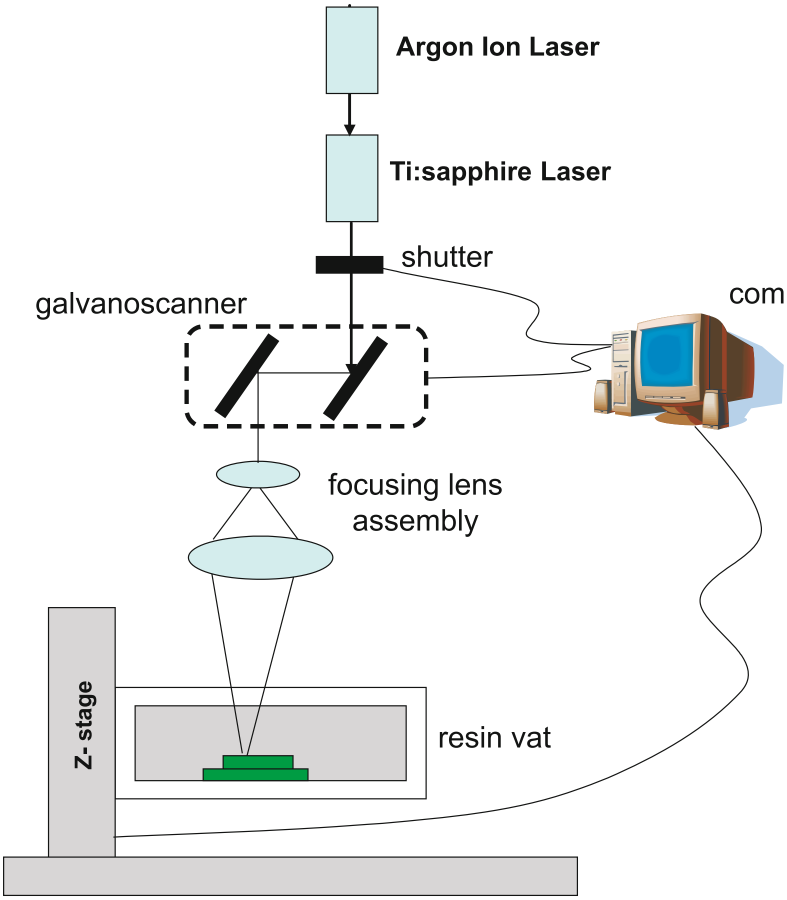
exposure passes through the vat on its way to the focal point, and so regions of the resin vat in addition to the focal point of the beam received light energy while the material at the beam focus is being polymerized. Although the intensity of the beam is lower in these other regions than at the focal spot, avoiding extensive polymerization in these other regions can be challenging. By using carefully designed resins that exhibit a very non-linear response to exposure dose it was shown to be possible though to use such methods to produce very small, complex 3D parts with feature resolutions well below 1 micron.

Two-Photon Microstereolithography

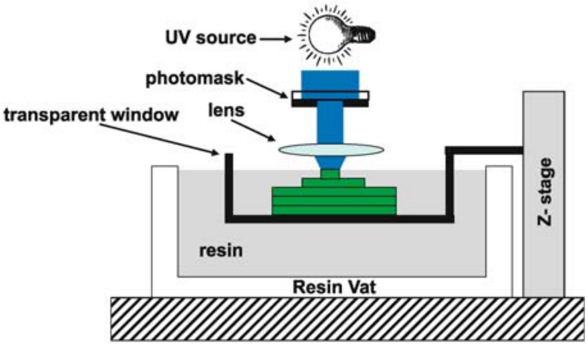
As mentioned in the discussion of the Super IH technique, a challenge in doing microstereolithography via polymerization in the resin volume (i. e. as opposed to surface polymerization) with a tightly focused beam is that the material being polymerized needs to have a highly non-linear response to either total exposure dose or to local light intensity. Such a non-linear response allows one to achieve polymerization with high spatial resolution without spurious polymerization in regions of the vat that are unavoidably exposed by the unfocused beam as it propagates through the vat on its way to the focal point. So-called two-photon processes can provide such a highly non-linear response to local light intensity that can help confine polymerization to the beam focal region. As described earlier in Fig. 2, in conventional photopolymerization processes, one photon is absorbed the polymerization initiator and results in the production of a radical, acid, or base that initiates polymerization of the monomer/oligomer mixture. This means that the rate of initiation locally in the resin is proportional to the local light intensity (I). In two-photon polymerization, a so-called two-photon absorption process is used that requires two photons to be absorbed by the photoinitiator to produce an active initiator (i. e. a radical, acid, or base). There are two general types of two-photon excitation processes. The first type of two photon reaction process is termed *sequential excitation* or *resonant two-photon absorption*. In this case, the photoinitiator first absorbs a photon and an intermediate excited state of the molecule of the photoinitiator is created that typically has lifetimes in the range of 10^{-4} to 10^{-9} s. However, the excited state intermediate created is not capable of going on to further produce the active initiator radical, acid, or base without additional energy. A second photon must be absorbed by the excited intermediate within its lifetime to result in the desired photochemical reaction and initiate polymerization. Therefore, it should be clear that the rate of initiation of polymerization in such a two-photon process will be proportional the local light intensity squared (I^2), which provides the desired non-linear dependence on local light intensity that helps to confine polymerization to the tightly focused region of the beam in an MSL tool. The other type of two-photon absorption process is termed *simultaneous two-photon absorption* or *non-resonant two-photon excitation*. In this case, no excited intermediate is produced and instead both photons must be absorbed essentially simultaneously, i. e. within the interaction time of the photon with the photoinitiator which is on the order of 10^{-15} s. The requirement that two photons arrive at the photoinitiator in such short times scales requires very high intensity laser sources for either type of two-photon process. An example of a schematic of such a two-photon MSL tool is shown in Fig. 5. Such two-photon systems have produced the smallest MSL manufactured objects to date, with feature resolutions in the tens of nanometers having been demonstrated.

Real Mask Projection Microstereolithography

In this MSL technique, a part is built by irradiating the photopolymerizable resin through a physical or "real" patterned mask in a manner similar to traditional photolithography. The mask in this case is generally either a glass or quartz plate that has been coated with an optically opaque film (e. g. metal) that has been removed in a pattern-wise fashion representing the cross-section of the object to be built. Fig. 6 shows a schematic of an apparatus that can be used for mask projection MSL. Although it is possible to simply use the mask to shadow mask the resin during exposure without the use of any lens elements in a manner similar to the proximity printing processes used in photolithography, the resolution of such processes is typically limited to many tens or hundreds of microns due to diffraction effects and difficulty in bringing the mask close to the liquid resin surface and maintaining a constant gap width. Therefore, most mask projection MSL systems use lens elements to focus an image of the mask onto the resin surface. This focusing of the mask image onto the resin surface can significantly improve the resolution of the process and offers the possibility to use a reduction lens system in which the size of the features on the mask is reduced in the projected image, thereby improving the resolution of the features in the manufactured part relative to the original mask patterns. After exposure of the resin surface through the mask, a new layer of resin is prepared on the surface of the resin vat in some manner and the exposure process is repeated. For example, in Fig. 6 an elevator arrangement similar to those shown earlier in the scanning MSL techniques is used to move the object lower into the resin vat and a fresh layer of resin flows over the object after each exposure. The main advantage of mask projection MSL



Microsterolithography, Figure 5 Schematic of an apparatus that can be used for direct volumetric fabrication of objects using two-photon photopolymerization

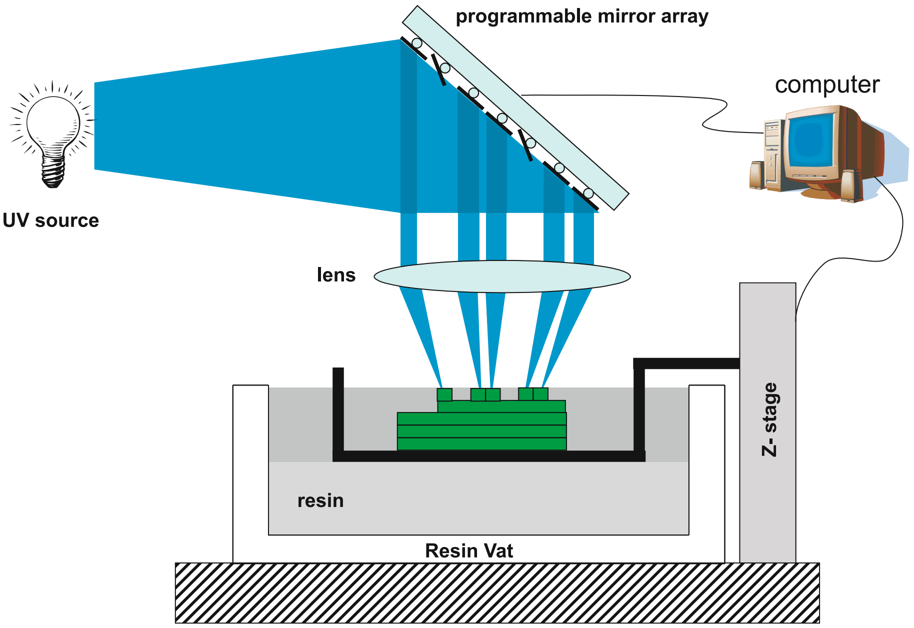


Microsterolithography, Figure 6 Schematic of an apparatus for real mask projection stereolithography

over scanning MSL techniques is that large areas of resin can be exposed simulataneously, resulting in much faster build times per layer and per total part. The main disadvantage of mask projection MSL is that a physical mask must be created for each different cross-section of the object that is to be built. For this reason, only objects with a constant cross-section or a few different cross-section profiles are built using this method. For producing very small scale objects, the cost of producing the physical masks can become significant.

Dynamic Mask Projection Microstereolithography

Dynamic mask projection MSL is in principle the same type of process as real mask MSL except that in this case a *dynamic mask* is used instead of a physical mask. The dynamic mask is capable of being changed arbitrarily for each layer that is exposed, thus allowing parts with any number of different cross-sections to be fabricated by such methods. A schematic of a dynamic mask projection MSL apparatus is shown in Fig. 7. The dynamic mask used in such methods generally consists of one of two types of systems:



Microsterolithography, Figure 7 Schematic of an apparatus for dynamic mask projection stereolithography

- a transmissive liquid crystal display (LCD) that is sometime referred to as an LCD light valve or
- a micromirror array similar those now common in optical computer projector systems (e. g. the micromirror arrays produced by Texas Instruments and referred to as digital light projection or DLP systems).

In either the LCD or micromirror dynamic mask, the LCD or micromirror array consists of a large number of individually controllable pixels. For example, current micromirror arrays that contain more than 800,000 individually addressable mirrors are available where each mirror in the array is a square mirror that is roughly 15 μ long on each side. Therefore, again using lens-based projection optical systems it is possible to produce complex 3D objects with feature resolution down in the micron scale range and below quite easily.

Light Propagation and Cure Modeling in Photopolymerization During Scanning-Based Stereolithography

In processes where photopolymerization is used to achieve part fabrication using scanning-based stereolithography, the two critical paraemeters that must be controlled are the line width and the line cure depth. Both of these qualities of the photopolymerized line of material formed as the laser or light spot is scanned across the resin are determined by the radiation absorption in the resin, radiation distribution in the resin, exposure energy or dose given to the material, and the photochemical response of the resin to the exposure energy.

The transmission of light through an absorbing medium such as the photopolymerizable resin used in stereolithography can be described by the Beer–Lambert law as

$$I(z) = I(0)\,\mathrm{e}^{-\alpha z} = I(0)\,\mathrm{e}^{-z/D_\mathrm{p}}\,, \qquad (1)$$

where z is the distance light has traveled in the absorbing medium, $I(z)$ is the light intensity at the point z, $I(0)$ is the incident light intensity at the surface of the absorbing medium, α is the absorption coefficient of the absorbing medium, and D_p is termed the depth of penetration of light into the resin. D_p is simply defined as the depth into the absorbing medium at which point the light intensity at that depth is equal to $1/\mathrm{e}$ of the intensity at the surface of the medium. D_p is one of the common parameter used to describe a photopolymerization process used for stereolithography. For a Gaussian irradiance distribution beam source, such as a laser that could be used to expose the resin in a scanning stereolithography apparatus, the intensity distribution at any point inside the resin volume for normal incidence of the beam at a point $(0, 0, 0)$ on the resin surface can be expressed as

$$I(x, y, z) = \frac{2P}{\pi W_0^2}\,\mathrm{e}^{-2r^2/W_0^2}\,\mathrm{e}^{-z/D_\mathrm{p}}\,, \qquad (2)$$

$$r = \sqrt{x^2 + y^2}\,, \qquad (3)$$

where P is the laser power and W_0 is the Gaussian half width. Now, for a beam that scans along a single axis, in this case the x-axis, it is possible to express the laser exposure energy in the resin volume along the scan line as

$$E(y, z) = \sqrt{\frac{2}{\pi}} \frac{P}{W_0 V} \mathrm{e}^{-2y^2/W_0^2} \mathrm{e}^{-z/D_\mathrm{p}}, \quad (4)$$

where V is the beam scanning speed along the scan axis (i. e. in this case along the x-axis). Obviously the maximum exposure dose or energy will be dpeosited into the resin at the resin surface in the center of the beam along the scan line. If one calls this maximum exposure energy $E_{\max}$, it can be defined as

$$E_{\max} = E(0, 0) = \sqrt{\frac{2}{\pi} \frac{P}{W_0 V}}. \quad (5)$$

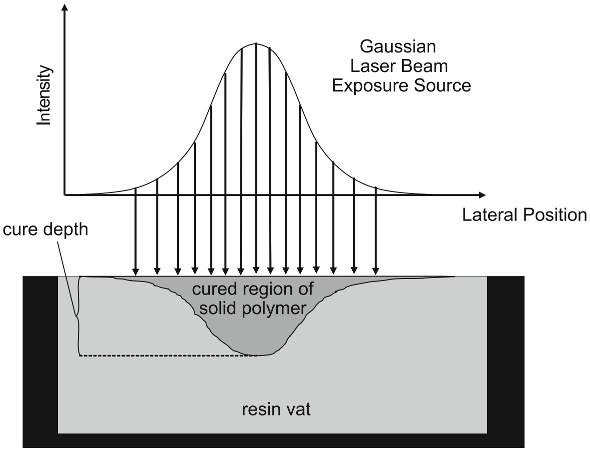
If one uses a threshold model for polymerization in which resin receiving more than a certain dose will become solid polymer, which is of course a gross oversimplification but which works reasonably well for SL process design, it is possible now to quantitatively describe the size and shape of the cured part due to SL exposure. Let us define the threshold exposure dose or energy required to turn the resin into solid polymer as E_c (i. e. the *critical exposure or critical energy*), then the so-called *cure depth* C_d, which represents the height of the single cured line formed due to the scanning beam, can be defined as

$$C_\mathrm{d} = D_\mathrm{p} \ln\left(\frac{E_{\max}}{E_\mathrm{c}}\right). \quad (6)$$

The line width (L_w) for a single cured line can also be obtained using the E_c criteria as

$$L_\mathrm{w} = W_0 \sqrt{2 \ln\left(\frac{E_{\max}}{E_\mathrm{c}}\right)}. \quad (7)$$

Figure 8 shows a schematic of the exposure process and result for a single line in cross-section. More generally, by using Eq. (4) in conjunction with the threshold criteria that resin which receives an exposure dose higher than E_c will become part of the polymerized solid object, it is possible to simulate the shape and size of a cured part. Such models are used in practice on stereolithography tools to perform the inverse process design needed to translate an object's CAD data into a beam scanning and exposure time recipe for making the desired solid object from the CAD data. In cases where the exposure beam is not Gaussian, similar results can be obtained assuming a different beam irradiance function.



Microsterolithography, Figure 8 Schematic of scanning stereolithography exposure process and resulting solid polymer line object produced from such methods during a single scan

It should be clear from this discussion that the two parameters, E_c and D_p can be used to provide a basic description of the SL or MSL process for a particular resin and exposure source combination. Experimentally, these parameters can be derived for a particular resin on a particular SL exposure tool by performing a series of experiments in which single line parts are made by varying $E_{\max}$ (i. e. by changing the laser scan speed for modulating the exposure source intensity). By measuring the cure depth of the resulting single line parts, it is possible to perform a nonlinear fitting of Eq. (6) to this data to determine E_c and D_p. It is also possible to derive these parameters from similar experiments using slightly different part types and SL protocols. Once these parameters are determined, they can then be used for the process planning required to fabricate a particular object from CAD data as mentioned earlier.

Key Research Findings

Stereolithography and microstereolithography techniques provide the ability to produce arbitrary objects directly from computer aided design data. Such methods have found widespread use in rapid prototyping applications and are beginning to see some application in rapid manufacturing applications. In scanning based systems, part feature resolutions on the order of 100 µ is common in commercial laser scanning systems. Two-photon photopolymerization methods can be used to significantly increase the resolution of such scanning based systems and to allow for direct 3D volumetric fabrication of object (i. e. as opposed to the layer-by-layer approach common to most SL and MSL methods). However, two-photon based SL and MSL has not been widely used commercially yet.

Dynamic mask projection SL and MSL tools have been recently developed and allow for the fabrication of objects at higher speeds and higher resolutions than single beam scanning tools, and such tools are likely to become more common in commercial applications in the coming years. Part feature resolutions on the order to one to 10 μ is relatively easy to obtain using such dynamic mask projection SL and MSL tools.

Future Directions for Research

As mentioned earlier, scanning-based stereolithography and microstereolithography are used quite widely for the rapid prototyping of objects. The main research directions for stereolithography include:

- finding ways to increase the speed with which parts are built,
- increasing the resolution and surface finish of built parts,
- developing new materials that can be used in conjunction with SL tools to produce functional parts, and
- using such advancements in materials and techniques to transition the methods to rapid manufacturing applications.

Research in two-photon MSL techniques is also very active, with current research directions including:

- developing better two-photon initiators,
- developing better apparati for two-photon MSL, and
- using the methods to perform tasks beyond traditional MSL part building, such as for the in situ fabrication of objects inside living cells and living systems.

Currently, mask projection microstereolithography is still much less common that scanning-based methods due to the fact that the micromirror arrays, which are now the most common form of dynamic mask used for such methods, are a relatively recent invention and have been commercially available for purchase for only a few years at this point.

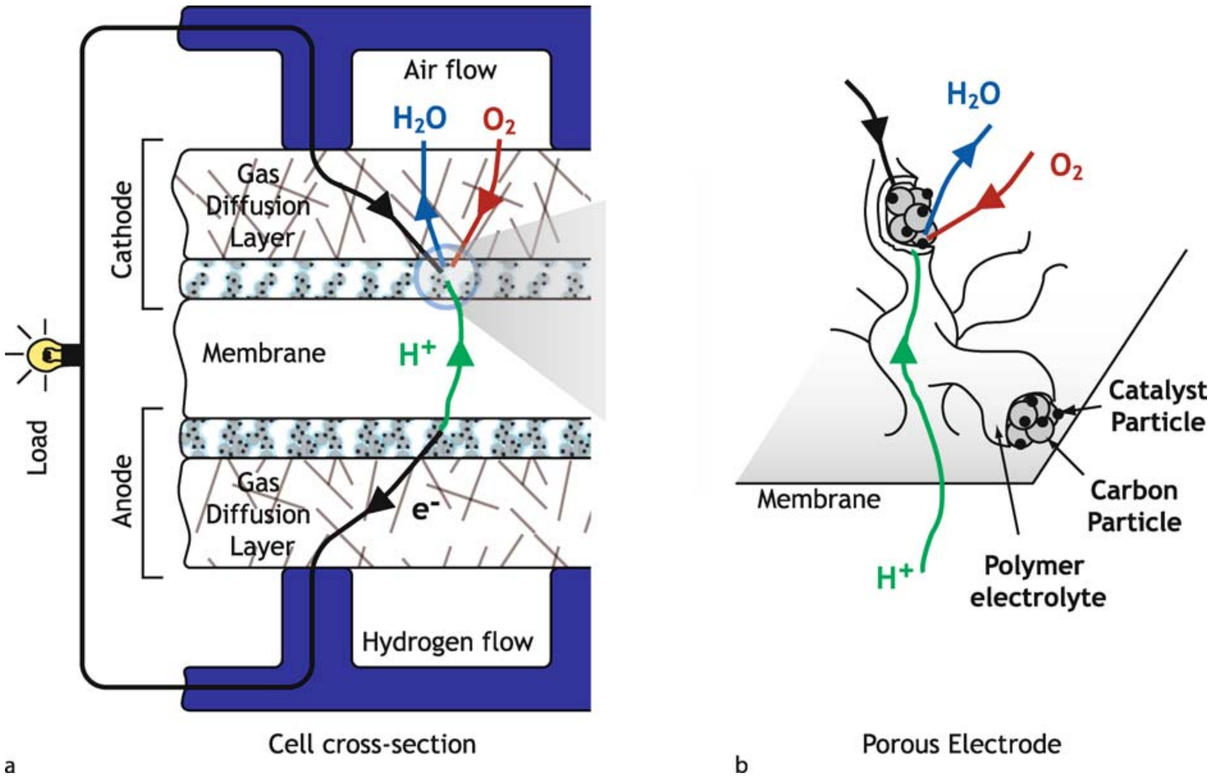
Definition

Micro fuel cells are miniature electrochemical energy conversion devices that generate a continuous electrical current from the flux of electrons exchanged between two half-reactions (reduction and oxidation) occurring in distinct regions of the cell. Microstructured hydrogen fuel cells are specifically implemented using microfabrication technologies and directly use hydrogen as a fuel.

Overview

Micro fuel cells are considered as promising power sources, offering longer autonomy for portable electronics and other devices traditionally powered by batteries. In contrast to electrochemical batteries, fuel cell power sources have distinct energy storage and power conversion components. The fuel cell can generate a constant level of power, as long as it is replenished with reactants and as long as products are removed. Hydrogen fuel cells typically have a planar layout consisting of anode and cathode electrode layers separated by a polymer electrolyte membrane, as illustrated in Fig. 1. Each electrode consists of a porous structure loaded with catalytic particles, such as platinum. They are covered by a diffusion layer and flow channels that deliver hydrogen or oxygen to the reaction sites. For fuel cells fed with hydrogen and oxygen (typically from the ambient air), the anode and cathode reactions are, respectively

M



Microstructured Hydrogen Fuel Cells, Figure 1 Operating principle and cross-section schematic of a hydrogen fuel cell

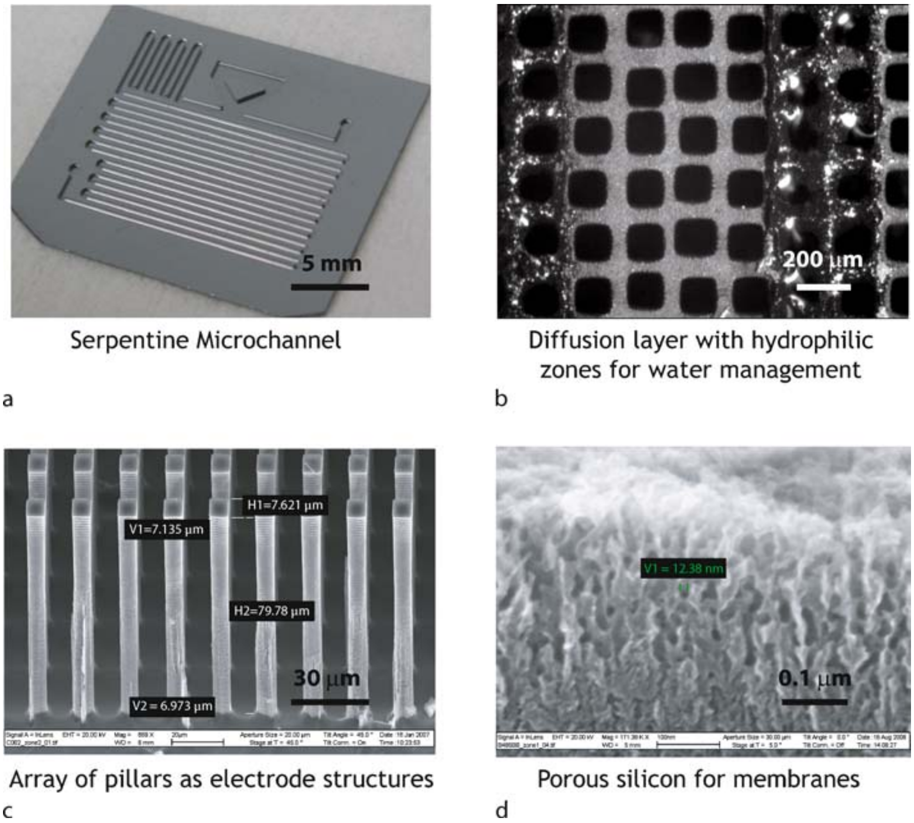
$$\begin{aligned} &\text{Anode:} && H_2 \overset{\text{Pt}}{\rightarrow} 2H^+ + 2e^- \\ &\text{Cathode:} && \frac{1}{2}O_2 + 2H^+ + 2e^- \overset{\text{Pt}}{\rightarrow} H_2O \end{aligned} \tag{1}$$

The protons (H^+) generated at the anode travel across the polymer electrolyte membrane to form water at the cathode. Electrons also travel to the cathode, but through an external circuit, providing the desired output electrical power.

The ideal cell potential between the two half-reactions for H_2/O_2 is 1.23 V at 25 °C. The actual cell voltage will be lower due to losses in the cell. As the current is increased from the open circuit condition, catalytic activation losses (dominant at the cathode) will initially reduce the voltage to ~ 1 V. Ohmic losses due to ionic resistance through the membrane and electrical resistance in the assembly (to a lesser extent) will further reduce the voltage in a linear fashion with current. The most common polymer electrolyte is Nafion (trademark of DuPont), which is a perfluorinated ionomer that must be humid to maintain good ionic conductivity. A limiting current will then be achieved, beyond which the mass transport of reactants (typically oxygen at the cathode) becomes insufficient to match the current, and the voltage drops to zero. Water accumulation at the cathode can restrict oxygen diffusion and lead to premature current limitation. Since power is the product of current and voltage, the maximum power level of the cell will be achieved before reaching the limiting current.

Micro Polymer Electrolyte Membrane Fuel Cells (μPEMFC) and their Challenges

Small hydrogen fuel cells can be similar to their large-scale counterparts, but some challenges differ [1]. For example, the mechanical assembly must apply sufficient pressure between the layers to ensure proper sealing and low electrical resistance, but upon miniaturization, this can easily dominate the fuel cell volume. The flow channels can be machined into the mechanical plates in a serpentine shape or in parallel channels aiming to provide uniform air and fuel delivery. In small-scale channels, however, the pressure drop can become important. Unfortunately, miniature blowers are not efficient and can often be as large as the fuel cell itself. The challenge of finding appropriate auxiliary components for watt-scale fuel cells suggests the use of air-breathing con-



Microstructured Hydrogen Fuel Cells, Figure 2 Examples of microstructures for hydrogen fuel cells: (**a**) microchannel flow field; (**b**) silicon micromachined diffusion media with porous coating for water management; (**c**) silicon pillars as electrode structures; (**d**) porous silicon as a membrane support material

figurations, where temperature gradients induce natural convection of the ambient air over the cathode to provide oxygen and remove the water generated. Although this approach simplifies the balance of plant, one has less control over the critical cathode flows. If the cell is too cold, weak natural convection will not succeed in removing water at the rate it is generated, so the cell will have a tendency to flood. In contrast, if the cell heats up too much, it will likely dry out and lead to increased ionic resistances. Although not discussed here, hydrogen storage and fuel delivery also remain critical roadblocks for the viability of hydrogen-based power sources.

Microfabricated Structures for PEMFC

Microfabrication techniques allow the patterning of large arrays of complex features down to the micrometer scale, without the cost associated with high-precision manufacturing. Figure 2 shows examples of silicon microfabricated structures for fuel cells, ranging from meso- to nanoscale. Photolithography can be used to transpose microchannel shapes or other microstructures on the surface of a silicon wafer or within photosensitive polymers. Deep reactive ion etching or laser micromachining allow the creation of these shapes in silicon, glass or metal substrates. The shapes can also serve as molds to form microchannel plates from flexible polymers, such as PDMS. These approaches have been explored to make microflow channel plates with enhanced mass transfer performance due to small channel diameters ($\sim 100\,\mu\text{m} \times 100\,\mu\text{m}$) [2]. Polymer approaches will often require bonding, while additional clamping plates may be necessary when using fragile silicon.

The gas diffusion layers are typically carbon paper or cloth, treated to be hydrophobic in order to prevent pooling of liquid water. Silicon plates with microfabricated perforations can be used instead, with the potential for integrating more advanced water management strategies. For example, specific regions of a silicon mesh can be treated to be hydrophilic, with the rest being hydrophobic. This approach tends to keep some water in the cell to prevent drying out, but wicks water out of the hydrophobic zones to allow unrestricted oxygen diffusion [3].

Traditional electrodes typically consist of a porous layer that combines platinum nanoparticles (diameter ~ 3 nm) supported on carbon particles, all covered with a thin Nafion layer. This layer must not only contain the catalyst but also act as an electronic conductor (carbon), ionic conductor (Nafion), gas diffusion media (oxygen) and prevent water from accumulating. Replacing such a structure with a microfabricated equivalent is a daunting task. Many configurations have been explored, such as high aspect ratio silicon columns covered with platinum and a thin Nafion layer [4], or simply covering the flow channel structures or membrane with a film of catalyst. These approaches have typically led to lower power densities than traditional porous electrodes, mainly due to the lower effective catalytic surfaces and the challenge in achieving the multifunctional specifications for the electrode.

Finally, silicon processing techniques have also been leveraged to make novel ion conducting membranes. Porous silicon can be readily created in a silicon substrate by an anodization process in HF. The result is a nanoporous structure with over 50% porosity. By forming thick membranes of porous silicon ($> 40\,\mu$m) loaded with sulfonic acid, ionic conductivities similar to Nafion were attained ($10^{-2} - 10^{-1}$ S/cm) [5].

Microfabrication therefore appears to be a viable approach to monolithically integrate the electrolyte with the electrodes, gas diffusion, water management structures and the flow fields. Based on examples of other microelectromechanical systems the microfabrication approach may lead to cost-effective manufacturing in large volumes of microstructured hydrogen fuel cells.

Performance Levels of μPEMFC

The best performance levels achieved to date are for micro fuel cells based on traditional membranes and electrodes, and using forced convection [6, 7]. For example, power levels of over 300 mW/cm^2 have been shown for pure pressurized oxygen, whereas 130 mW/cm^2 was achieved for free convection of ambient air. Significant efficiencies, or voltages, have also been demonstrated at the peak power values, ranging from 0.4 to 0.7 V for various implementations. Most demonstrations were, however, done in a laboratory setting with external control and monitoring.

Future Needs for Research and Development

Only a small spectrum of the broad range of device configurations and materials has been explored, so there is significant opportunity for innovation. Advances in nanomaterials for electrodes, such as carbon nanostructures [8], and other fuel cell fabrication approaches can have a significant impact on the field of μPEMFC. Innovative fabrication must be accompanied by judicious optimization at the meso-/micro-/nanoscales, ranging from two-phase flow in microchannels to diffusion in nanoporous structures. Future developments will best be served by an increased understanding of the multiple functions that must be met by the various fuel cell elements. Further studies of transport and electrochemical phenomena in micro- and nanofabricated structures specifically designed for test purposes could take an important role in the learning process. Finally, commercialization will only be possible by addressing the challenges in system-level design, fuel supply, power management, packaging and testing.

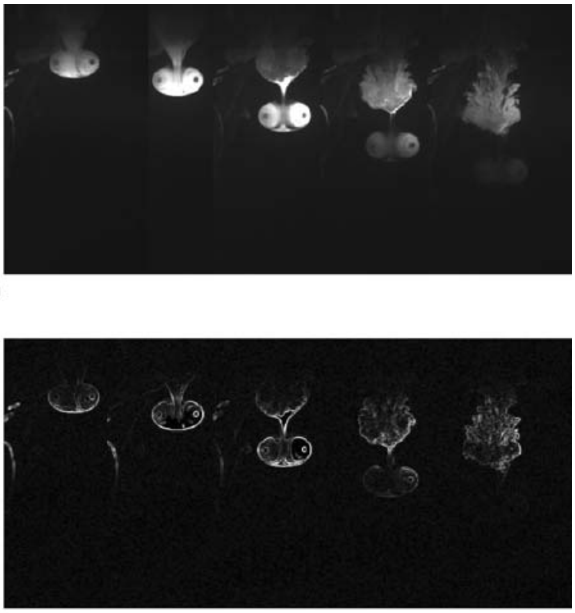
Definition

Synthetic jets are jets with no net mass but a finite momentum flux. A common technique for creating a synthetic jet is using actuation of a Helmholtz cavity as depicted in Fig. 1. The cavity has an orifice and at least one flexible wall that can be actuated by various means. The jet formation is due to cyclic motion of the flexible wall in two distinct phases: ingestion and expulsion. During the ingestion phase the cavity is expanded and low-momentum fluid is ingested inside the cavity (Fig. 1a). The subsequent outward diaphragm movement expels the fluid, forming a vortex ring or a jet depending on the formation number (Fig. 1b). Repetition of this cycle results in a pulsatile jet. Because of the asymmetry of the flow during the inflow and outflow phases, a net fluid impulse is generated in each cycle, even though there is no net mass flow through the chamber over one cycle. Furthermore, the expelling jet will entrain additional fluid, adding to the net fluid momentum that is generated.

Figure 2 shows the direct numerical simulation of vortex ring formation at the exit of a nozzle. The vortex rings entrain surrounding fluid and travel downstream from the orifice because of self-induced velocity. The flow field of a synthetic jet might be initially comprised of a periodic array of vortex rings that are created at the exit orifice. A jet is formed by the interacting vortices. The vortices could be initially laminar or turbulent, but the final jet is often turbulent and the flow at the far field resembles that of conventional continuous and pulsed jets (see Fig. 3).

Overview

The formation and evolution of synthetic jets are dominated by vortex formation and interactions. In this respect, a synthetic jet is similar to a pulsed jet. However, a synthetic jet is distinguished from a pulsed jet in that the synthetic jet is entirely formed by the working fluid of the surrounding fluid. As a result in a synthetic jet a net momentum is added to the flow without a net mass injection across the system boundary. Synthetic jets are also distinct from classical streaming flows, as the mean induced motions are often of the same order as the oscillation amplitude, while for streaming flows the mean motion is of second order.



Microsynthetic Jets, Figure 3 Starting synthetic jet. The first two ingestion/expulsion cycles are visualized. In the first cycle a laminar vortex ring emanates from the orifice in a stationary domain. The following vortex ring is turbulent due to chaotic motion inside the cavity after the ingestion period. The stagnation streamline that passes through the stagnation point and separates the flow that is driven by the expulsion phase and the ingestion phase is marked in bold red. From Glezer and Amitay [3]

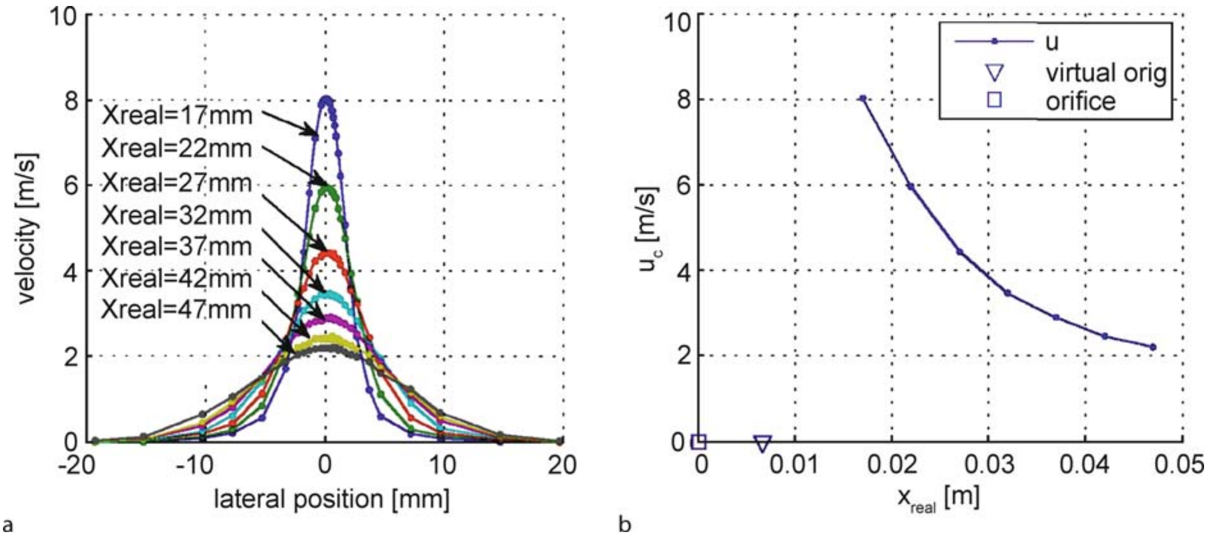
This entry is mostly focused on isolated synthetic jets. Interaction of synthetic jets with a cross flow is not covered. The reader is referred to [2, 3] and references therein.

Actuation Techniques

Imposing an oscillating pressure drop across an orifice can result in the formation of a synthetic jet. The oscillating pressure drop can be created by acoustic waves or by mechanical means such as boundary movement. Various actuation techniques can be employed for forcing the movement of the flexible wall. These include, but are not limited to, electrostatic, electromagnetic, and piezoelectric actuation. Each of these actuation technologies has advantages, disadvantages, and trade-offs in terms of performance metrics such as force capability, total displacement, actuation bandwidth, ease of integration to particular applications, and manufacturability. In electrostatic or magnetic actuations, the energy is stored in the gap between the flexible wall and an electrode. Electromagnetic actuators are often more effective in producing high-amplitude deflection of the deformable wall due their high stored energy density; at microscales the energy density of electromagnetic actuation is typically three orders of magnitude higher than that of electrostatic actuation. However, creating a magnetic field is often achieved by passing current through an electric coil, resulting in heat dissipation. An effective actuation technique at the microscale is piezoelectric actuation. Piezomaterials operate with high force and speed and the motion is fully reversible and repeatable.



Microsynthetic Jets, Figure 6 (**a**) Averaged velocity profiles at various distances from the actuator. (**b**) Centerline velocity drop as a function of distance from the actuator. X_{real} is the distance of the measurement position from the orifice and u_c is the centerline velocity

Applications of Synthetic Jets

Synthetic jets have attracted significant interest in recent years due to their potential application in flow control (see Fig. 4), in particular performance control of aerodynamic surfaces through fluidic modification of their apparent aerodynamic shape. Application of synthetic jets can move the local streamlines in the vicinity of a synthetic jet and cause an apparent modification in the shape of the boundary. Such shape modifications are often achieved by operating a synthetic jet at timescales that are below the characteristic time scales of the mean flow. Synthetic jets are also employed for forced cooling of electronic devices, steering mechanism for capsule endoscopy, thrust generation, and jet noise reduction, among others.

Key Research Findings

The characteristic dimension of a synthetic jet scales with the orifice diameter. As a result, is it in principle possible to form jets over a wide range of length scales. The axisymmetric vortex rings, including those created at the exit of a Helmholtz cavity, may be characterized by two main parameters: one is the Reynolds number of the flow and the other is the formation number. The formation number is defined as the ratio of the stroke length to the orifice diameter, $L = \int_0^T u_0(t)dt$, where T is the expulsion time, $u_0(t)$ is the averaged streamwise velocity at the orifice, and D is the orifice diameter. Some other parameters that affect the resulting jet are the geometry of the cavity and orifice, actuation frequency, and actuation profile.

The time-averaged static pressure near the orifice plane is often lower than the far-field pressure. As a result, in the absence of a radial mean momentum there will be a net entrainment toward the jet center. The periodic flow direction reversal during the ingestion and expulsion phases creates a saddle stagnation point on the centerline closely downstream of the orifice that moves along the centerline during the ingestion stroke (see Fig. 5).

The frequency response of a synthetic jet often has a signature of two natural frequencies that mainly depend on the device dimensions and material properties. One of these frequencies is associated with the natural frequency of the vibrating membrane and the other is associated with the natural frequency of the Helmholtz cavity. The resonant frequency of Helmholtz resonators f_H, to a first approximation, is given by

$$f_H = \frac{c}{2\pi}\sqrt{\frac{A}{VL}}\,, \tag{1}$$

where c is the speed of sound, A is the orifice cross-sectional area, L is the length of the orifice, and V is the cavity volume. The maximum result is achieved by designing the cavity dimensions so that the two frequencies are matched. The natural frequency of the diaphragm can be calculated from well-known formulas for membrane vibrations.

Rathnasingham and Breuer [4] developed the first low-order model of a synthetic jet using a control volume model for the flow and an empirical model for the structural dynamics of the diaphragm. A lumped element model

of a piezoelectric-driven synthetic jet actuator was derived in [5].

Flow Modeling of a Synthetic Jet

An important aspect of the recent surge in investigations of synthetic jets is in modeling the spreading rate, centerline velocity drop, and average velocity profile at various distances away from the orifice. This is, of course, important when predicting the actuator response to control inputs. Figure 6 shows the gradual spreading of a synthetic jet as the measurement location is moved away from the orifice. The decay of the averaged centerline velocity u_c is also shown. If the radial distance is nondimensionalized by the virtual location of momentum source $x_{virtual} = x_{real} - x_0$, and the velocity is normalized by the centerline velocity, the experimental data collapse to an almost single curve, as shown in Fig. 7. This suggests self-similar behavior.

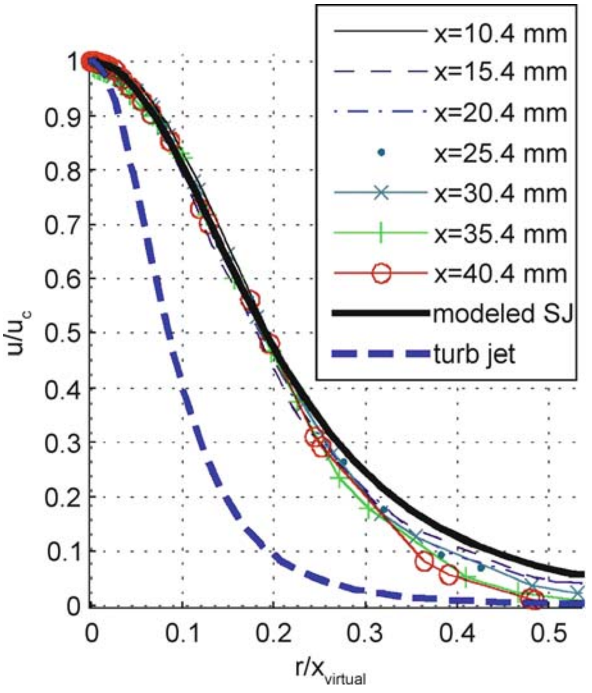
The classical model of a normal turbulent jet was recently extended to a synthetic jet [6, 7]. This is summarized in this section. Axisymmetric free turbulent jets can be solved analytically by using the Prandtl mixing-length model. The model findings are summarized by

$$u = \frac{3}{8\pi}\frac{J}{\rho\epsilon_0 x}\left(1+\frac{\xi^2}{4}\right)^{-2}, \quad (2)$$

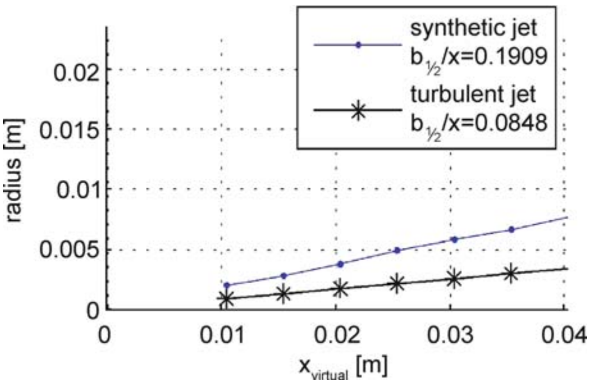
$$v = \sqrt{\frac{3J}{16\pi\rho}}\frac{\xi}{x}\left(1-\frac{\xi^2}{4}\right)\left(1+\frac{\xi^2}{4}\right)^{-2}, \quad (3)$$

where u is the axial velocity, v the radial velocity, ρ the fluid density, x the axial coordinate, r the radial coordinate, $\xi\sqrt{\frac{3J}{16\pi\rho}\epsilon_0^2}\frac{r}{x}$ the similarity variable, and $J/\rho = 2\pi\int_{r=0}^{\infty} u^2 r dr$ the momentum flux per unit density (kinematic flux). Note that in eq. (2) the jet centerline velocity is inversely proportional to the distance from the jet origin. This could be employed to determine the virtual origin of a synthetic jet; i.e. a point of zero cross-section.

Vargas et al. [6] found that the main difference between a normal turbulent jet and a turbulent synthetic jet, to a first approximation, is in the apparent difference in virtual viscosity. This was attributed to the pulsatile nature of a synthetic jet that results in higher mixing, more effective spreading, and consequently higher turbulent viscosity. They directly used experimental data to estimate the virtual viscosity ϵ_0 to be 0.0361 ± 0.002. This value is more than twice the value of 0.0161 reported in the literature for a normal turbulent jet. Therefore, for a turbulent synthetic jet $\epsilon_0 = 0.0361\sqrt{J/\rho}$. This analytical model is shown in Fig. 7 where good agreement with the experimental data is observed. For comparative reasons, analytical results for a normal jet are also shown in Fig. 7. As expected and depicted in Fig. 8 a synthetic jet spreads at a much faster rate than a normal jet.



Microsynthetic Jets, Figure 7 Normalized velocity profiles for experimental and analytical data for a synthetic jet and a conventional turbulent jet. Note that $x_{virtual} = x_{real} - x_0$ and u_c is the centerline velocity



Microsynthetic Jets, Figure 8 Spreading rate of synthetic and normal turbulent jets

The flow volume per second can be calculated to be

$$Q = 2\pi\int_0^{\infty} u r dr = 8\pi\epsilon_0 x = 0.907\sqrt{J/\rho}x\,, \quad (4)$$

Note that this quantity for a laminar jet is $8\pi\nu x$ independent of the jet momentum; that is, independent of the

excess of pressure under which the jet leaves the orifice. For a synthetic jet, the virtual viscosity and the flow volume per second are not constant and are functions of the jet momentum.

Further Reading

This brief list of further reading is limited to 10 citations. A general review of single and multiple synthetic jet flows is presented in [3]. The flow field of a two-dimensional synthetic jet that is formed normal to an orifice in a flat plate was studied in detail by Smith and Glezer [2]. Mittal and Rampunggoon [8] studied synthetic jets numerically and investigated the virtual aeroshaping effect of synthetic jets. Analytical modeling of turbulent synthetic jets and self-similar solutions are presented in [6]. The effect of formation number (the ratio of the length of the ejected fluid slug during the expulsion phase to the orifice diameter) on the flow and thrust generation in a synthetic jet was investigated in [7]. Lumped element analysis of synthetic jet actuators is considered in [5]. Using synthetic jets for jet vectoring is proposed in [9] and application of an array of synthetic jets to vector and modify the cross-section of an axisymmetric continuous jet is presented in [10].

Definition

Microturbines are miniature rotating machines that convert fluid energy into mechanical energy, implemented using microelectromechanical systems technologies or other

small scale manufacturing approaches. They are characterized by the use of fluid flow to set a mechanical component (rotor) into rotation, to drive a compressor, pump, generator or other rotating components. Microturbine-based systems include micro gas turbine engines for propulsion and micro steam turbines for power generation.

Overview

Rotating machinery is commonly used at large scale to meet our society's daily needs for electric power generation, propulsion, cooling, and pumping, to name a few. The implementation of systems that include turbines, generators and pumps at very small scale, say a few millimeters or less, is however challenging from engineering and manufacturing perspectives. Silicon microfabrication processes and other technologies developed to create microelectromechanical systems (MEMS) can be leveraged to enable the miniaturization of rotating machinery. For example, photolithographic patterning, etching and wafer bonding have been shown as viable approaches to create millimeter scale microturbines, as illustrated in Fig. 1.

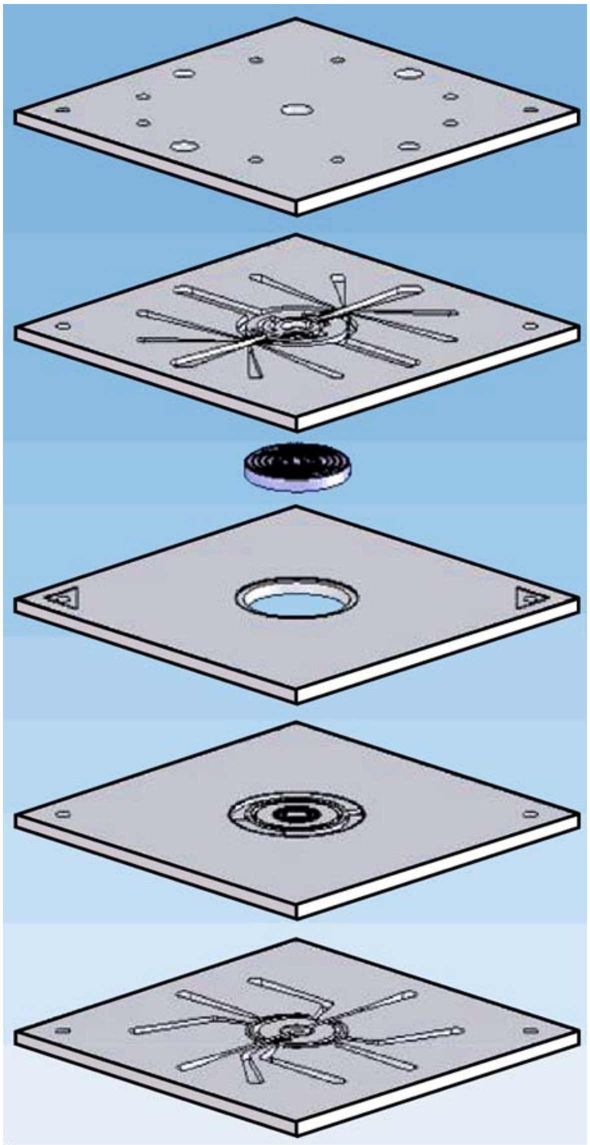
This chapter addresses the design and use of microturbines by discussing the main types of devices based on microturbomachinery and the key fluidic components that compose them. Specifically, the operating principles and characteristics of microturbines and fluid film bearings will be presented.

Cube-Square Law

As a thermal and fluidic system is miniaturized, certain physical phenomena become more or less predominant with scale, according to the *Cube-Square law*. Let's consider a machine with a characteristic dimension of length scale l, such as its length or diameter. Surface forces and fluxes, such as friction, pressure, heat transfer, and mass flow, will decrease proportionally to a characteristic area of the machine, hence as l^2. Volumetric effects, such as inertia, gravity or mass, will decrease as l^3. With respect to each other, the volumetric effects will decrease more rapidly than surface phenomena as the machine is miniaturized:

$$\frac{\text{Surface}}{\text{Volume}} \alpha \frac{l^2}{l^3} = \frac{1}{l}; \text{ ratio} \uparrow \text{ as } l \downarrow \tag{1}$$

For aerodynamic machines, the Cube-Square law implies that friction forces will tend to become more important compared to inertial forces. This is captured by the Reynolds number:



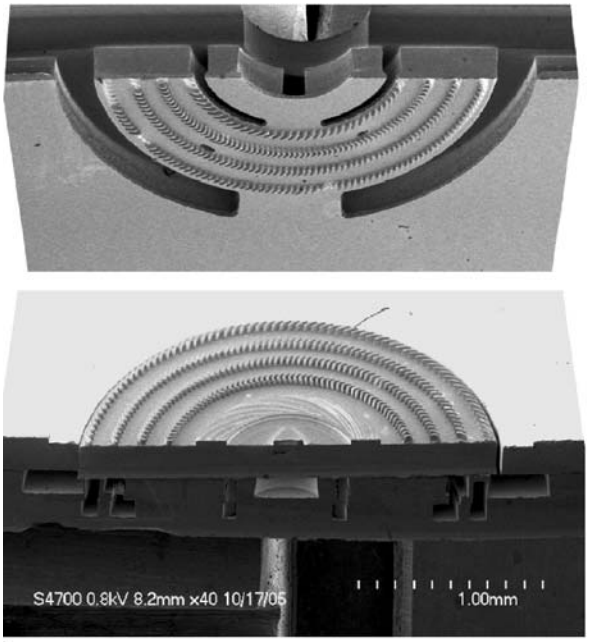
a

Microturbines, Figure 1 (**a**) Exploded view of a microturbine-driven micropump as the core rotating component for a Rankine steam turbine power plant-on-a-chip. The device is fabricated using deep reactive ion etching and wafer bonding of 5 wafers.

$$\text{Re} = \frac{\text{Inertial forces}}{\text{Viscous forces}} = \frac{\rho V l}{\mu}; \downarrow \text{ as } l \downarrow \tag{2}$$

expressed as a function of the fluid density ρ, dynamic viscosity μ, and a characteristic flow velocity V. Small scale turbomachinery is therefore expected to operate at low Re, typically characterized by predominantly laminar flow and low adiabatic efficiency.

Heat transfer will also become more important at small scales. The Stanton number is a non-dimension quantity that measures the ratio of heat transferred between a fluid



b

Microturbines, Figure 1 (**b**) Perspective view of an opened and sectioned device. The 4 mm diameter rotor is shown with four microturbine blade rows. The top portion of the device with stator blades is raised for visual access

and its adjacent structure to the heat capacity of the flow. It can be expressed as:

$$\mathrm{St} = \frac{\text{Heat transfer to wall}}{\text{Heat transport by flow}} = \frac{h}{\rho C_\mathrm{p} V} \tag{3}$$

where C_p is the fluid's specific heat. The convective heat transfer coefficient, h, typically increases at smaller scales [1], so for similar fluid properties and flow velocities, the Stanton number will increase. The impact is that flows in microturbomachinery can rarely be considered adiabatic.

Furthermore, conduction in the structures also tends to becomes predominant. The Biot number represents the ratio of heat transferred by convection to heat conduction in the solid:

$$\mathrm{Bi} = \frac{\text{Heat transfer to wall}}{\text{Heat conduction in solid}} = \frac{hl}{k_\mathrm{s}} \tag{4}$$

expressed as a function of the thermal conductivity of the solid, k_s. When using thin microfabricated layers and high thermal conductivity materials (such as silicon), the thermal resistance in the solids is diminished; this enhances conduction in the structures. This suggests that a conjugate heat transfer representation that combines convection in the fluid and conduction in the structures may need to be solved to predict the temperature distributions and performance of microturbomachinery.

Power Density of Microturbomachinery

The Cube-Square law can also guide the evaluation of power density for microturbines. The fluid to mechanical power conversion for a turbine is expressed as the product of mass flow and change of specific total enthalpy across the turbomachine, Δh_t. Thermodynamic properties of a fluid, such as pressure, temperature, and enthalpy do not fundamentally change with scale. For equivalent thermodynamic cycles, the power of a turbine therefore scales simply as the mass flow, which can be expressed in terms of an average flow velocity, V, through a characteristic flow area, A, proportional to l^2. For constant thermodynamic and flow properties, the power density of a turbine therefore scales as:

$$\frac{\text{Power}}{\text{Volume}} = \frac{\dot{m}\Delta h_\mathrm{t}}{\text{Volume}} = \frac{(\rho AV)\Delta h_\mathrm{t}}{\text{Volume}} \alpha \frac{l^2}{l^3} = \frac{1}{l} \tag{5}$$

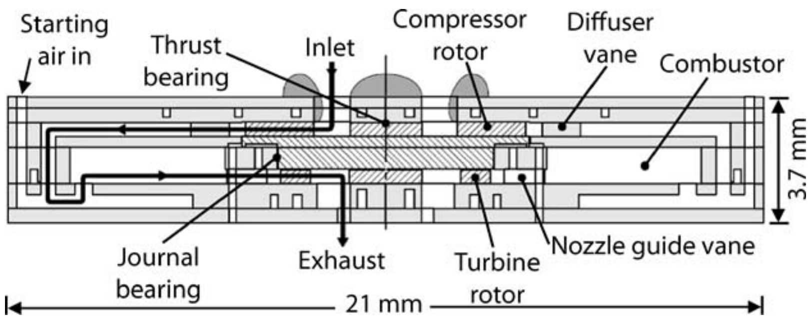
Miniaturization from meters to millimeters should therefore lead to turbomachines with 1000× higher power per unit size or weight. In practice, this gain will not be as dramatic since low Re flows, heat loss and less flexible manufacturing capabilities at small scale will reduce the efficiency and diminish the output power per unit flow rate compared to large scale turbines. Current achievements to date confirm however that a gain in power density clearly results from miniaturization [6].

Applications of Microturbines

Microturbines, pumps and compressors are key components used to implement thermodynamic cycles for power generation, propulsion, or cooling. Thermodynamic power cycles use a working fluid that changes state (pressure and temperature) in order to convert heat into mechanical work. To achieve high power density, the pressures and temperatures of the fluid in the cycle should be kept to the high levels common at large scale. Common cycles are the Brayton gas power cycle and the Rankine vapor power cycle, described next.

Brayton Cycle

The pressure of a low temperature gas is first raised by the work of a compressor before entering a combustion chamber where it is mixed with a fuel and ignited to raise its temperature. The hot and high pressure gases are then expanded across a turbine. The turbine therefore extracts energy from the flow and converts it into mechanical power that is available to drive the compressor. In



Microturbines, Figure 2 Cross section schematic of the MIT H_2 demo micro gas turbine engine constructed of six silicon wafers [2]

the case where the component efficiencies are sufficient, the power provided by the turbine is equal or exceeds the power required by the compressor. The turbine exhaust gases can either provide thrust for propulsion of an aircraft or can be further expanded through a turbine to drive a generator. To complete the cycle, the Brayton cycle can reject the turbine exhaust gases to the atmosphere and breathe in fresh air. Conventional gas turbine generators and jet engines implement the Brayton cycle at macro-scale. At micro-scale, one can use MEMS technology to create millimeter scale microturbines as electric power generators for portable electronics or for the propulsion of micro air vehicles.

Rankine Cycle

The main difference between the Rankine and Brayton cycles is the compression process. In the Rankine cycle, the fluid is pumped in liquid phase instead of gas phase. This requires significantly less power, leaving more turbine output power for useful work. Water is typically used as the working fluid, both in liquid an vapour state, so phase change processes are therefore required (evaporation and condensation). Unless a source of cool water is readily available, the Rankine cycle must be implemented as a closed cycle with heat rejection to condense the steam at the exit of the turbine, before pumping it. Two-phase flow heat exchangers are therefore required. Heat is added to the fluid to evaporate and superheat it before it enters the turbine using another two-phase flow micro heat exchanger. At macro-scale, steam turbine generators are used in nuclear and coal power plants to convert the thermal energy released by the reactions into electricity. The heat source is external to the device, providing significant flexibility for the source. At small scale, micro steam turbine power plants-on-a-chip can also convert heat from various sources into electricity. Heat can either come from the combustion of a fuel in an external combustor or as waste heat from the exhaust of vehicles or industrial processes. Microturbines can therefore provide a means to improve the efficiency of automobiles and manufacturing plants by converting waste heat in electricity.

Other than for implementing thermodynamic power cycles, microturbines can be used in situations where natural flows exists, including environmental, industrial or biological flows. Coupled with a generator, the microturbines could provide power for implantable or distributed sensors, for example. They could also simply provide a measurement of the flow rate through it. Finally, microturbines provide an alternative to electric/magnetic motors by providing an approach to set a rotor in rotation by simply providing a pressurized fluid. The rotor could then perform various functions, such as optical scanning or modulation for example.

Basic Methodology

Two main approaches have been taken to implement microturbines: semiconductor batch processing or traditional precision manufacturing.

Traditional Precision Manufacturing

Miniature turbine-based systems can be fabricated using high precision machining. Relatively standard configurations can be implemented such as miniature gas turbine generators, that consist of a shaft to which is attached the turbine rotor, generator, compressor and supported by ball bearings. Approaches to make the small parts include high-precision milling of metals and ceramics, electro-discharge machining (EDM) of metals, and micro-molding of ceramics. Although many of the concepts presented herein apply to such miniature turbines, the focus will be on silicon MEMS-based microturbines.

Silicon Batch-Processed Microturbines

This approach was initiated by Epstein [2] at the Massachusetts Institute of Technology (MIT) in the mid-

1990s, in the context of building micro gas turbine engines in silicon using microfabrication technologies. Although the realizable geometries and materials available are limited with this approach, the MEMS implementation of microturbines promises low cost, high volume batch fabrication, and the ease of integration of instrumentation and other electromechanical elements. Silicon is a well adapted material for high speed rotating micromachinery, since it has a high strength and relatively low density to minimize centrifugal loads. Since it is a brittle material, surface defects and cracks can lead to catastrophic failure of the device. Thankfully, single crystal silicon wafers, the starting material prepared for the semiconductor industry, are virtually defect free and polished to submicron precision. Furthermore, most etching techniques lead to smooth, well defined surfaces, with average fracture strength up to 4 GPa. Thermally, silicon is a high thermal conductor (like a metal), which tends to reduce the probability of thermal stresses in the structure. Unfortunately, this also make thermal insulation an important challenges in applications where heat loss is detrimental, such as micro heat engines. Although glass or quartz could be of interest from a thermal isolation perspective, etching techniques remain limited in comparison to silicon.

The main processes typically used to build silicon microturbines are: deep reactive ion etching (DRIE) of silicon to form the turbine blades, rotor, or microchannels in the bulk of the substrate; and aligned wafer bonding to assemble multiple substrates (previously etched) to form the bearings components adjacent to the rotor. Figure 1 illustrates the exploded view of a 5-wafer device and a cross section of the fabricated device with a 4 mm rotor. Given the two-dimensional nature of photolithography and deep reactive ion etching, the blades of a typical microturbine configuration are defined in the plane of the wafer and are laid out for radial flow. Here, fluid film bearings support the rotor by applying a distributed pressure field on it. The small gaps required are created once again by deep reactive ion etching and wafer bonding. A journal bearing is formed around the rotor by etching a narrow circumferential trench that defines the rotor and provides space for a film of air around its periphery. Air bearings above and below the rotor are created by etching a shallow recess on the wafers on either side of the rotor before bonding. The following sections will describe these components in more detail.

Turbomachinery

In a planar turbine configuration, the flow expands radially through circumferential rows of blades. Stator blade rows are fixed and tend to deviate the flow in the tangential direction. The swirling flow then enters the next blade row that is attached to the disk, the rotor. The curved rotor blades turn the flow in the opposite direction, which imparts a reaction force on the rotor. With respect to the center of the disk, this force is a moment, or torque T, that sets the rotor in motion. This process of fluid to mechanical energy conversion is best described by the conservation of angular momentum applied to a control volume enclosing a blade row:

$$T_{\text{blade row}} = (\dot{m} r V_\theta)_{\text{out}} - (\dot{m} r V_\theta)_{\text{in}} \tag{6}$$

where $\dot{m}$ is the mass flow, r is the radius, and V_θ is the tangential component of the flow velocity. The mechanical power extracted by a rotor blade row is the product of the torque and the rotational speed Ω. For a turbine with multiple pairs of rotors and stators (i. e. stages), the total power of the turbine, $\dot{W}_\text{T}$, will be the sum for all rotor blade rows:

$$\begin{aligned} \dot{W}_\text{T} &= \sum\nolimits_{\text{rotors}} \Omega \cdot T \\ &= \Omega \cdot \sum\nolimits_{\text{rotors}} \left[(\dot{m} r V_\theta)_{\text{out}} - (\dot{m} r V_\theta)_{\text{in}}\right] \end{aligned} \tag{7}$$

The turbine power can also be related to the flow properties using the first law of thermodynamics, $\dot{W}_\text{T} = \dot{m}\Delta h_\text{t} - \dot{Q}$, defined as a function of the change of the fluid's total (or stagnation) enthalpy h_t, and the rate of heat transfer to the flow $\dot{Q}$. For a constant mass flow through the turbine, the total power per unit mass flow can be expressed as the Euler turbine equation:

$$\frac{\dot{W}_\text{T}}{\dot{m}} = \Delta h_\text{t} - \frac{\dot{Q}}{\dot{m}} = \Omega \cdot \sum\nolimits_{\text{rotors}} \left[(r V_\theta)_{\text{out}} - (r V_\theta)_{\text{in}}\right] \tag{8}$$

For incompressible, adiabatic flow with negligible change in flow velocity throughout the turbine, the change in total enthalpy can be approximated as $\Delta h_\text{t} \approx \Delta h = \Delta (u + P/\rho) \approx P/\rho$, where ΔP is pressure drop. The power per unit mass flow becomes:

$$\frac{\dot{W}_\text{T}}{\dot{m}} = \frac{\Delta P}{\rho} = \Omega \cdot \sum\nolimits_{\text{rotors}} \left[(r V_\theta)_{\text{out}} - (r V_\theta)_{\text{in}}\right] \tag{9}$$

Equation 9 relates the turbine power and mass flow to the pressure drop and flow velocities, so it is the starting point for turbine design and analysis.

Conservation of mass is also used to define the average radial flow velocities V_r, as a function of geometry. At a given radial location r of flow passage height h, the mass flow is simply expressed as:

$$\dot{m} = \rho A V_r = \rho (2\pi r h) V_r = \text{constant} \tag{10}$$

M

The flow angles are defined by the blade angles in the relative reference frame of the blade row of interest.

For adequate design and performance predictions, nonideal effects such as blockage, pressure loss, deviation, and endwall secondary flows should also be considered. If the wall and flow temperatures differ, significant heat transfer can also occur and should be considered, especially for compressible flows. Extensive literature and a solid design basis on the aerodynamics of microturbomachinery are not yet available since the range of Re encountered $(100 < \mathrm{Re} < 10{,}000)$ is not common in past applications. Furthermore, experimental measurements are challenging at the microscale with traditional instrumentation. The use of computational fluid dynamic (CFD) modeling is therefore required for advanced microturbine design.

Bearings

Based on Eqs. 9 and 10, we note that turbine power essentially scales as the cube of a characteristic velocity. This implies that high rotational speeds are of paramount interest to achieve the power density levels promised by the Cube-Square law. The challenge is however to provide a bearing solution for high speed rotation with minimal friction and wear, that will support the axial and radial loads, and be readily microfabricated and integrated in the microsystem. Other rotating MEMS devices found in the literature typically rely on dry friction in pin-hole bearings, which are only viable for low speed operation. Ball bearings are commonly used for rotating machinery at macroscale, as well as for small turbine engines. An alternate approach for high speed microturbines is to support the rotor on fluid film bearings, which will be described here.

Thin films of pressurized air, steam or water (depending on the working fluid available in the microsystem) separate the rotor from the static structure all around it. They are referred to as *hydrostatic* bearings when the pressurized fluid is provided externally to the bearing or as *hydrodynamic* bearings when the pressure field is directly created by the relative motion of the bearing surfaces. Thrust bearings provide forces along the axis of the rotor, while a journal bearing on the periphery of the rotor supports radial loads. Thrust bearings can consist of steps or spiral groove patterns for hydrodynamic operation, or arrays of holes (restrictors) that pressurize a narrow gap in hydrostatic operation. In its simplest form, the journal bearing can consist of a uniform cylindrical gap. More advanced configurations include wave shaped clearances, foil bearings, or tilting pad bearings. The main difference with conventional macroscale bearings is the shape factor, dictated by microfabrication. For example, the journal bearing is typically a trench etched by deep reactive ion etching through a silicon wafer. The axial length is therefore limited to the wafer thickness, leading to low ratios of length to rotor diameter, $L/D < 0.1$. The resulting high speed, short journal bearing is well outside the range of experience found in the literature.

The bearings (i. e. support system for the rotor) play two main roles for microturbines: force balance and dynamic centering. In steady-state operation, the rotor will position itself in order to balance the axial forces on it. This implies that as the turbine pressure is increased, a proportional and opposite force must act on the rotor to maintain its axial position and prevent non-lubricated friction. This can be achieved with a balance piston (i. e. an area of the rotor on the side opposite to the turbine over which a pressure is applied) that scales with the turbine inlet pressure. Alternatively, one can design a symmetric rotor to balance forces (with a turbine on both sides of a disk), but at the cost of fabrication complexity. The second role is to maintain the rotor away from the static structures when subjected to shock, vibrations, and other external excitations. The bearings must therefore provide sufficient stiffness and damping. The stiffness of a fluid film bearings results from a change in the pressure field when the rotor is displaced slightly. The bearing provides a restoring force by reducing its internal pressure as the rotor moves away from the bearing surface. This creates an imbalanced net force on the rotor (normal to the bearing surface) that tends to push the rotor back to its initial position. This restoring principle can be implemented with hydrodynamic or hydrostatic bearings. In hydrodynamics, a larger gap reduces the shear forces and therefore lowers the pressure build up. In hydrostatics, a constant pressure reservoir supplies flow to the bearing surfaces through restrictors, hence the pressure in the bearing depends on the pressure drop across the restrictors. One approach to vary the pressure drop across the restrictor is to change the flow rate through it, by connecting the restrictor in series with a variable flow resistance, for example. Consider the case where the variable resistance is formed by a gap between the rotor and the bearing surface. As the rotor moves to increase the gap, the flow resistance decreases and a larger flow rate will pass through. The pressure drop across the upstream restrictors will therefore increase due to the higher flow rate. The pressure in the bearing clearance therefore drops, lowering the force on the rotor, and providing a restoring net force opposite to the rotor motion.

Key Research Findings

Development efforts to date have demonstrated most of the components required to create microturbine-based power

MEMS. System-level studies have also been done to provide design guidelines for component development and to predict overall performance. This section describes the results achieved to date and the main conclusions that can be drawn from this work.

Traditional Precision Manufacturing

Using high precision metal miling and ceramic molding, 10 – 12 mm diameter turbine rotors supported on ball bearings or fluid film bearings have been demonstrated up to 870,000 rpm [3]. The turbines typically consist of mixed flow single stage impellers or axial flow configurations. Target power levels for miniature gas turbine generators are on the order of 100 W with overall efficiencies of 5%. Performance levels demonstrated by a simpler air-driven turbine-generator device (10 mm diameter, axial flow, ball bearings) were 44 W of electrical power generation with a compressed air-to-electricity conversion efficiency of 16% [4]. These preliminary results suggest that the technical challenges using this approach are achievable, but sufficient components efficiencies will be required to implement the Brayton gas turbine power cycle. The complex manufacturing and assembly of this approach are most amenable for low volume, high cost, specialized applications.

Silicon Batch-Processed Microturbines

The turbomachinery configurations are significantly different when implemented using lithography-based microfabrication techniques. The layout is purely radial, with the blade shapes defined in the plane of the wafer by lithography and etching. Similarly, the bearings and other components must be reinvented to comply with the constraints of microfabrication and integration. Research and development efforts on the core components of a micro gas turbine engine have been extensively studied under the micro gas turbine engine program at MIT over the past decade [2]. In addition, research programs on devices implementing alternate cycles, such as the Rankine microturbine by Fréchette et al. [5], have explored the core technologies for microturbine-based systems with different requirements. The primary findings from this work are presented here.

Microturbomachinery

Single-stage microturbines on 4.2 mm diameter rotors have been demonstrated at rotational speeds of over 1.4 million rpm, which corresponds to 5 W of mechanical power [6]. The power density of the turbine is calculated to be 3500 MW/m^3, which is a least twice that of high performance turbines in commercial transport jet engines, supporting the trend proposed by the Cube-Square law. The performance matches well with CFD predictions, suggesting that current numerical modeling is adequate at this stage of development. Turbine isentropic efficiency at this scale is predicted to be in the range of 55 – 70%, which is acceptable for a Rankine power cycle, but marginal to close the Brayton cycle. Since the Rankine cycle typically operates at very high pressure ratios, multistage turbines are required to expand the working fluid. Multi-stage turbines with significantly shorter blade chord (100 µm vs. 1 mm) were also demonstrated on 4 mm rotors. Turbine isentropic efficiency of 35% was measured at 330,000 rpm (average $Re = 266$) [7]. Predictions suggest an increase in efficiency up to 63% at a design rotor speed of 1.1 million rpm due to the increase in Re at higher speed.

These experimental demonstrations confirm that silicon microfabrication is a valid approach to implement microturbines. The relatively simple structures survived the centrifugal loads at high speeds. In addition, rotor balancing was not required after fabrication, a required step for traditional high speed rotors.

M

Bearings

These high speed demonstrations also confirm the ability of fluid film bearings to be implemented in power MEMS. The journal bearing was operated in a hydrostatic mode by forcing air axially along the cylindrical bearing gap. Pressure drop at the entrance of the gap was found to vary as a function of the radial clearance, leading to a restoring radial force. Modeling and experimental investigations of very short plain journal bearings suggest that stable hydrodynamic operation would require the rotor to be offset radially, to within a clearance of $1 - 2$ µm. This close proximity is not practical, hence hydrostatic operation is preferred. Alternate journal bearing designs, such as foil bearings and tilted pad bearings deserve further investigation.

Various thrust bearing configuration have been successfully demonstrated, including central and annular hydrostatic thrust bearings with $1 - 2$ µm operating gaps and 8 – 10 µm diameter restrictors, as well as hydrodynamic spiral groove thrust bearings. Since the ratio of clearance to radial extent is not as small as traditional bearings, developing flows in the entrance region of the bearings are not necessarily negligible. Beyond these entrance regions, well-established lubrication theory, such as the Reynolds equation for lubrication films, is found to be appropriate. The representation of the gas as a continuum becomes questionable for clearance of less than 1 µm, however. Slip

boundary conditions should therefore be considered below this scale.

Other Components

Electromechanical Generators

Microfabricated generators on the millimeter and watt scales have also been demonstrated for mechanical to electrical energy conversion. Electrostatic induction micromotors operating above 2 MHz and 100 V have been fabricated and integrated with microturbomachinery and fluid film bearings [8]. Performance levels to date are however limited to the sub-watt range. These require a small clearance between the disk and the stator, leading to high viscous losses. They are however fabricated with standard semiconductor materials (dielectrics and conductors), which facilitates their integration. Electromagnetic induction and permanent magnet generators have also been fabricated and characterized with an external drive. The fabrication processes for magnetic machines is however challenging, since they require laminated cores, coils with multiple windings, and the integration of permanent magnet materials. Their operation is limited in temperature due to the Currie point of the magnetic materials and their mechanical strength is less than single-crystal silicon. Their use in high speed, high temperature power MEMS must therefore be considered carefully. To their advantage, they operate with large clearance, which reduces the viscous losses in the generator and have been demonstrated to generate over 1 W of electrical power at 40% of mechanical-to-electrical conversion efficiency [9].

Microcombustors

As a heat source, micro-combustors have been developed to burn hydrogen or a hydrocarbon fuel with oxygen from the ambient air. Combustion requires mixing of the fuel and air, followed by a chemical reaction. The time required for combustion to occur defines the length of the combustion chamber. Although the mixing time can be reduced with miniaturization, the reaction time is independent of scale. Furthermore, a miniature combustion chamber will be prone to heat loss since the surface area dominates over the reaction volume at smaller scale. Nevertheless, complete combustion of hydrogen in $0.2\,cm^3$ micro-combustors has been successfully demonstrated, without noticeable effects to the silicon structures [2]. In the Brayton cycle, combustion occurs directly in the working fluid, allowing high operating temperatures. In the Rankine steam cycle, heat from the combustor must be transferred to the working fluid through a heat exchanger, limiting the operating temperatures.

Microfabrication

Most of the MEMS-based microturbine devices demonstrated to date consisted of deep reactive ion etched, single-crystal silicon wafers that are fusion bonded. Stacks of up to six such wafers have been assembled to create micro-combustors and microturbines. The main fabrication challenges stem from the need to achieve the level of tolerances required for the proper operation of the rotating components. The journal bearing designs prone high aspect ratio trenches with minimal taper, such as 15 μm wide trenches of 400 μm in depth. Etch uniformity is also important to minimize the imbalance of the silicon rotors. As the turbine blades are etched, a non-uniformity in etch rate across a rotor would lead to a center of mass that would be offset from the geometric center. This offset must be significantly less than the journal bearing clearance to prevent a wall strike as the rotor is accelerated through its natural frequency. An offset on the order of 2 μm has been readily achievable for 4 mm diameter rotors with 150 mm tall blades on a 300 μm thick disk [2]. At increased dimensions of 8 mm diameter and 400 μm tall blades, the level of imbalance becomes excessive and often prevents high speed operation as fabricated.

From a thermal perspective, silicon has noticeable limitations. First, since silicon transitions from a brittle to a ductile behavior in the proximity of 950 K, high speed rotors could experience creep from the centrifugal loads above this temperature. To address this issue, fabrication approaches to reinforce silicon rotors with silicon carbide have been explored. A second challenge is thermal management, which stems from the high thermal conductivity of silicon and the short length scales separating hot and cold streams. The approach to date has focused on allowing heat to conduct through the structures and recuperate the heat loss with the working fluid. This fluidic cooling approach facilitates the fabrication, since silicon can still be used, but to the detriment of performance and efficiency. Alternatively, silicon could be replaced by less conductive materials, such as glass or alumina, but at the expense of mechanical strength and ease of micromachining. The integration of non-traditional MEMS materials in the process flow is also a challenge for magnetic machinery.

Micro Power Generation Systems

Based on the core components and technologies described above, various turbine-based microsystems are at different stages of development. Given the complexity of these microsystems, their development requires an incremental

approach where the core components are initially developed independently (as described above), then gradually integrated as subsystems of increased functionality. Each step typically requires the redesign and fabrication of the components that are combined on a single chip, given their strong interaction. The value of establishing a solid design base at each stage of development is therefore important.

Micro Gas Turbine Engines

The MIT H_2 demo micro gas turbine engine, illustrated in Fig. 2, is designed as a 6-wafer stack that encloses an 8 mm single stage compressor and 6 mm turbine bonded to form the rotor [2]. The design speed is 1.2 million rpm with a mass flow of 0.36 g/s of air. It is predicted to deliver 0.1 N of thrust or 17 W of shaft power. Envisioned applications include jet propulsion for micro air vehicles and portable power generation. The core rotating component, acting as a turbocharger, has been demonstrated at speeds above 400,000 rpm with an external air supply. Further development to operate the engine in close cycle with combustion is required.

Rankine Microturbine

A Rankine steam turbine power plant-on-a-chip for power generation from waste heat is also under development [5]. The device design consists of 4 mm rotors with multi-stage microturbines, magnetic generators and a spiral groove viscous micropump, integrated with two-phase flow microchannel evaporators and condensers. The 1 cm^2 chips are predicted to deliver up to 12 W of electrical power with thermal-to-electrical conversion efficiency of 1 – 10%, according to the temperature of the heat source. This technology could be used for waste heat recovery from automobile exhaust or industrial processes. The rotating subsystem (turbopump shown in Fig. 1) has been demonstrated up to 330,000 rpm, validating the multistage turbine models, micropumps design, and seal functionality. Thermal insulation is required in the device to prevent heat leakage from the hot steam in the turbine to the liquid in the pump.

Other Microturbine Applications

Air-driven microturbines could also find applications other than power generation. For example, an optical modulator based on a rotating grading machined on the rotor has been demonstrated up to speeds of 60,000 rpm, driven by compressed air. The device integrated glass and silicon wafers to form the wafer stack.

Future Directions for Research

Microfabrication

Since microfabrication is one of the most limiting factors in the development of microturbines and power MEMS in general, further research in this area is required. Of most importance are:

- Insulating materials, such as glass, quartz, alumina, and porous silicon and their microfabrication methods to create high aspect ratio structures compatible with wafer bonding;
- Integration of electromagnetic machinery into the process flow;
- Understanding the materials issues related to durability of high speed rotating micromachinery and their failure modes;
- Process control to achieve the tolerances in bond alignment and deep reactive ion etching of critical structures.

System and Components

- Losses and heat transfer in moderate Reynolds number flows ($10 < Re < 10000$);
- Advanced fluid bearings with broad stability margins, high speed capability, and self-sustained operation;
- System level integration of on-chip and off-chip components;
- Address a broader range of applications, such as micro-compressors for cooling, rocket pumps, flow metering, and biochemical processing.

Micro-Wave Rotor

Definition

Wave rotor is a promising technology which uses unsteady waves to create a self cooled dynamic pressure exchange between fluids. For high-pressure, high-temperature topping cycles, it results in an engine overall pressure ratio and temperature increase which in turn generate higher efficiency and lower specific fuel consumption. The microscale version of the wave rotor has applications for portable power generation, small propulsion equipment and microscale heat exchangers.

Definition

Ion mobility spectrometry is an analytical technique that separates ions based on their mobilities through an electric field in a non-ionic medium. Ion mobility spectrometry

separates compounds based on the differences in mobilities, which depends on the size and charge of the ion, electric field, and interaction between the ions and the medium. Ion mobility spectrometry is an established method of choice for the detection of explosives and illicit drugs. Commercial ion mobility spectrometers are available and are widely employed in public areas.

Overview

In an ion mobility spectrometer analyte ions are moved by an applied electric field along a tube, where the ions experience multiple collisions with neutral drift gas molecules. Ion mobility spectrometry offers milliseconds-fast analysis time, simple operation and maintenance, low cost instrumentation, and portability. Ion mobility spectrometry is now the method of choice in drug and explosive detection, and is widely employed in public areas like airports, customs, courthouses and correctional institutions. There are more than ten commercial companies that manufacture bench-top, portable and hand-held ion mobility spectrometry devices. Moreover, there are currently more than forty major research groups worldwide that focus on different aspects of ion mobility spectrometry research: studying the fundamentals of ion mobility spectrometry, expanding the technique for new applications, and coupling with new ionization and separation techniques.

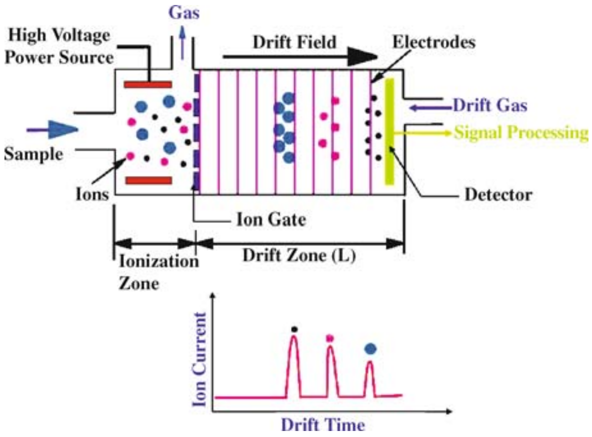
Schematic of a typical ion mobility spectrometer is shown in Fig. 1. An ion mobility spectrometer consists of an ionization source, an ion mobility drift tube, a detector, and supporting electronics. The samples are usually ionized by radioactive Nickel-63, electrospray ionization source, corona discharge, or photoionization source. The ions travel through the drift tube while colliding with the medium molecules, usually air or nitrogen, at atmospheric pressure. The resulting ion velocity is proportional to the applied electric field and mobility of the ion.

The ion mobility, K, is the ratio of the ion velocity, v_d, to the magnitude of the applied electric field, $\boldsymbol{E}$. The ion mobility is constant under low-field conditions where the $\boldsymbol{E}/N$ quotient is typically less than 2 Td ($1\,\text{Td} = 10^{-17}\,\text{Vcm}^2$). Ion mobility can be determined from the experimental parameters as:

$$K = \frac{v_d}{E} = \frac{L^2}{Vt_d} \tag{1}$$

where the drift length, L, is the lengthwise distance from the ion shutter to the detector, the drift time, t_d, essentially is the time an ion takes to travel this distance, and V is the electric potential.

A theoretical relation between ion mobility and the charge and size of the ion was developed by Revercomb and



Miniaturized Ion Mobility Spectrometry, Figure 1 Schematic of an ion mobility spectrometer, showing the location of the ionization region and drift region, which are separated by an ion gate. In the ionization zone, sample vapor is ionized using an ionization source. Ions are then gated by an electronic shutter into the drift zone. Ions move down the drift region due to the electric field (also known as drift field) and collected by the detector. Smaller ions move faster than larger ions, hence require less drift time

Mason [1]:

$$K = \frac{3}{16N} \cdot \left(\frac{2\pi}{\mu kT}\right)^{1/2} \cdot \frac{ze}{\Omega_D} \tag{2}$$

where N is the number density of the drift gas, μ is the reduced mass, k is the Boltzmann constant, z is the charge of the ion, e is the elementary charge, and Ω_D is the collision cross section of the ion. To account for the dependence on temperature, T, and pressure, P, and to facilitate comparison among different experimental settings, the mobility constant is commonly normalized to 273 K and 760 mm Hg and reported in literature as the reduced mobility, K_0:

$$K_0 = K \times \left(\frac{273}{T}\right) \times \left(\frac{P}{760}\right). \tag{3}$$

Separation Efficiency and Resolution

Several expressions are used to describe the separation efficiency of ion mobility spectrometry. These include the peak width at half height, $w_{1/2}$, the resolving power, R_p, and the number of theoretical plates, N. These terms can be expressed in theory and from experimental data. The peak width at half height is the width of a mobility peak at 50% of its height, and it has units of milliseconds. The experimental resolving power of an ion mobility spectrometer is determined by measuring the drift time (t_d) and peak

width at half height ($w_{1/2}$) of a single mobility peak:

$$R_p = \frac{t_d}{w_{1/2}} . \tag{4}$$

The typical resolving power obtained from a commercial 3.9 cm long ion mobility spectrometer is about 30, and the resolving power obtained from a research grade 20 cm long ion mobility spectrometer is around 100. The resolving power of ion mobility spectrometry is related to the chromatographic theoretical plate numbers by the following equation:

$$N = 5.55 \left(R_p\right)^2 . \tag{5}$$

Therefore, a commercial ion mobility spectrometer has roughly 5000 theoretical plates, whereas a research grade ion mobility spectrometer has approximately 55,000 theoretical plates.

The diffusion limited resolving power can be expressed as:

$$\text{Diffusion Limited } R_P = \left(\frac{V\,ez}{16kT \ln 2}\right)^{1/2} = \left(\frac{E \cdot L \cdot ez}{16kT \ln 2}\right)^{1/2} . \tag{6}$$

While the diffusion limited resolving power estimates the possible separation power of an ion mobility spectrometer, the theoretical resolving power determines its separation power by taking the additional consideration of the actual operation parameters, such as the ion shutter pulse width and pressure as:

$$\text{Theoretical } R_P = \frac{\frac{L^2}{V \cdot K_0} \times \frac{P}{760} \times \frac{273}{T}}{\sqrt{\left(t_g^2 + \left(\frac{16kT \ln 2}{V\,ez}\right) \cdot \left(\frac{L^2}{V \cdot K_0} \times \frac{P}{760} \times \frac{273}{T}\right)^2\right)}} \tag{7}$$

The efficiency of an ion mobility spectrometer can be computed by expressing the experimental resolving power as a percentage of the theoretical resolving power as

$$\text{Efficiency} = \frac{\text{Experimental } R_P}{\text{Theoretical } R_P} \times 100\% \tag{8}$$

Basic Methodology

There are two major types of ion mobility spectrometers. The first type is the gas phase time-of-flight ion mobility spectrometer, which detects the analyte signal as a function of the arrival time. The second type is the gas phase differential mobility spectrometer, which measures the analyte signal as a function of the compensation voltage. The separation in gas phase time-of-flight ion mobility spectrometry is based on the mobility of the analytes, with the analytes having faster mobility reaching the detector sooner. On the other hand, in gas phase differential mobility spectrometer, the separation is based on the variance in mobility as a function of changing electric field. Both time-of-flight ion mobility spectrometry and differential mobility spectrometry have been reviewed extensively in the past. For detail and advanced information on ion mobility spectrometry, readers are advised to consult references [1–6].

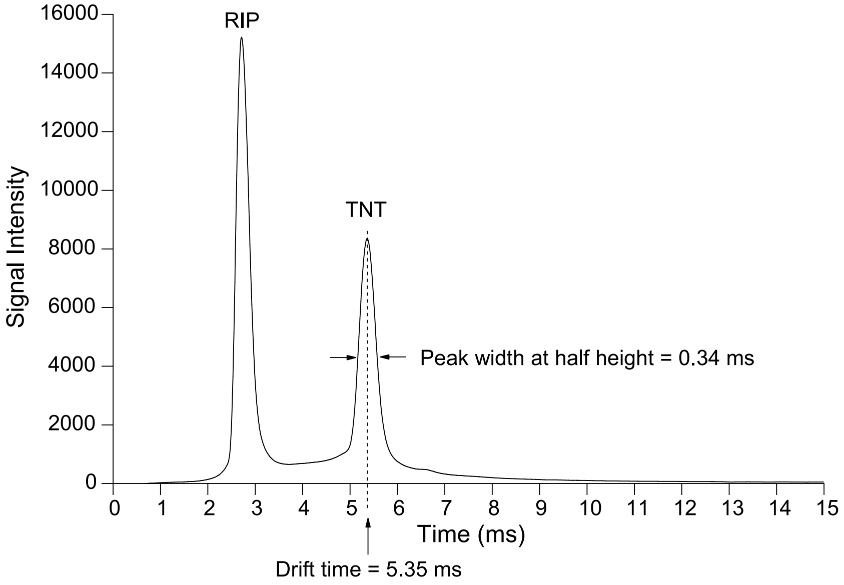
Gas Phase Time-of-Flight Ion Mobility Spectrometer

Figure 1 shows a schematic view of a gas phase time-of-flight ion mobility spectrometer. There are two sections, separated by an ion shutter, in an ion mobility spectrometer: the ionization or desolvation region and the drift region. A typical ion mobility drift tube (Fig. 1) contains individual metal guard rings, connected in series with resistors (not shown here), which establish a homogeneous electric field along the drift tube. Bradbury–Nielsen gate and Tyndall gate are the most common versions of ion shutter.

The ion shutter opens periodically to let in a pulse of ions into the drift region of the spectrometer. The length of time that the ion shutter remains open is called the pulse width, t_g. The gated ions collide with neutral drift gas molecules at atmospheric pressure while traveling down the drift region due to a uniform electric field along the drift channel. The purpose of the drift gas is to sweep off neutral species out of the system. Ions finally strike the detector and generate an electrical signal for identification. Separation in ion mobility spectrometry is based upon the differences in the size, shape and charge of the ions, as well as the physical and chemical interaction between the ions and the drift gas molecules. It is obvious that smaller ions move faster than larger ions due to their smaller cross-sectional areas, and hence require less drift time than that of larger ions.

Separation of Trinitrotoluene Using Ion Mobility Spectrometry – An Example

In this section, trinitrotoluene (TNT), a common military explosive, is selected as the analyte of interest to show the typical parameters of an ion mobility spectrometry analysis. Trinitrotoluene, with its molecular weight of 227.1 Da, has a reduced mobility of 1.54 $cm^2V^{-1}s^{-1}$ in air. In ion mobility spectrometer with a 3.9 cm drift tube and an applied electric field of 250 Vcm^{-1}, operating at 200 °C



Miniaturized Ion Mobility Spectrometry, Figure 2 Ion mobility spectrum of 100 ng trinitrotoluene as analyzed by ITEMISER (GE Interlogix), a commercial ion mobility spectrometer. Two peaks were observed, the chloride reactant ion peak (RIP) and the trinitrotoluene (TNT) peak. The TNT peak had a drift time of 5.35 ms, with a peak width of 0.34 ms

and 700 torr, trinitrotoluene would have a drift time of 5.4 ms with a detection limit in the ppb range. Fig. 2 shows an ion mobility spectrum of trinitrotoluene analyzed by ITEMISER (GE-Interlogix), a commercial bench-top ion mobility spectrometer with a 3.9 cm long drift tube and a diffusion limited resolving power of 47. From Eq. (1), the experimental mobility of TNT can be calculated as $2.90\,\mathrm{cm^2V^{-1}s^{-1}}$ and reduced mobility of TNT can be determined from Eq. (3) as $1.54\,\mathrm{cm^2V^{-1}s^{-1}}$. The experimental peak width at half height, as shown in Fig. 2, was 0.34 s. The experimental resolving power is therefore 16 and the experimental number of theoretical plates is 1400. The theoretical resolving power of this instrument is 23 and the efficiency of the instrument is 68%.

Gas Phase Differential Mobility Spectrometer

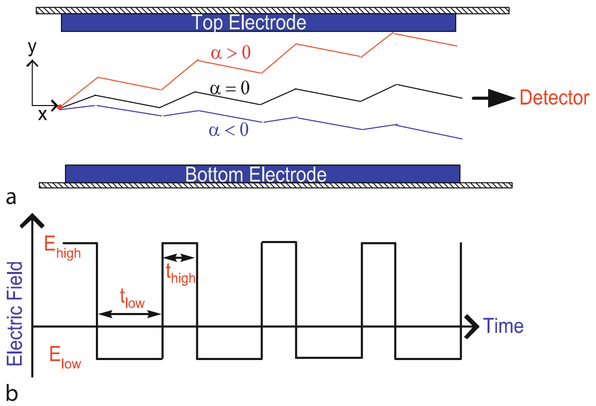
The working principle of differential mobility spectrometry (DMS), also known as field asymmetric waveform ion mobility spectrometry (FAIMS), is significantly different from that of conventional drift tube time-of-flight ion mobility spectrometry (TOFIMS). In DMS, sample ions are allowed to move through a carrier gas under specialized waveform electric fields. Generally a rectangular shaped wave with a high positive field ($\boldsymbol{E}_{\mathrm{high}}$) is applied for a shorter period (t_{high}) and a low negative field ($\boldsymbol{E}_{\mathrm{low}}$) is used for a longer time (t_{low}). Figure 3a shows a schematic of a DMS for analytes separation; the associated waveform electric field distribution is shown in Fig. 3b. This technique takes advantages of differences in mobility during high and low electric field periods. Experimental results show that mobility of ions changes nonlinearly with applied electric field if the ratio of electric field to gas density exceeds 40 Td [7]. For instance, at atmospheric pressure, some ions such as CO^+CO demonstrate increase in mobility with increasing electric field, while others (N_4^+, N_3^+, N^+) show decrease or no change in mobility with increasing electric field strength [7]. Therefore, in a gas phase, the electric field dependent ion mobility can be written as

$$K(\boldsymbol{E}) = K(0)\,[1 + \alpha(\boldsymbol{E})] \tag{9}$$

Where $K(0)$ is the mobility of ions at low electric field, and its value remains constant for a particular ion. Equation (9) indicates that the value of α will determine whether the mobility of ions will change with increasing electric field. The net displacement of an ion in the y-direction over one cycle of asymmetric field can be expressed as

$$\Delta y_{\mathrm{cycle}} = K(\boldsymbol{E}_{\mathrm{high}})\,\left|\boldsymbol{E}_{\mathrm{high}}\right|\,t_{\mathrm{high}} - K(\boldsymbol{E}_{\mathrm{low}})\,\left|\boldsymbol{E}_{\mathrm{low}}\right|\,t_{\mathrm{low}} \tag{10}$$

Hence, under the action of waveform electric field, shown in Fig. 3b, the ions with $\alpha > 0$ will have a net drift toward positive y-direction after each cycle, and these ions will



Miniaturized Ion Mobility Spectrometry, Figure 3 (**a**) Schematic view of a differential ion mobility spectrometer. For ions of positive α, the effective ion mobility increases with increase in electric field, while for ions with $\alpha < 0$, the mobility decreases with increase in electric field. It is important to note that at low electric field strength ($\boldsymbol{E} < 10{,}700$ V/cm at atmospheric pressure) the value of α is zero. (**b**) Cyclic waveform electric field used to generate asymmetric field in the drift tube

eventually hit the top wall. On the other hand, the ions with $\alpha < 0$ will reach bottom wall by drifting in the negative y-direction due to the waveform electric field. The net drifting, of a particular type of ions in a cycle, in the vertical direction can be stopped by applying a DC compensation electric field depending on the direction of drifting. For instance, a negative compensation electric field is required if $\alpha > 0$, and vice versa. Therefore, a mixture of ions in a carrier gas can be completely separated by ramping or sweeping of DC electric field applied to the system.

Photoionization method was used to form the free electrons, and the drift gas was maintained at atmospheric temperature. These spectra were averaged over 20 scans, and the drift times were adjusted for a uniform drift potential of −500 V

Key Research Findings

Gas Phase Time-of-Flight Ion Mobility Spectrometer

Current research in miniaturized gas phase time-of-flight ion mobility spectrometry can be categorized by its drift tube design. The most common type is still the stacked-ring design with multiple guard rings. Additionally, there is the *cigarette-rolled* design, fabricated with low-temperature cofired ceramics.

Stacked-Ring Design

The stacked-ring design stemmed from the work of Earl W. McDaniel at Georgia Institute of Technology [7]. This design consists of a stack of guard rings which are connected in series with resistors, establishing a uniform electric field. The ring electrodes are insulated from one another by physical distance and insulating spacers, such as ceramic rings or sapphire balls.

Currently there are four commercial companies offering handheld and portable gas phase time-of-flight ion mobility spectrometers, with drift tubes shorter than 5 cm: Smiths Detection, Bruker-Daltonics, GE-Interlogix, and G.A.S. Gesellschaft für analytische Sensorsysteme mbH. Table 1 presents their respective instruments and their major applications. These instruments generally use an applied electric field of around 250 $\mathrm{V\,cm^{-1}}$, and they operate at either ambient or elevated temperature, and at atmospheric pressure. The samples are ionized by radioactive nickel-63 source mostly, but also by corona discharge and photo-ionization source.

Besides the commercial spectrometers, there are also reports of novel prototypes of miniaturized gas phase time-of-flight ion mobility spectrometers. Xu et al. [8] fabricated a miniature ion mobility spectrometer; their miniature IMS device was 35 mm in length having a 1.7 mm diameter drift channel. There were 25 metal electrodes

Miniaturized Ion Mobility Spectrometry, Table 1 List of commercially available miniaturized gas phase ion mobility spectrometers

Company	Instrument	Application
Bahia-21	MO-2M	Explosives
Bruker-Daltonics	RAID-1	Chemical warfare agent

stacked in the channel and separated by insulator spacers. The electrodes were made of oxygen-free high density copper (OFHC) with a thickness of 0.33 mm. The insulator spacers were made of Macor with an inner diameter of 3 mm, outer diameter of 15.7 mm, and thickness of 1.1 mm. Total 24 miniature resistors were connected between the electrodes to form a voltage divider. Each resistor had 1 MΩ with 1% uncertainty. To apply the drift voltage along the channel, a power supply was connected to end electrodes and the voltage was distributed to sequential electrodes through these resistors. They observed a linear decrease in potential along the channel which indicated a nearly homogeneous electrostatic field produced in the drift region. The electrode next to the detector plate was ac-grounded through a capacitor so the electric current due to ion movement would not be coupled to the detector.

They used a frequency-quadrupled Nd:YAG laser as an ionization source, and negative ions were formed by binding free electrons with NO, O_2 and methyl iodide (CH_3I) [8]. Figure 4 illustrates the mobility spectra of negative ions obtained from the aforementioned miniaturized IMS. A single peak (Fig. 4a) was found when nitric oxide was provided in the ionization region and argon was used as a drift gas. Two ion peaks (Fig. 4b), one due to NO^- and the other due to the residual oxygen, appeared when the drift gas was switched to nitrogen (with 1.2 ppm oxygen and 1.1 ppm moisture) from argon. Figure 4c presents the mobility spectrum when a mixture of nitric oxide and methyl iodide was introduced in the ionization region, and nitrogen was used as the drift gas [8].

The multipurpose sensor project at Washington State University and Boise State University involves design and construction of a miniaturized ion mobility device for measuring sub-surface organic contaminants. The remote controlled capability of the miniaturized ion mobility device is suitable for long-term monitoring at contamination sites. Their ion mobility device featured stainless steel guard rings, insulated by Macor ceramic rings, with a 6.8 cm drift length and an electric field of 452 $V cm^{-1}$. The ion mobility device, including its sampling module, supporting electronics and wireless data transmission, was housed inside a cone penetrometer that was pushed into the ground by a hydraulic jacking system. Figure 5 shows the cross-sectional view of the cone penetrometer, which can be pushed down to forty feet below ground. The cone penetrometer was tested at a field site known to have trichloroethylene contamination. Figure 6 illustrates the ion mobility spectrum, with trichloroethylene detected from the contaminated soil sample. This sub-surface ion mobility device has a detection limit of 6 ppb_v-trichloroethylene, and is capable of detecting trichloroethylene in a mixture with gasoline, jet fuel, and diesel.

LTCC Cigarette Roll Design

Although the stacked-ring design has dominated for four decades, the design is not suitable for miniaturization in terms of mass production. An ion mobility spectrometer, even at miniature size, can easily have over a hundred parts and required labor-intensive construction. For example, an ion mobility spectrometer of 20 electrodes requires 20 insulating spacers, 20 resistors, an ion gate, and over 20 electrical connections among the electrodes, the resistors, and the ion gate. The ultimate goal of a miniaturized system is one that can be mass produced cost effectively by automation. Sandia National Laboratory explored low temperature co-fire ceramic as a potential solution for mass-producing miniaturized ion mobility spectrometers [9]. The rolled design, that replaced the stacked-ring design, eliminated many parts by using machine to print electrodes and resistors onto an unfired sheet of pliable low temperature co-fire ceramic. The low temperature co-fire ceramic is made of glass and proprietary organic compounds, which burn off during the firing process. The printed low temperature co-fire ceramic can then be rolled into the required size. After being fired, the rolled tube with the printed electrodes and resistors fused with the ceramic into one piece. Only minimal manual connections are required for this fabrication process.

Gas Phase Differential Mobility Spectrometer

A miniaturized drift chamber is particularly useful for proper functioning of DMS since this technique requires very high electric field. In miniaturized drift tube, the distance between top and bottom electrodes is scaled down to microns. Hence, a very high electric field can be obtained by applying relatively low voltages across the electrodes.

Miller and co-workers [10] first fabricated a miniaturized DMS using Pyrex substrates and heavily boron doped silicon wafer. Silicon wafer of 500 μm thick was placed in between the two Pyrex substrates and determined the thickness of the drift tube. Titanium (40 nm) and Gold (120 nm) were deposited on the Pyrex substrates to form ion filter, a deflector electrode and a detector electrode. Patterning of Ti/Au electrodes was performed by conventional lift off process using Shipley 1822 photoresist. Once the electrodes were formed, silicon wafers were diced into strips and bonded with Pyrex by the anodic bonding process. A photo-ionization source (10.6 eV photo discharge lamp, $\lambda = 116.5$ nm was connected to the device to provide a means for the photons to enter the ionization region [10].

Figure 7 shows the spectra for xylene isomers obtained from a micro fabricated radio-frequency DMS described above [10]. It is important to note that the structural isomers of xylene (meta-, para-, and ortho-) have the same molecular weight, but they differ in position of the second methyl group. Ortho-xylene is 1,2-dimethylbenzene, meta-xylene is 1,3-dimethylbenzene, and para-xylene is 1,4-dimethylbenzene. At low electric field, they have similar cross-section and can only be separated by an ion mobility spectrometer with ultra-high resolving power. However, owing to the differences in mobilities at high electric field, m-xylene could be separated from p- and o-xylenes, although p- and o-xylenes were inseparable [10].

Future Directions for Research

One shortcoming of gas phase ion mobility spectrometry is its inability to maintain high resolving power at small scale. The separation efficiency of time-of-flight ion mobility spectrometry is limited by the low-field requirement, the speed of ion shutter gate relative to the drift time of analyte ion, and the space charge effect.

In order to maintain the desired high resolving power, the drift length must be increased when higher voltages are used. As a result, gas phase ion mobility spectrometry suffers from low resolving power when the instrument size is reduced. While laboratory-size gas phase ion mobility spectrometry instruments, with a drift length of 20 cm, routinely achieve a resolving power of 100, miniaturization of gas phase ion mobility spectrometry results in much lower resolving power. Thus, gas phase ion mobility spectrometer could not be scaled down to function as a micro sensor without sacrificing resolving power.

To circumvent this problem, researchers ventured away from signal averaging to employing time-dispersive data acquisition, such as Fourier transformation and Hadamard transformation, and reported an increase in signal-to-noise ratio and an improvement in resolving power.

Adding a separation dimension in tandem with ion mobility spectrometry improves the separation power of a miniaturized device, in terms of increasing the number of peaks that it can separate. Multicapillary columns and gas chromatograph had been coupled at the front end of miniaturized ion mobility spectrometers to pre-separate otherwise co-eluting mobility peaks. The added dimension is ideal for separating analytes with close mobilities and also for separating complex samples.

Definition

Mixing is the homogenization of an initially heterogeneous substance through bulk motion and/or molecular diffusion. In the development of mixing processes, it is necessary to evaluate the ability of each process to mix rapidly and uniformly. Mixing measures quantify the degree to which a substance is homogenized.

Overview

Mixing is a crucial process in many micro- and nanofluidic systems. Despite the small length scales involved, molecular diffusion alone is often insufficient to rapidly produce a uniform mixture. The small length scales also make it impractical to produce turbulent flow, which is typically used to mix rapidly in macroscale systems. Special consideration has thus been given to the design of small-scale devices that rapidly mix fluid under laminar flow conditions. A key requirement of this development is the ability to consistently quantify the degree to which fluid is mixed in a device by a given protocol.

Fluid mixing has been discussed in the scientific literature for over a century. In 1894, O. Reynolds described fluid mixing as a three-step process [10], which is consistent with the modern view [8, 9]. First, the substance is

stretched in at least one direction and, due to volume conservation, attenuated in an orthogonal direction; second, the substance is folded, piled, or wrapped back upon itself; and third, in a miscible fluid mixture, molecular diffusion completes the homogenization. The first two steps, namely stretching and folding, are often performed concurrently and can be viewed as a result of stirring. Through fluid motion, stirring breaks up large-scale inhomogeneities, stretching out interfaces and layering together distinct regions of fluid. In miscible fluids, the third step, namely molecular diffusion, is also occurring concurrently. In many cases, however, the effects of stirring dominate in the early stages of the mixing process. Furthermore, every process does not include all three steps: immiscible fluids inhibit or prevent diffusion across interfaces, and some techniques, such as hydrodynamic focusing (see passive mixing), stretch the fluid but do not fold it. How best to produce these steps in an effective mixing device depends on the properties of the components, the initial state of the system, the desired outcome, and the available technology.

Despite the long history of fluid mixing as a subject of scientific inquiry, the best tools for quantifying the mixedness of a system are not clearly determined. To quote J. Ottino, a mixing measure "should be selected according to the specific application and it is futile to devise a single measure to cover all contingencies" [8]. Nevertheless, it is useful to identify a few measures that provide a basis for evaluating device performance. The context for this discussion will be systems relevant to micro- and nanofluidic applications, with focus on mixing fluid containing a diffusing (and perhaps reacting) ▶ tracer such as a dye. The measures discussed here require the ability to observe and measure variations in the spatial distribution of this tracer.

Numerous mixing measures have been proposed through the years. The most often used measures are based on the variance of the concentration of a tracer substance, with Danckwerts' intensity of segregation [4] being the most common. These measures have been in use for decades and are considered the standard. However, practical implementation of these measures depends on a somewhat arbitrary course-graining of the domain, and in the ideal limit of a smooth distribution they do not account satisfactorily for the important effects of stirring. Measures based on the Shannon entropy [3] display similar behavior and are less commonly used, so these are not discussed here in detail.

A recent development are multi-scale measures of mixing that can be defined as weighted sums of the coefficients in a Fourier decomposition of the concentration field. These measures, including the mix-variance [5] and multi-scale mixing efficiencies [11], do not depend on a choice of ▶ coarse-graining scale, they are able to capture the effects of stirring even when diffusion is negligible, and they show promise for evaluating mixing in micro- and nanofluidic devices.

Most of the experimental setups used to characterize small-scale mixing devices use miscible fluids containing a passive diffusive tracer such as dye. This tracer will have a spatially and temporally varying concentration $c(\boldsymbol{x},t)$, where $\boldsymbol{x}$ is the vector position and t is time. A stirring mechanism (see, e. g., ▶ microfluidic mixing) will impose a velocity distribution $u(\boldsymbol{x},t)$ that advects the tracer, and the tracer will diffuse with a molecular diffusivity D. If the flow is incompressible and the domain of interest does not have sources or sinks of concentration, or a net concentration flux at the boundary, then the total concentration in the domain is conserved and the average concentration, namely

$$c_{\text{ave}} = \frac{1}{V}\int c(\boldsymbol{x},t)\,\mathrm{d}V\,, \tag{1}$$

is constant in time. In this case one can consider, without any loss of generality, the scalar field $\theta(\boldsymbol{x},t) = c(\boldsymbol{x},t) - c_{\text{ave}}$. For incompressible fluid, $\theta(\boldsymbol{x},t)$ evolves according to the advection–diffusion equation

$$\frac{\partial\theta}{\partial t} + \boldsymbol{u}\cdot\nabla\theta = D\,\nabla^2\theta\,. \tag{2}$$

Multiplying Eq. (2) by θ and integrating this product over the fluid domain gives

$$\frac{\mathrm{d}}{\mathrm{d}t}\,\|\theta\|_2^2 = -2D\,\|\nabla\theta\|_2^2\,, \tag{3}$$

where $\|\theta(\cdot,t)\|_2$ is the L_2-norm given by

$$\|f(\boldsymbol{x})\|_2 = \int |f(\boldsymbol{x})|^2\mathrm{d}V\,, \tag{4}$$

which is proportional to the scalar variance

$$\sigma^2 = \frac{1}{V}\int |f(\boldsymbol{x})|^2\mathrm{d}V\,. \tag{5}$$

That is, by Eq. (3) the variance of a conserved scalar concentration will decrease with time when that scalar is diffusive. The rate of decrease in $\|\theta\|_2^2$ is proportional to the molecular diffusivity D and depends on the variance of the concentration gradients, and the long-time, steady-state limit of the system is a uniform concentration, $c(\boldsymbol{x},t)\to c_{\text{ave}}$ or $\theta(\boldsymbol{x},t)\to 0$. A more rapid decay indicates better mixing, which is the basis for using the intensity of segregation and related quantities as mixing measures. Stretching and folding by the flow field do not appear explicitly in Eq. (3), but this deformation acts to

M

increase local concentration gradients and improve mixing. In the absence of diffusion, $\|\theta\|_2^2$ is constant in time, which seems to indicate that no mixing occurs. However, it is clear that stirring will mix up the fluid even in the absence of diffusion, and it would be useful if the applied mixing measure captured this behavior. In micro- and nanoscale systems, mixing is often needed on time scales for which bulk diffusion is negligible, which makes it important to accurately quantify the effects of stirring. Addressing this role of stirring in the mixing process is a major motivation for the development of multi-scale mixing measures.

A key requirement for proper mixing evaluation is to clearly define better or more efficient mixing. In most micro- and nanoscale applications the objective is to obtain a sufficiently homogeneous substance as quickly as possible using whatever means available, in which case the mixing time or mixing length is of primary interest. This definition of better mixing is assumed here. In contrast, energy expenditure is crucial in many macroscale applications, and a slower mixing protocol may be considered more efficient. The mixing measures considered here do not account for the energy used during the mixing process.

One approach to developing laminar flow mixing devices is to design for chaos using mathematical models and tools from dynamical systems theory. In this approach, the quality of the system is determined using chaos measures such as Poincaré sections and Lyapunov exponents, which are based on passive particle kinematics. The underlying assumption in this approach is that there is a strong connection between the generation of chaos and efficient mixing. For more information on chaos and its measures, see ► chaotic flow.

Basic Methodology

Mixing measures quantify the spatial homogeneity or, similarly, inhomogeneity in a (fluid) system initially comprised of multiple distinct regions or species. The exact computation of any measure depends in part on how one distinguishes between different species and on what one means by a homogeneous mixture. The evolution of the measure as the system is mixed can depend significantly on the initial distribution of the different species, and the final state of the system depends on whether not the mixing process involves a chemical reaction or a concentration source. Thus, accurately quantifying the ability of a system to mix well, particularly if comparison is to be made with other systems, requires consistent use of initial conditions and careful characterization of the fluid (in)homogeneity, in addition to a good choice of mixing measure.

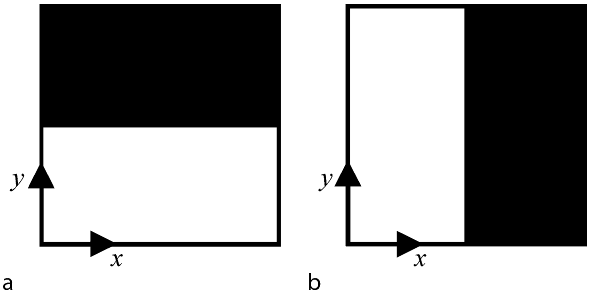
Determining the Scalar Field

The mixing measures discussed here quantify the spatial distribution of some scalar field that becomes homogenized by a mixing process. Accurately computing a mixing measure requires quantifying the local values of this scalar. In both experimental and computational analyses of mixing, measurement or prediction of the continuous scalar field $c(\boldsymbol{x}, t)$ almost always results in a discrete set of N values $c_\mathrm{i}(t)$ that each represent the average of $c(\boldsymbol{x}, t)$ within a small element of area $\mathrm{d}A_\mathrm{i}$. This forced binning has some effect on the computation and interpretation of the mixing measures.

One common approach of making an experimental measurement is to use a colored or fluorescent dye in a transparent device, shine light through the device, and record the image with a camera. In this optical method, the quantity being measured is, for example, the intensity of light captured by each pixel in a charge-coupled device (CCD) array. The dependence of this intensity on the local dye concentration should be determined through a controlled calibration process, including the minimum observable concentration and the functional relationship between intensity and concentration. Background noise due to flaws or features in the device should be removed by subtracting out the image containing no dye. The analysis is simplest if the calibration results are uniform across the region being evaluated; if this region has varying fluid depth, for example, then this uniformity is not likely. The lighting and camera settings must be consistent throughout the experiment for these steps to give reliable data. Of course, if something other than optical sensing is used, it is still necessary to calibrate the measurements, account for background noise, and maintain consistent experimental settings.

Note that in some cases the substance being mixed cannot be viewed as a continuously varying concentration field. For example, in a suspension of large biomolecules it is (usually) desirable for these molecules to maintain their integrity, which forces even a fully mixed system to remain inhomogeneous at length scales on the order of the molecule size. Obviously, the definition of the scalar field or the implementation of a mixing measure must be adjusted for situations such as this.

The imaging technique described above produces a planar image. Pixel intensities are a result of light passing through the full depth of the device, and thus depend on the depth-averaged concentration. The distribution in Fig. 1a, when sensed using a light below and CCD array above, i. e. averaged in the y-direction, cannot be distinguished from the fully mixed case. Care must be taken so that a case such as this is not misinterpreted. If features of a distribution



Mixing Measures, Figure 1 Example initial distributions

through the depth of a device must be resolved in order to accurately evaluate the mixing process, then an alternate technique such as confocal microscopy should be considered. Another option in this case is to test the device by monitoring the product of a chemical reaction that depends on the level of mixing [6].

Initial Distributions

The choice of initial inhomogeneity, such as the concentration distribution, can have a significant influence on how rapidly a system becomes well mixed. Consider, for example, mixing with the linear shear flow

$$u(y) = U y \tag{6}$$

in the domain $0 \le y \le 1$, where u is the velocity component in the x-direction. If the initial distribution is that shown in Fig. 1a, the flow has no effect on it and mixing is due solely to diffusion. If instead the initial distribution is that shown in Fig. 1b, the length of the interface between the black and white fluids increases linearly in time, and mixing progresses faster than for Fig. 1a. In general, the appropriate choice of initial distribution will depend on the design of the device, the intended use of the system, and the results of the calibration process. Ideally this distribution will allow observation of both strengths and weaknesses in the mixing device. Placing dye only in a poorly mixed region (such as in a regular, or elliptic, island; see ▶ chaotic flow) will lead to a poor characterization of the device; conversely, placing too much dye over a large portion of the domain may lead to overestimating the device's capability.

Comparisons between devices are best made when the initial distributions are all similar for both, but it can be difficult to determine similar initial distributions for different mixing protocols. If the initial distributions are significantly different, care must be taken when making any device comparisons. One approach is to characterize the mixing performance of a device for several relevant initial distributions, something that currently is not standard practice in the evaluation of micro- and nanoscale mixers.

Reference States

Mixing measures are typically defined with respect to a reference state c_{ref}. This state may be the average of the concentration field being considered, $c_{\mathrm{ref}} = c_{\mathrm{ave}}$, the average concentration of the final well-mixed state, $c_{\mathrm{ref}} = c_{\mathrm{mix}}$, or it may be a more complicated function of position. When there are sources or sinks of concentration [11], chemical reactions involving the observed species [7], or variations in the thickness of the region of interest, the system does not necessarily become completely homogeneous even when fully mixed, and a non-uniform field $c_{\mathrm{ref}}(\boldsymbol{x})$ should be used to accurately measure mixing.

Mixing measures are often normalized with respect to the initial distribution. This normalization gives a dimensionless measure and helps account for some variation in the initial distribution, such as small changes in concentration levels between tests. As discussed above, however, a dimensionless measure cannot account for large or fundamental differences in initial distribution.

In a closed system, the initial distribution, the well-mixed reference state, and the progression of mixing are all imaged at the same location. Obviously this is not possible in an open system such as a microchannel, in which the mixing progresses as the fluid moves axially. The initial distribution is present only at the inlet of the channel and thus serves to normalize the result at every location considered in the analysis. The well-mixed reference state, however, can often be determined at each location by passing a mixed solution through the system.

Variance-Based Mixing Measures

The *intensity of segregation* introduced by Danckwerts [4] is defined as

$$\Phi_1 = \frac{\sigma^2}{\sigma_0^2}, \tag{7}$$

where σ^2 is the variance of the instantaneous scalar field $c(\boldsymbol{x})$ being considered, namely

$$\sigma^2 = \frac{1}{A} \int |c(\boldsymbol{x}) - c_{\mathrm{ref}}|^2 \, \mathrm{d}A, \tag{8}$$

σ_0^2 is the variance of the initial distribution, and c_{ref} is the reference state (see above). It is assumed here that the scalar field is planar and defined over a region with area A.

M

This measure is initially $\Phi_1 = 1$ and decays to zero as the domain becomes homogeneous.

The distribution $c(\boldsymbol{x})$ is typically not a continuous function but rather a discrete set of N values c_i, such as the pixel intensities in a CCD array. Each c_i can be viewed as the average value of $c(\boldsymbol{x})$ within a *bin* with size $\mathrm{d}A_i$. If the bin size distribution is consistent between the current and reference states, then the variance is given by the sum

$$\sigma^2 = \frac{1}{N}\sum_{i=1}^{N} |c_i - c_{\mathrm{ref}}|^2 . \tag{9}$$

Thus, in practice this measure is based on a course-grained representation of the scalar field, and the results will depend on the choice of bin size [3]. In some investigations this bin size is taken to be the resolution of the imaging measurement, but this choice is somewhat arbitrary. An advantage of course graining is that it gives the ability to dictate the scale at which mixing is considered important. Also, bin sizes can be chosen to capture the effects of stirring even when diffusion is negligible. However, since the results depend on the choice of scale, whether or not the system appears well mixed is somewhat arbitrary, and consistent comparison between experiments is difficult.

One occasional modification of the intensity of segregation is to use the *coefficient of variation* [1]

$$\mathrm{COV} = \frac{\sigma}{c_{\mathrm{ave}}} , \tag{10}$$

where c_{ave} is the average of the instantaneous scalar field $c(\boldsymbol{x})$ and $c_{\mathrm{ref}} = c_{\mathrm{ave}}$. The mixing measure is thus

$$\Phi_1' = \frac{\mathrm{COV}}{\mathrm{COV}_0} = \frac{(c_{\mathrm{ave}})_0}{c_{\mathrm{ave}}} \sqrt{\Phi_1} , \tag{11}$$

although sometimes COV is used directly. This measure is typically used to evaluate mixing for cases in which the average concentration is not conserved.

There are at least 36 other related statistical measures [2], two of which are

$$\Phi_2 = 1 - \frac{\sigma^2}{\sigma_0^2} , \tag{12}$$

and

$$\Phi_3 = 1 - \frac{\sigma}{\sigma_0} . \tag{13}$$

Both of these measures have an initial value of zero and increase to one as the system becomes homogeneous. Boss [2] conducted a comparison of these measures using 9 evaluation criteria. The measures Φ_2 and Φ_3 rank the highest in that comparison, with their primary advantage over Φ_1 being that they increase in value as mixing increases. Boss [2] concludes that Φ_3 is the best of these indices for determining the state of any mixture.

Multi-Scale Mixing Measures

Multi-scale mixing measures can be viewed as an extension of the course-graining approach to the above measures. Instead of quantifying the homogeneity of the system using a single course-grain scale, or bin size, the multi-scale measures average over a range of scales. These measures can be computed directly as an average over different bin sizes, or as weighted sums of the coefficients in the Fourier decomposition of the instantaneous concentration field [5]

$$c(\boldsymbol{x}) = \sum_{\boldsymbol{k}} \hat{c}_{\boldsymbol{k}} \exp\{\mathrm{i}\, 2\pi\, (\boldsymbol{k}\cdot\boldsymbol{x})/L\} , \tag{14}$$

where $\boldsymbol{k} = (k_1, \dots, k_n)$ is the n-dimensional wave-number vector. Differences between these measures lie in the weighting assigned to different scales.

The current definitions of these measures require the scalar field to be spatially periodic. Since this is almost never the case, the analysis takes place on a periodic continuation of the domain; i. e. it is assumed that the domain consists of an infinite number of periodically arranged copies of the original.

The Mix-Norm [5] is the measure that results from averaging over all possible scales. This measure is given in terms of the Fourier coefficients $\hat{c}_{\boldsymbol{k}}$ as

$$\Phi_4(c) = \sqrt{\sum_{\boldsymbol{k}} \Lambda_{\boldsymbol{k}} |\hat{c}_{\boldsymbol{k}}|^2} , \tag{15}$$

where $\Lambda_{\boldsymbol{k}}$ is the weighting factor. For a one-dimensional scalar field (e. g. data from a single line of pixels), the weighting factor is given by

$$\Lambda_k = \int_0^1 \frac{\sin^2(k\pi s)}{(k\pi s)^2}\, \mathrm{d}s , \tag{16}$$

and for a two-dimensional scalar field it is

$$\Lambda_{\boldsymbol{k}} = 2\Gamma(1) \int_0^1 \frac{J_1^2(s\pi k)}{(s\pi k)^2}\, \mathrm{d}A , \tag{17}$$

where Γ is the gamma function, J_1 is a Bessel function of the first kind, and k is the magnitude of $\boldsymbol{k}$. In both cases, $\Lambda_{\boldsymbol{k}}$ must be computed numerically, and the values decay monotonically with increasing k. The *Mix-Variance* is then defined as $\Phi_4^2(c - c_{\mathrm{ref}})$. Note that these two measures as defined in [5] are not normalized by the initial values.

The multi-scale mixing efficiencies [11] are obtained by noting that weighting the Fourier coefficients, as in Eq. (15), is related to examining the variance of concentration gradients. The authors in [11] examine the following gradients of the relative scalar field

$$||\nabla\theta||_2^2 = \sum_{\boldsymbol{k}} k^2 |\hat{\theta}_{\boldsymbol{k}}|^2 , \tag{18}$$

which focuses on small scales, and

$$||\nabla^{-1}\theta||_2^2 = \sum_{\boldsymbol{k}} \frac{|\hat{\theta}_{\boldsymbol{k}}|^2}{k^2} , \tag{19}$$

which focuses on large scales. The multi-scale mixing efficiencies are defined as

$$\Phi_5 = \frac{||\nabla\theta_0||_2^2}{||\nabla\theta||_2^2} \tag{20}$$

and

$$\Phi_6 = \frac{||\nabla^{-1}\theta_0||_2^2}{||\nabla^{-1}\theta||_2^2} . \tag{21}$$

These measures give a somewhat arbitrary weighting to the various scales in the problem, but separating large and small scale effects can lend important insight into the progression of the mixing.

Mixing Time, Mixing Length, and Mixing Rate

In many cases it is useful and practical to define an index that quantifies how long it takes for the fluid to become well mixed. These indices require the choice of a measure to characterize the time-dependent evolution of mixing in the system, and the results depend on this choice of measure.

For the mixing time or mixing length, a threshold level is defined, say 95% mixing, and this index gives the time or length needed for the system to reach this threshold. For example, choosing the measure Φ_3 and a threshold level of 95% mixing, the mixing length L_{95} gives the length of microchannel needed to achieve $\Phi_3 \geq 0.95$ using a given mixing protocol. As with all the measures, the result will also depend on the initial distribution.

For the mixing rate, it is assumed that efficient mixing will lead to exponential decay or increase in the mixing measure. For example, again choosing the measure Φ_3, which increases with mixing, the mixing rate R is defined by fitting the curve $1 - \exp(-Rt)$ to the data.

Future Directions for Research

In general, the investigation and development of small-scale mixing devices would benefit from a more careful and consistent evaluation of mixing quality. Regardless of which measure is used, the importance of initial condition and system calibration make it difficult to directly compare the current mixing studies of different devices developed and tested in different laboratories. A single study that examines mixing in several competing devices using a consistent, carefully documented procedure would likely be quite instructive.

Further development and application of multi-scale mixing measures are needed. Work is currently being done to formulate the mix-norm and mix-variance for arbitrary domains [5], which will make this tool more widely applicable. Multi-scale measures are slightly more difficult to compute than the traditional single-scale measures based on the variance of concentration, but they can capture the effects of stirring and they show promise for quantifying mixing quality. However, this multi-scale approach is new enough that its application is currently quite limited. Comparisons need to be made between the different multi-scale measures and with the traditional measures to clearly establish which is the more appropriate and useful tool.

Model reduction

Definition

Model Order Reduction (MOR) is a set of theories and techniques that reduce the order of a complex dynamic system while preserving its essential properties and input-output behavior for efficient and accurate simulation and design.

Overview

Microfluidics technology holds great promise for a wide spectrum of applications in the realm of genomics, proteomics, diagnostics, and drug discovery. In contrast to the sophisticated analysis and processing functionalities that have been achieved to date, efficient modeling and design of microfluidic devices continues to be a challenge. This is primarily attributed to the increasing complexity of today's microfluidic chips, arising from the integration of more components and functions, and accompanied by the interplay of multiple physicochemical phenomena, such as fluid flow, heat transfer, mass transport, electrokinetics, biochemistry, and structural mechanics.

Currently, multiphysics-based high fidelity numerical analysis is the dominant technique that allows coupled analysis of these phenomena and provides detailed information of spatio-temporal variations of the field variables. However, prohibitive CPU time and memory requirements make it unsuitable for system-level modeling and design of entire microfluidic devices. Therefore, in order to truly enable simulation-based chip design with rapid turnaround time, compact models with substantially reduced computational expense (while capturing the underlying physicochemical phenomena, remaining basic conservation laws, and accounting for chip complexity) are highly desired.

In general, compact models are classified into three categories: ►primitive models, ►macromodels, and ►behavioral models [1]. A primitive model is the constituent element (e. g., capacitors, inductors, and resistors etc.) in a complex system and is typically represented as a single Differential-Algebraic Equation (DAE) derived from basic conservation laws in different domains. The difference between macromodels and behavioral models is subtle, and both describe the dynamic response of a device via a set of equations. Macromodels are constructed via assembly of primitive models or a set of DAEs in a system-level representation, while the behavioral models are more generic and effective forms and built on the underlying domain-physics [1].

Strictly speaking, Model Order Reduction (MOR) refers to compact model generation procedures that lump the

spatial dependency of device behavior, extract the most typical characteristics of the governing equations, and, hence, reduce the order of the problem. MOR originally derives from control theory and is widely used in electronic and MEMS design. Many of the techniques are based on subspace projection (such as Arnoldi approach and Proper Orthogonal Decomposition). In addition to these well-established methods, we will also introduce some other useful approaches, such as ► Artificial Neural Networks (ANNs) and analytical methods (e. g., Method of Moments), which have been recently reported for modeling of microfluidics systems.

Basic Methodology

Electric Analogy

The electric analogy is one of the most extensively used methods for flow and species transport modeling in channel-based microfluidic systems. A microfluidic network is equivalent to an electric circuit, of which each component can be individually described by resistors, conductors, and inductors Eqs. (1) and (2) show the *RLC* circuit models in electric and fluidic domain,

$$\Delta\Phi = L_e \frac{dI}{dt} + R_e I + \frac{1}{C_e}\int I\,dt \quad \text{(electric)} \tag{1}$$

$$\Delta P = L_f \frac{dQ}{dt} + R_f Q + \frac{1}{C_f}\int Q\,dt \quad \text{(fluidic)} \tag{2}$$

where subscripts e and f are, respectively, for the electric and fluidic quantities; P is pressure and ϕ is potential; t is the time, I is the electric current; Q is the volumetric flow rate. L, R, and C represent the inductance, resistance, and capacitance of the component, which for fluidics arise from the fluid inertia (momentum acceleration), viscous shear force at channel walls, and fluid compressibility. Depending on the physical phenomena involved and component types of interest, Eq. (2) can be further simplified, e. g., in microfluidics the fluid compressibility is normally absent and the third term on the R.H.S of Eq. (2) can be neglected. Next, we will discuss typical cases that are often encountered in electric analogy-based microfluidic modeling.

Transient Pressure Driven Flow in a Channel of Constant Cross-Section

For a channel with a constant cross-section, its fluidic resistance is written as

$$R_f = \begin{cases} \dfrac{12\beta l \mu}{d^4\left[1 - \frac{192\beta}{\pi^5}\sum\limits_{i=1,3,5\ldots}^{\infty}\frac{\tanh(i\pi/2\beta)}{i^5}\right]} & \text{(rectangular channel)} \\ \dfrac{8\mu l}{\pi r_c^4} & \text{(circular channel)} \end{cases} \tag{3}$$

where μ is the dynamic viscosity of the fluid, l is the channel length, $\beta = d/h$, d, and h are the aspect ratio, width, and depth of the rectangular channel. r_c is the radius of the circular channel. The fluidic inductance is given by [2],

$$L_f = \frac{\rho l}{A_c} \tag{4}$$

where ρ is the fluid density and A_c is the cross-sectional area of the channel.

Coupled Pressure Driven and Electroosmotic Flow (EOF) at Steady State

When flow in a microchannel is driven by both electric potentials and pressure gradients that are externally applied or internally induced, electroosmotic flow (EOF) and streaming current need to be taken into account. Streaming current is caused by the effective movement of the counter-ions in the diffuse layer of the Electric Double Layer (EDL) due to pressure gradients. Equations (1) and (2) are then rewritten as,

$$\begin{cases} Q = \frac{\Delta P}{R_f} + \frac{\Delta\Phi}{R_{EOF}} = G_f\Delta P + G_{EOF}\Delta\Phi \\ I = \frac{\Delta P}{R_{st}} + \frac{\Delta\Phi}{R_e} = G_{st}\Delta P + G_e\Delta\Phi \end{cases}$$

$$\text{or}\quad \begin{bmatrix} Q \\ I \end{bmatrix} = \begin{bmatrix} G_f & G_{EOF} \\ G_{st} & G_e \end{bmatrix} \cdot \begin{bmatrix} \Delta P \\ \Delta\Phi \end{bmatrix} \tag{5}$$

where the inductance term is neglected for steady-state flow; G refers to the conductance, the reciprocal of the resistance; G_f is the fluidic conductance; G_{EOF} reflects the flow rate contribution from EOF; G_{st} the electric conductance of the streaming current due to pressure-driven flow; and G_e the electric conductance attributed to the EOF convection and conduction of species under electric field. Equation (5) is a generalized form and obtained by cross-sectional integration of the pressure-induced and electroosmotic flow velocity and current density. The expression for G_f, G_{EOF}, G_{st} and G_e depends on the cross-sectional shape of microchannels, buffer and species properties [3].

Elastic Structural Elements in Microfluidics

In addition to the fluid flow, electric analogy can be also applied to modeling elastic structural elements (e. g.,

valves and membrane chambers) and their coupling to flow in microfluidic devices. For valves, the interaction between the movable structure and the surrounding flow is strong and normally categorized into reverse and forward flow modes. In the reverse flow mode zero flow rate or a constant leakage is assumed, while in the forward flow mode a non-linear pressure-flow static characteristic (i. e., fluidic resistance) is used [2], which is given in Eq. (6)

$$Q = \frac{\gamma}{\mu} \Delta P^3 \tag{6}$$

where γ is a factor depending on the geometry and stiffness of the valve. The clamped membrane is another widely used structural element in micropumps. Activated by external forces (e. g., electrostatic and piezoelectric etc.), it propels the fluid flow through its volumetric change due to the membrane compliance. Therefore, elastic membranes are typically modeled as capacitors (storing fluid mass),

$$\Delta P = \frac{1}{C_{\text{mem}}} \int_s \delta \, \mathrm{d}\Gamma \tag{7}$$

where C_{mem} is the capacitance of the membrane, δ is the spatial deflection of the membrane, Γ is its total surface area, and ΔP is the net pressure applied to it. The models for structure elements are often assembled to the fluidic element models to achieve system-level simulation and design of the entire microfluidic device [2].

In practice, a lot of microfluidic devices often involve irregular component geometry (e. g., junctions and channels with variable cross-sections) and, hence, their R, L and C values in Eqs. (1) and (2) are not directly available. In this case, high-fidelity simulations that enable spatio-temporal analysis and/or an ensemble of experimental data are used to identify and extract these values. Usually, an interface linking the detailed device simulation and macro-model generation needs to be established to automate *RLC* value extraction. Such a procedure is called automatic macromodel extraction [1].

Arnoldi-Based Model Order Reduction

Arnoldi-based algorithm is a classical Krylov subspace-based [4] MOR technique. In particular it is suited to investigate linear transport problems in microfluidics, such as heat transfer, species diffusion, and low-Reynolds flow (negligible fluid inertia). The underlying philosophy of Arnoldi-based algorithm is to reduce the dimension of the spatially semi-discretized form of the original governing PDEs using moment-matching of transfer functions.

Before presenting Arnoldi-based algorithm, we introduce fundamentals of the projection subspace. Consider a system of first-order ODEs given below

$$\begin{cases} \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}t} = \mathbf{A} \cdot \boldsymbol{X} + \mathbf{B} \cdot \boldsymbol{Z} \\ \boldsymbol{Y} = \mathbf{C} \cdot X \end{cases} \tag{8}$$

where $\boldsymbol{X}(t) \in \mathrm{Re}^n$ is the state vector of unknowns (a function of time), n is the dimension of the system and the total number of ODEs. $\mathbf{A} \in \mathrm{Re}^n \times \mathrm{Re}^n$ is the system matrix, $\boldsymbol{Z} \in \mathrm{Re}^m$ is the input vector. $\mathbf{B} \in \mathrm{Re}^n \times \mathrm{Re}^m$ is the scatter matrix relating the input function to each state $\boldsymbol{X}$. $\boldsymbol{Y} \in \mathrm{Re}^p$ is the output vector containing quantities of interest, and $\mathbf{C} \in \mathrm{Re}^p \times \mathrm{Re}^n$ is the gather matrix, which links the system state to the output. Often the number of Eq. (8) is so large that it is prohibitively expensive for an efficient system-level simulation. Hence, we seek for a transformation matrix $\mathbf{V}$ that projects the behavior of the state vector $\boldsymbol{X}$ into a subspace with low-dimension r, which is given by

$$\boldsymbol{X} = \mathbf{V} \cdot \boldsymbol{X}_r + \varepsilon\,, \ \ \boldsymbol{X}_r \in \mathrm{Re}^r\,, \ \ r \ll n\,, \ \ \varepsilon \approx 0 \tag{9}$$

where $\mathbf{V} \in \mathrm{Re}^n \times \mathrm{Re}^r$ consists of r n-dimensional vectors that contain a basis for the reduced subspace. $\boldsymbol{X}_r \in \mathrm{Re}^r$ represents the equivalent of $\boldsymbol{X}$ in the reduced subspace, $\varepsilon \in \mathrm{Re}^n$ is a small error. When the subspace is located (i. e., $\mathbf{V}$ is determined), Eq. (8) can be projected on it to obtain a system with lower dimensions (that is $r \ll n$) while the essential behavior is still preserved. This can be expressed as

$$\begin{cases} \frac{\mathrm{d}\boldsymbol{X}_r}{\mathrm{d}t} = \mathbf{A}_r \boldsymbol{X}_r + \mathbf{B}_r \boldsymbol{Z} \\ \boldsymbol{Y} = \mathbf{C}_r \boldsymbol{X}_r \end{cases} \tag{10}$$

Note that even through projection, the input $\boldsymbol{Z}$ and output $\boldsymbol{Y}$ vector of the system remain unchanged. For large-scale system, an effective and prevalently used projection subspace is the Krylov subspace [4].

The Arnoldi-based algorithm begins with a spatial discretization of the governing PDEs to attain the dynamic system equations as Eq. (8). Specifically, here $\boldsymbol{X}(t)$ is the state vector of unknowns (a function of time) on the discrete nodes and n is the total number of nodes; $\mathbf{A}$ is formulated by the numerical discretization; $\boldsymbol{Z}$ defines the functions of boundary conditions and source terms; $\mathbf{B}$ relates the input function to each state $\boldsymbol{X}$. Equation (8) can be recast into the frequency domain in terms of transfer function $T(s)$. $T(s)$ then is expanded as a Taylor series at $s = 0$ yielding,

$$T(s) = \sum_{k=0}^{\infty} m_k s^k \tag{11}$$

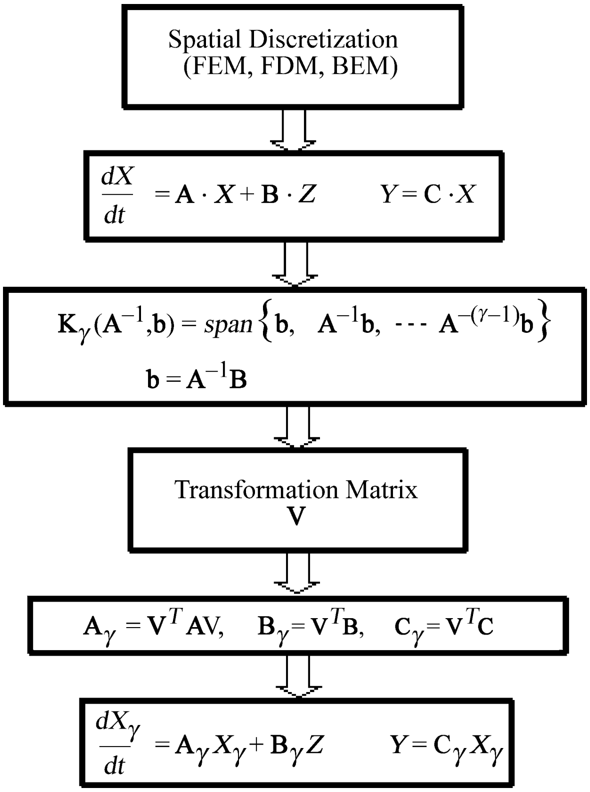
where m_k is the k-th moment of the transfer function $T(s)$. To match the moments between the original (Eq. (8)) and the reduced system (Eq. (10)) up to degree r (i. e., $m_k = m_{rk}$, where m_{rk} is the k-th moment of the transfer function for the reduced system, $k = 0, \ldots r-1$), we can calculate the first r orthogonal bases $\boldsymbol{v}_i$, $i = 1, \ldots, r\}$ that span the Krylov space [5]

$$\mathbf{K}_r(\mathbf{A}^{-1}, \mathbf{b}) = span\left\{\mathbf{b},\ \mathbf{A}^{-1}\mathbf{b},\ \mathbf{A}^{-2}\mathbf{b},\ \ldots \mathbf{A}^{-(r-1)}\mathbf{b}\right\} \tag{12}$$

where $\mathbf{b} = -\mathbf{A}^{-1}\mathbf{B}$. The transformation matrix $\mathbf{V}$ is then explicitly obtained by $\mathbf{V} = [\boldsymbol{v}_1, \boldsymbol{v}_2, \ldots \boldsymbol{v}_r]$. Projecting Eq. (8) onto the Krylov subspace, the reduced system characteristics is given by

$$\mathbf{A}_r = \mathbf{V}^{\mathrm{T}}\mathbf{A}\mathbf{V},\ \mathbf{B}_r = \mathbf{V}^{\mathrm{T}}\mathbf{B},\ \mathbf{C}_r = \mathbf{V}^{\mathrm{T}}\mathbf{C} \tag{13}$$

The detailed implementation steps for ►Arnoldi-Based Model Order Reduction are illustrated and summarized in Fig. 1.



Model Order Reduction (MOR), Figure 1 Flow chart for Arnoldi-Based MOR

Proper Orthogonal Decomposition (POD) Based MOR

For microfluidic systems with strong non-linear effects, ►Proper Orthogonal Decomposition (POD) based MOR (also called Karhunen–Loève decomposition) is employed to locate the low-dimensional subspace for modeling. POD is a technique that extracts the orthogonal basis function spanning the reduced subspace using an ensemble of data from numerical simulations of the original full systems. This is different from the Arnoldi-based MOR algorithm, which relies only on the system matrix from numerical discretization of the original full equations without solving them.

The POD-based MOR begins with a computationally expensive but accurate analysis (e. g., finite element, finite difference or finite volume), which yields an ensemble of vector or scalar fields (*snapshots*) $X_k(\boldsymbol{x})$ and $k = 1, \ldots N_\mathrm{s}$, where X is the state variables (such as velocity fields, pressure distribution, and fluid temperature etc.), X_k is the k-th snapshot in time, $\boldsymbol{x}$ is the spatial coordinates, and N_s is the total number of the snap shots. We then seek for the most characteristic basis function ϕ that best matches the given snapshots $X_k(\boldsymbol{x})$, which is written in a mathematic form as

$$\min\ \lambda = \sum_{k=1}^{N_\mathrm{s}} (\phi(\boldsymbol{x}) - X_k(\boldsymbol{x}))^2 \tag{14}$$

where λ is the objective function. Note that $(\phi(\boldsymbol{x}) - X_k(\boldsymbol{x}))^2$ in Eq. (14) represents the sum of its value at all grid points on $\boldsymbol{x}$. Equation (14) is mathematically equivalent to

$$\max\ \lambda = \frac{1}{N_\mathrm{s}} \sum_{k=1}^{N_\mathrm{s}} \frac{(\phi, X_k)^2}{(\phi, \phi)} \quad \text{subject to} \quad (\phi, \phi) = 1 \tag{15}$$

where $(g, q) = \int_\Omega g(\boldsymbol{x})q(\boldsymbol{x})\,\mathrm{d}\Omega$ defines the inner product of g and q. Equation (15) implies that ϕ with the maximum mean square projection on the ensemble set of X_k is the most characteristic basis functions that are desired. Define linear operator $\boldsymbol{R}$:

$$\boldsymbol{R}\phi = \frac{1}{N_\mathrm{s}} \sum_{k=1}^{N_\mathrm{s}} \int_\Omega X_k(\boldsymbol{x})X_k(\boldsymbol{x}')\phi(\boldsymbol{x}')\,\mathrm{d}\boldsymbol{x}' \tag{16}$$

then

$$(\boldsymbol{R}\phi, \phi) = \frac{1}{N_\mathrm{s}} \sum_{k=1}^{N_\mathrm{s}} \int_\Omega \int_\Omega X_k(\boldsymbol{x})\phi(\boldsymbol{x})X_k(\boldsymbol{x}')\phi(\boldsymbol{x}')\,\mathrm{d}\boldsymbol{x}\,\mathrm{d}\boldsymbol{x}'$$

$$= \frac{1}{N_s} \sum_{k=1}^{N_s} (\phi, X_k)^2 \tag{17}$$

Substitute Eq. (17) into Eq. (15), we can obtain

$$\max\ \lambda = \frac{(\boldsymbol{R}\phi, \phi)}{(\phi, \phi)} \tag{18}$$

It can be easily proven that maximization of λ in Eqs. (15) and (18) is essentially equivalent to the following eigenvalue problem [6]

$$\boldsymbol{R}\phi = \lambda\phi \tag{19}$$

Equation (19) can be solved using the method of snapshots, that is, ϕ is expressed as a linear combination of the original data ensemble,

$$\phi(\boldsymbol{x}) = \sum_{i=1}^{N_s} w_i X_i(\boldsymbol{x}) \tag{20}$$

where w_i is the weight for each snapshot and will be determined to yield the maximum in Eqs. (15) and (18). Substituting Eq. (20) into Eq. (19), it is straightforward to obtain

$$HW = \lambda W \tag{21}$$

where

$$H_{ki} = \frac{1}{N_s} \int_\Omega X_k(\boldsymbol{x}) X_i(\boldsymbol{x})\, \mathrm{d}\boldsymbol{x}, \quad W = [w_1\ w_2\ \ldots\ w_{N_s}]^{\mathrm{T}} \tag{22}$$

H_{ki} is the correlation matrix for snapshots, and is symmetric and positive definite. Once the eigenvectors of Eq. (21) are determined, they can be substituted into Eq. (20) to obtain the basis functions. We can sort the eigenvalues of Eq. (21) in descending order ($\lambda_1 > \lambda_2 > \cdots > \lambda_{N_s}$). From Eq. (15), we can have

$$\lambda_k = \frac{1}{N_s} \sum_{k=1}^{N_s} (\phi_k, X_k)^2 \tag{23}$$

It shows that the eigenvalue λ_k is a measure of how well the basis function ϕ_k represents the snapshots. The first basis function ϕ_1 corresponding to λ_1 represents the most typical characteristics of the snapshots. Therefore, by examining the relative magnitude of λ_k, we can determine the appropriate number r of ϕ for the model that lowers its dimension while still retaining modeling accuracy.

In addition, an alternative approach based on Singular Value Decomposition (SVD) technique to find out the orthogonal basis function is also used on many occasions and is proven mathematically equivalent to the method presented above. The key concept of this approach is to minimize a least-squares measure of the *error* between the state variables projected on the original and reduced subspace, which can be described by

$$\min \sum_{k=1}^{N_s} \left| X_k - \mathrm{proj}\big(X_k, \mathrm{span}\{\phi_1 \cdots \phi_r\}\big) \right| \tag{24}$$

It has been shown that the basis function ϕ is simply the column vectors of Ψ, which as shown in Eq. (25) is obtained by taking the SVD of the matrix containing the snapshot ensemble $\widetilde{X} = (X_1, \cdots, X_{N_s})$ [7],

$$\widetilde{X} = \Psi \Theta \Pi^T \tag{25}$$

Given the known orthogonal basis function ϕ, subsequent macromodeling is straightforward. We first approximate the exact solution X of the original equations as a series superposition of the basis function ϕ and the time-dependent coefficients $\alpha_i(t)$

$$\hat{X}(\boldsymbol{x}, t) = \sum_{i=1}^{r} \alpha_i(t)\phi_i \tag{26}$$

where $\hat{X}(\boldsymbol{x}, t)$ is the approximate solution. Assuming all the governing equations (e. g., Navier–Stokes, continuity, convection–diffusion etc.) can be formulated using a differential operator $\boldsymbol{L}$,

$$\boldsymbol{L}(X) = f \tag{27}$$

where f is the source term. Typically a Galerkin method is employed to reduce the original PDEs into dynamic system ODEs with low dimensions. Apply the Galerkin condition [6], we can obtain

$$\big(\phi, \boldsymbol{L}(\phi) - f\big) = 0 \tag{28}$$

Equation (28) yields a set of ODEs, which are summarized as

$$\mathbf{M}\dot{\alpha}(t) + \mathbf{K}\alpha(t) + \alpha^T \mathbf{N}\alpha + \mathbf{F} = 0 \tag{29}$$

where $\alpha(t) = \left[\alpha_1(t), \alpha_2(t), \ldots \alpha_r(t)\right]^T$; $\mathbf{M}$ is the mass matrix; $\mathbf{K}$ is the diffusion matrix; $\mathbf{F}$ arises from external sources, and $\mathbf{N}$ is the inertia matrix for fluid flow. For linear transport phenomena (e. g., species transport and heat transfer in known flow field), $\mathbf{N}$ is absent and the convection effects are included in $\mathbf{K}$. The time dependent vector $\alpha(t)$ is readily obtained by time integration, and then substituted into Eq. (26) for $\hat{X}(\boldsymbol{x}, t)$. Fig. 2 summarizes the POD and Galerkin method-based MOR procedure.

Artificial Neural Networks

The Artificial Neural Network (ANN) methodology is particularly useful for capturing the complex multiphysics nature of microfluidic devices. An ANN is an information processing paradigm inspired by the way the human nervous system processes information. The ANN consists of a network of processing elements called neurons. Depending upon the connections between these elements and element parameters, the ANN can exhibit a complex global behavior. The ANN is determined by its topology, number of layers, number of neurons per layer, neuronal transfer functions and interconnecting weights. Figure 3(a) shows an example of the most common type of ANN topology, consisting of several layers of neurons: an *input* layer connected to the layer of *hidden* units, which are in turn connected to a layer of *output* units. The activity (output) of the input neuron represents the raw information that is fed into the network. The activity of each hidden unit is determined by the activities of the input units (z_i) and the weights (w_i) on the connections between the input and the hidden units [8]. Figure 3b shows the general principle of determination of output Y_k of a neuron k as a function (func) of the weighted inputs to the neuron from the previous layer's activations, which is described by

$$Y_k = \text{func}\left[\sum_{i=1}^{N_i} w_i z_i\right] \qquad (30)$$

where N_i is the number of inputs to the neutron k. ANNs can be trained to generate an arbitrary number of outputs in response to an arbitrary number of inputs. This flexibility allows them to be used to model complex multiphysics phenomena without significantly compromising on accuracy of the model.

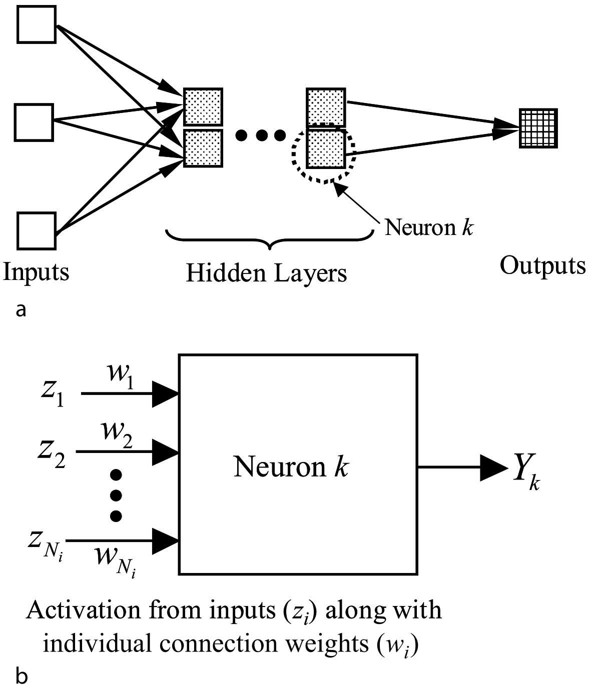
Analytical Approaches

Currently, analytical approaches are still the most preferred tools for model reduction in microfluidic research community. While it is impossible to enumerate all of them in this chapter, we will discuss one particular technique – the Method of Moments, which has been systematically investigated for species dispersion modeling [9, 10]. The Method of Moments was originally proposed to study Taylor dispersion in a circular tube under hydrodynamic flow. Later it was successfully applied to investigate the analyte band dispersion in microfluidic chips (in particular electrophoresis chip). Essentially, the Method of Moments is employed to reduce the transient convection–diffusion equation that contains non-uniform transverse species velocity into a system of simple PDEs governing the spatial moments of the species concentration. Such moments are capable of describing typical characteristics of the species band (such as transverse mass distribution, skew, and variance).

For the sake of brevity, we consider the species band in a 2D channel (while it can be readily extended to the 3D case). Its concentration c is governed by

$$\frac{\partial c}{\partial t} + u\frac{\partial c}{\partial x} = D\left(\frac{\partial^2 c}{\partial x^2} + \frac{\partial^2 c}{\partial y^2}\right) \qquad (31)$$

where t is the migration time of the species band; x and y are the axial and widthwise coordinates; u is the axial species velocity and is a function of y; D is the species diffusion coefficient. We define the dimensionless axial coor-



Model Order Reduction (MOR), Figure 3 (**a**) An example of a general feed-forward network with multiple hidden layers and a single output layer. (**b**) Output of a single neuron k with incoming neural activations (z_i) and connection weights w_i

dinate ξ, widthwise coordinate η, and time τ in a new coordinate frame that moves at the average velocity U of the species band

$$\xi = (x - Ut)/d, \quad \eta = y/d, \quad \tau = Dt/d^2 \tag{32}$$

where d is the channel width. In terms of these dimensionless variables, Eq. (31) is formulated as the following form in concentration $c(\xi, \eta, \tau)$:

$$\frac{\partial c}{\partial \tau} = \frac{\partial^2 c}{\partial \xi^2} + \frac{\partial^2 c}{\partial \eta^2} - \mathrm{Pe}\chi \frac{\partial c}{\partial \xi} \tag{33}$$

where $\mathrm{Pe} = Ud/D$ is the Péclet number, characterizing the ratio of axial convective and transverse diffusive transport rates, and χ is the normalized species velocity relative to the average:

$$\chi(\eta) = (u - U)/U \tag{34}$$

If the species band is entirely contained in the channel, Eq. (33) holds effectively over the axial domain $-\infty < \xi < \infty$ and $c \to 0$ as $\xi \to \pm\infty$. Thus, we can define the

Model Order Reduction (MOR), Table 1 Different MOR techniques and compact models

Method	Numerical Simulation	Type

spatial moments of the species concentration as

$$c_p(\eta, \tau) = \int_{-\infty}^{\infty} \xi^p c(\xi, \eta, \tau)\, \mathrm{d}\xi\,, \quad m_p(\tau) = \int_0^1 c_p\, \mathrm{d}\eta \tag{35}$$

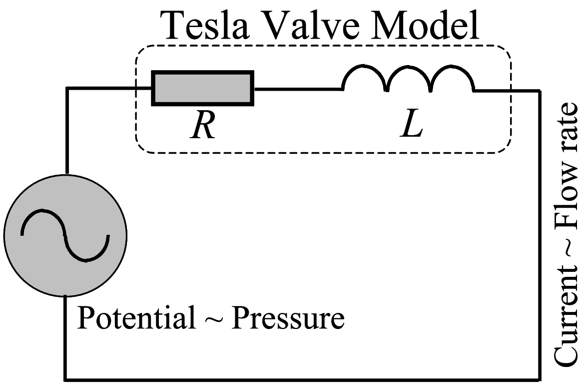
Here, c_p is the p-th moment of the species concentration in the axial filament at η, and m_p is the p-th moment of the average concentration of the band. For species dispersion modeling, it is sufficient to obtain the moments up to the second order. Specifically, c_0 provides the transverse distribution of the species mass in each axial filament within the channel and m_0 is the total species mass and can be chosen as $m_0 = 1$ without losing generality. c_1 gives the axial locations of the centroid of the axial filaments in the species band, and hence indicates the skew of the band. m_1, the transverse average of c_1, is the axial location of the centroid of the entire species band in the moving frame (ξ, η). Finally, m_2 can be used to determine the variance σ^2 of the species band by $\sigma^2 = d^2\left(m_2/m_0 - m_1^2/m_0^2\right)$ [10]. Table 1 summarized different MOR techniques and corresponding compact models features.

Key Research Findings

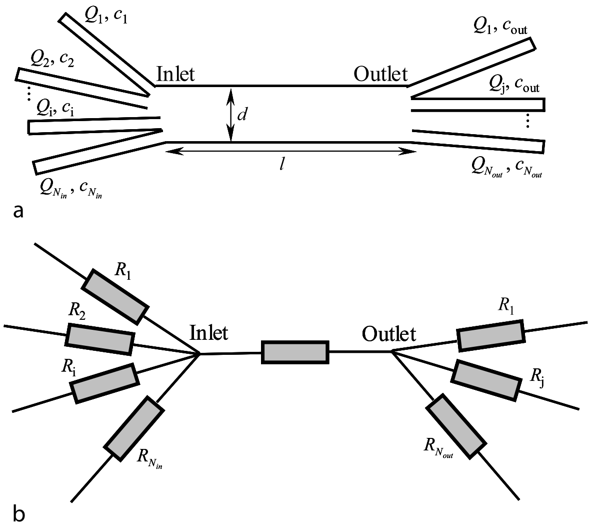
The ultimate goal of MOR is to obtain reduced models for fast and efficient simulation and design of microfluidic devices. In this section, we consider key research findings of MOR in fluid flow and species transport that have proven useful for system-level simulation and design.

Fluid Flow

For coupled pressure-driven and electrokinetic flow, Xuan and Li [3] obtained the conductance coefficients (Eq. (5)) for a microfluidic channel of circular cross section, although the approach can be generalized to a variety of microchannels. Specifically, $G_\mathrm{f} = -\pi r_\mathrm{c}^4/8\mu l$, $G_\mathrm{EOF} = G_\mathrm{st} = \pi \varepsilon_r \varepsilon_0 r_\mathrm{c}^2 \zeta J_1/\mu l$, and $G_\mathrm{e} = -\pi \varepsilon_r^2 \varepsilon_0^2 \zeta^2 J_2/\mu l - \pi r_\mathrm{c}^2 \tilde{\sigma} J_3/l$, where ε_r is the rela-



Model Order Reduction (MOR), Figure 4 The equivalent *RL* electronic circuit of a microfluidic circuit including the Tesla valve



Model Order Reduction (MOR), Figure 5 (**a**) Schematic of the multi-input and multi-output microfluidic channels. (**b**) Equivalent electric resistor network for flow computation

tive permittivity of the fluid, ε_0 the permittivity of vacuum, $\tilde{\sigma}$ the electric conductivity of the liquid, $J_i (i = 1, 2, 3)$ are constants depending on fluid properties and channel size. In many cases the streaming effects are negligible, the coexistent pressure-driven and electrokinetic fluid flow are completely decoupled and their flow rate and electrical current can be calculated independently using simple resistor Kirchhoffian networks.

Automatic macromodel extraction that takes advantage of high-fidelity device simulations (e. g., FEM, FVM, and BEM) to extract *RLC* values in irregular microchannel geometries has also been reported. Turowski et al. [11] approximate the microfluidic *Tesla valve* as a *RL* circuit (serial connection of a resistor *R* and an inductor *L* in Fig. 4) and performed both steady and transient analysis to extract its fluidic resistance and inductance. The macromodels are then stitched together for an overall system simulation on the pumping performance.

Projection subspace-based MOR techniques, such as Arnoldi algorithm and POD, have also been used. Yang et al. [5] considered the lateral air damping effects in MEMS devices. The Navier–Stokes equation governing airflow at the microscale is reduced into a parabolic-typed PDE by neglecting the inertia term, and then solved using the Arnoldi approach. Yang et al. [6] applied the POD to extract the basis function using snapshots from CFD analysis of a single 3D L-Shaped Channel. The reduced ODE set is then obtained by applying the Galerkin method to Navier–Stokes and continuity equations. System-level simulation of serpentine channels that are constructed by concatenating constituent L-shaped channels was also demonstrated with 1% error and at least three orders of speedup. As an alternative approach, Qiao et al. [7] used the SVD algorithm to extract the basis function and investigated electrokinetic flow at irregular geometries, such as cross-, T-, and L-shaped microchannels.

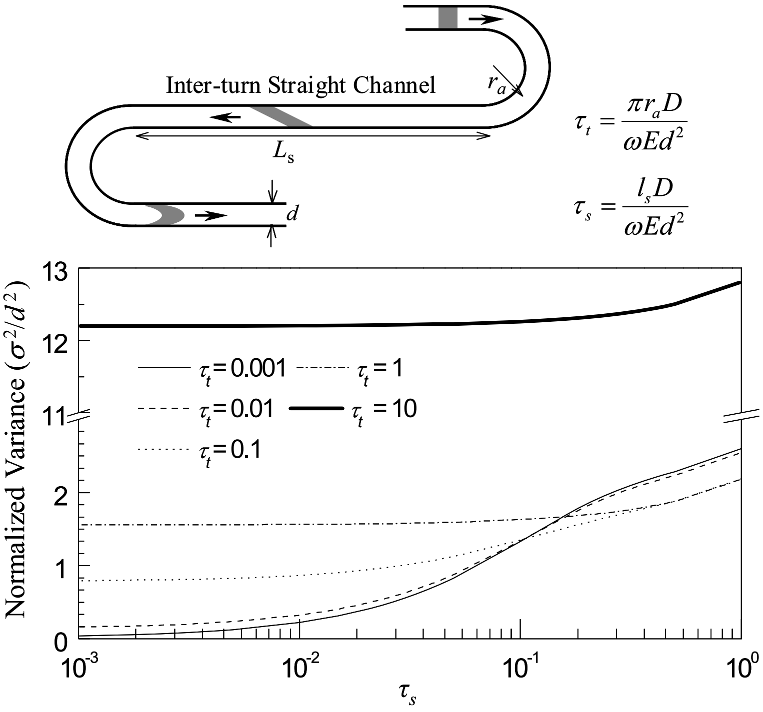
Species Transport

The electric analogy also played a major role in evaluating the steady-state species concentration in microfluidic networks. By applying the principle of flow and species balance to a multi-input and multi-output microchannel involving no reaction, we can obtain

$$\sum_{i=1}^{N_{\text{in}}} Q_i = \sum_{j=1}^{N_{\text{out}}} Q_j \quad \text{and} \quad \sum_{i=1}^{N_{\text{in}}} Q_i c_i = c_{\text{out}} \sum_{j=1}^{N_{\text{out}}} Q_j \qquad (36)$$

where N_{in} and N_{out} are the total number of the braches at the channel inlet and outlet, Q_i and Q_j, respectively, are the flow rates at the i-th flow-in branch and the j-th flow-out branch (Fig. 5a). In order to calculate the distribution of the flow rate Q, the microfluidic network is typically modeled as an assembly of fluidic/electric resistors (Fig. 5b) and solved using the Kirchhoff's law as discussed above. Given the species concentrations in the most-upstream inlet reservoirs, those at downstream channels then can be explicitly determined. For Eq. (36) to be valid, a constraint of transversely complete mixing and uniform species concentration at the end of each channel (a single value c_{out} is used for all outgoing streams in Eq. (36)) is imposed, i. e., $\text{Pe} \times d/l \ll 1$.

ANNs have been used to develop behavioral models to enable efficient system-level simulation of integrated microfluidic devices. Magargle et al. [8] reported a feed-forward ANN-based model for an injector device that is used in electrophoretic separation chips. They used the Buckingham-π theorem to select dimensionless groups



Model Order Reduction (MOR), Figure 6 Dependence of dispersion variance of species band on dimensionless times (τ_t and τ_s)

that aided in reducing the size of the variable space for the training simulations. Finite-element analysis of the governing equations was performed to train the ANN. This model was then used to extract an explicit analytical equation that can be used in a system-level modeling and simulation of complex electrophoresis microchips. The model achieved a computational speedup of more than four orders of magnitude over the numerical solution.

To predict the transient behavior of species bands in microchannel networks, Wang et al. [10] developed a generalized, analytical dispersion models using method of moments. The model takes into account of several factors contributing to species band-broadening, such as Joule heating- and geometry-induced non-uniformity in axial velocity along the channel's cross section, as well as non-uniformity in traveling distance at turns. By neglecting appropriate terms of χ in Eq. (34), the model could be reduced to the special cases including Joule heating dispersion in straight channels or turn-geometry induced dispersion in complex (i. e., serpentine, spiral, and their combinations) electrophoresis microchips. Figure 6 illustrates the dependence of dispersion variance of the species band on the dimensionless times τ_t and τ_s in the widely used complementary-turn electrophoresis chips with Joule heating dispersion neglected. As shown in Fig. 6, both dimensionless times lump the combinational effects of the material properties (species electrokinetic mobility ω and diffusivity D), channel sizes (d, l_s, and mean turn radius r_a), and operational parameter (electric field E) and characterize the ratio of the migration time to the transverse diffusive time constant of the species band. It shows that when τ_t and τ_s are small (i. e., when species convection is dominant), the band distortion caused by the first turn is largely cancelled by the second turn, leading to minor overall dispersion variance. On the other hand, at large τ_t, species diffusion is more significant and the band is uniformly distributed across the turn, the foregoing canceling effect is not present and the total band variance increases markedly.

Future Directions for Research

In contrast to the rapid growth of microfluidic technology, the microfluidic MOR techniques, have not kept pace. The application of MOR techniques exhibits an obvious imbalance. Electric analogy and analytical approaches are still the mainstream tools prevalently used in microfluidic modelling and design. Other MOR techniques (e. g., Arnoldi method, Artificial Neural Network, and POD) that derive from control theory and other disciplines receive less attention, even although they are effective in addressing the inherent complexities arising from high dimensions, irregular geometries, and multiphysics.

Therefore, efforts that bridge these MOR and multidisciplinary research in microfluidics are strongly desired. Recently, Vasilyev et al. [12] demonstrated an elegant work on macromodeling of non-linear system behavior of complex BioMEMS components based on a stabilized balanced truncation plus trajectory piecewise-linear approach, which can be considered as a meaningful step toward the direction. In addition, inadequate effort has been focused on the development of MOR techniques dedicated to the segments of the species transport and biochemical reactions in microfluidics. To a major extent, this limits the utility of the current microfluidic CAD tools to achieve the goal of establishing microfluidics as an efficient platform for the detection, analysis, and manipulations of bio-samples.

Definition

Classical molecular dynamics is a computer simulation method to study the equilibrium and transport properties of a classical many-body system by solving Newton's equations of motion for each component. The hypothesis of this methodology is that the properties of the matter or the transport phenomena can be understood through the observation of statistical properties of a small molecular system under certain microscopic interactions among its constituents. The main justification of the classical molecular dynamics simulation method comes from statistical mechanics in that the statistical ensemble averages are equal to the time averages of a system.

Overview

Many challenges in understanding the nature and developing new technologies are related to the classical many-body problem, i. e., the behavior of a system composed of many particles. Even though modern physics has provided powerful theoretical and experimental techniques to study the behavior of individual particles at the atomic or molecular level, the behavior of a many-body system remains a difficult problem because of its inherent complexity. Emerging in the 1950s, and starting to receive widespread attention from the mid-1970s, molecular dynamics has become a promising tool to solve complex many-body problems, as the rapid developments of digital computers are making this methodology more and more powerful. Today, the molecular dynamics simulation method is well accepted as an important research approach in addition to theoretical and experimental investigations. Molecular dynamics can be used to verify a theoretical result by performing a numerical experiment or to explain an experimental observation by modeling the situation and extracting detailed information to provide a physical insight. Using the molecular dynamics simulation method to study the properties of liquids has a long and rich history. The efforts in the early stages mainly focused on development of models that reflected more realistically the interactions between molecules, and the work focused on modeling physical properties such as density, enthalpy of evaporation, critical points, etc. Modeling of micro- and nanofluidic transport phenomena such as electroosmotic flow started more recently during the mid-1990s, and now using molecular dynamics to study the fundamentals of micro- and nanofluidic phenomena is well accepted.

There are two main classes of molecular level simulation techniques, namely the Monte Carlo simulation method and molecular dynamics simulation method [1]. The Monte Carlo method is a stochastic method that extracts system properties by solving for the statistical average of stochastically generated ensemble microconfigurations (microstates) under a certain macrostate (the description of the system at macroscopic level using properties such as temperature and pressure). Because of the stochastic manner in the generation of microstates in Monte Carlo simulations, it is difficult to reflect the dynamical properties of the system. On the other hand, molecular dynamics is a more deterministic method that monitors the motion of each molecule in the system under certain intermolecular potentials by solving the equations of motion, and hence can reveal the dynamical properties of the system. Both Monte Carlo and molecular dynamics methods can be used to determine equilibrium properties of a system, and the Monte Carlo method has the advantage of being easier to code and more efficient for systems in which the intermolecular force is difficult to derive from the potential function. However, molecular dynamics is more powerful in the sense of its capabilities of studying transport coefficients and time correlation functions.

Molecular dynamics itself can be further divided into two classes: classical molecular dynamics and ab initio molecular dynamics. Classical molecular dynamics treats molecules as point masses and the interactions between molecules are represented by simple potential functions, which are based on empirical data or from independent quantum mechanical calculations. The so-called ab initio molecular dynamics unifies classical molecular dynamics and density-function theory, and takes into account the electronic structure when calculating the forces on atomic nuclei. In this entry, we only present a brief summary of the classical molecular dynamics simulation method. Readers interested in Monte Carlo or ab initio molecular dynamics simulation methods are referred to other entries such as ▶ Monte Carlo Method or *Car-Parrinello Molecular Dynamics*.

Molecular dynamics studies the properties of matter or transport phenomena by constructing an atomic or molecular system with the initial microscopic state of a system specified in terms of the positions and momenta of the constituent atoms or molecules, which can be obtained either from theoretical consideration or from experimental results. Molecular dynamics also requires a model potential to simulate the interactions among atoms and molecules, in which way physics comes in to play a role. The model interaction potential should obey the fundamental laws of physics and chemistry, and capture the important features of the intermolecular interactions that

determine the property of interest. It needs to be remembered that the model is just an approximation to the interactions in the real world and the results from the molecular dynamics simulation have to be tested against proved theoretical or experimental findings, i. e., it should be able to reproduce some properties of matter like density distribution, transport coefficients and so on. Starting from the initial set-up of the system with given intermolecular potentials, Newton's equations of motion are integrated for each atom or molecule to calculate the positions and velocities of the Atoms or molecules in the system as time progresses. After the system reaches equilibrium, the properties of the model system can be extracted from the motion of the atoms or molecules using statistical mechanics methods.

Molecular dynamics provides a methodology for detailed microscopic modeling at the molecular level, which is becoming an indispensable tool for both fundamental studies and applied research. Today, molecular dynamics simulation is widely applied in physics, chemistry, biochemistry and materials sciences, studying the behavior of various kinds of solids, liquids and gases. The applications of molecular dynamics in the micro- and nanofluidics field widely span different topics such as electric double layer structures, electroosmotic flow, interactions between liquids and macromolecules, etc. Over the past two to three decades, several well-accepted molecular dynamics simulation codes have been developed by different research groups. Even though all these codes can model fluidic systems, different codes may be more pertinent to different problems because of the research interest of the developers. The most popular simulation packages include AMBER, CHARMM, NAMD, LAMMPS, DL-PLOY and GROMACS, which are available online and some of them are free to download. Molecular dynamics codes developed and used only by the developers' groups are also applied to many micro- and nanofluidic studies.

It is certainly impossible to cover every aspect in detail of even just the classical molecular dynamics simulation method in this short entry. Quite a few books on the general molecular dynamics simulation method have been published [1–3], which contain much more detailed information for interested readers.

Basic Methodology

For a system composed of N atoms, after constructing the initial microscopic state by specifying the positions and momenta of all atoms under certain constrains such as the given total energy and volume, the behavior of the system is fully determined by the classical equations of motion for the atoms

$$m_i \ddot{\boldsymbol{r}}_i = \boldsymbol{f}_i \tag{1}$$

$$\boldsymbol{f}_i = -\frac{\partial V}{\partial \boldsymbol{r}_i} \tag{2}$$

where m_i and $\boldsymbol{r}_i$ are the mass and Cartesian coordinates of atom i and $\boldsymbol{f}_i$ represents the total force acting on atom i by all other atoms in the system and the external force field, which can be derived from the potential energy function $V(r_1, r_2, \cdots, r_N)$.

Interaction Potential

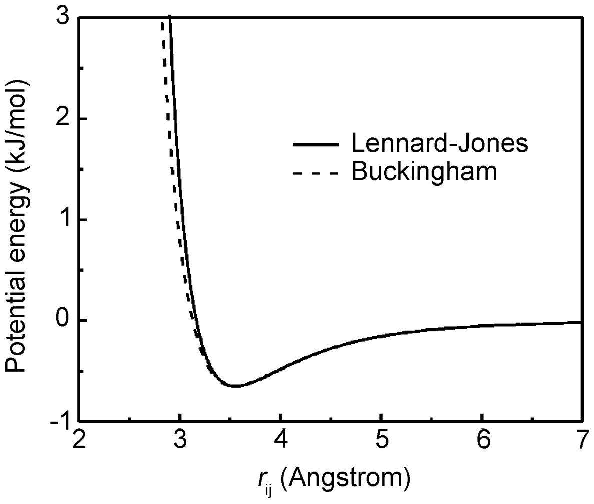
A set of realistic intermolecular potentials are arguably the most important part of a successful molecular dynamics simulation. For a simple atomic system, the potential energy can be written in terms of the coordinates of individual atoms, atom pairs, atom triplets, etc.:

$$V(r_1, r_2, \cdots, r_N) = \sum_i v_1(r_i) + \sum_i \sum_{j>i} v_2(r_i, r_j) + \sum_i \sum_{j>i} \sum_{k>j>i} v_3(r_i, r_j, r_k) + \cdots \tag{3}$$

The notation $\sum_i$ in the first term indicates a summation over all atoms in the system and $v_1(r_i)$ represents the potential in an external force field. The second term, usually called the pair potential, is probably the most important energy term in a molecular dynamics simulation. The pair potential sums over all distinct atom pairs i and j without counting any pair twice. The function $v_2(r_i, r_j)$ depends only on the separation between atoms i and j and hence can also be expressed as $v_2(r_{ij})$. Three-body and other multi-body potentials are normally avoided in molecular dynamics simulations since they are not easy to implement and can be extremely time consuming. The multi-body effects are usually taken into account by modifying the pair potential, i. e., using an *effective* pair potential, which is not the exact interaction potential between the two atoms. According to the range of the interactions, the pair potential can be divided into two categories, i. e. short-range interaction potentials and long-range interaction potentials. Different algorithms are adopted to treat the short-range and long-range interaction potentials.

Short-Range Interaction Potentials

Short-range interaction potentials apply to those interactions that attenuate rapidly as the distance between the atoms increases. The most commonly used short-range



Molecular Dynamics Simulation Method, Figure 1 The Lennard–Jones and Buckingham interaction potentials

interaction potential is probably the Lennard–Jones $12-6$ potential (as shown in Fig. 1):

$$v_2^{\mathrm{LJ}}(r_{ij}) = 4\varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] \tag{4}$$

The Lennard–Jones potential includes a strongly repelling term proportional to $1/r_{ij}^{12}$, which represents the excluded volume by an atom, and a long attractive tail of the form $-1/r_{ij}^{6}$, which models the effect of attractive interactions between induced dipoles due to fluctuating charge distributions. This potential provides reasonable simulation results for the properties of liquid argon. The parameters σ_{ij} and ε_{ij}, the effective diameter and the depth of the potential well between different atoms, can be calculated by using the combination rules since normally the effective diameter and the depth of the potential well are only available for the atoms of individual elements. The most frequently used combination rule is the Lorentz–Berthelot formula:

$$\sigma_{ij} = \frac{\sigma_{ii} + \sigma_{jj}}{2}\,, \tag{5}$$

$$\varepsilon_{ij} = \sqrt{\varepsilon_{ii}\varepsilon_{jj}}\,. \tag{6}$$

Another commonly used potential function, the Buckingham potential (also shown in Fig. 1), has a more flexible and realistic repulsion term than the Lennard–Jones potential, but it is also more expensive to compute. The potential can be written as

$$v_2^{\mathrm{BH}}(r_{ij}) = A_{ij}\exp(-B_{ij}r_{ij}) - \frac{C_{ij}}{r_{ij}^{6}} \tag{7}$$

where the constants A_{ij}, B_{ij} and C_{ij} are in general different for different atom pairs.

In a molecular dynamics simulation, it takes a double loop to calculate the potential energy or force and the time for this calculation is proportional to N^2, which is the most time-consuming and computationally expensive part in the simulation and limits the speed of the program execution. For short-range interactions, since the potential value drops to zero very rapidly as the distance increases, it is a common practice to restrict the evaluation of the interaction potential to a limited region of space. A cutoff radius, R_{c}, is usually introduced, beyond which the interaction potential is set as zero. A common choice is $R_{\mathrm{c}} = 2.5\sigma_{\max}$. The cutoff radius approach reduces the computation time significantly since the potential/force calculations are skipped for those atoms that are not in the cutoff sphere. However, the separations of all distinct pairs still have to be calculated at each time step to examine if they are in the interaction range or not, which also takes a lot of time. The situation gets worse rapidly for larger systems since this calculation scales with N^2. In order to solve this problem, Verlet introduced a technique in 1967 [4] and the strategy is to construct a neighbor list for each atom, which stores the indices of all neighbor atoms falling in the sphere with a radius of $R_{\mathrm{c}} + R_{\mathrm{s}}$. Here R_{s} is called the skin radius. Therefore, in a force routine, not all atoms but only those in the neighbor list will be tested to see if they are in the range $r_{ij} < R_{\mathrm{c}}$. The neighbor list is reconstructed as less frequently as possible but has to be done before any unlisted atoms come into the interaction region.

Long-Range Interaction Potentials

Long-range interaction potentials apply to those interactions that attenuate slowly as the distance between the atoms increases. A very common long-range interaction potential is the Coulomb potential, which scales as $1/r_{ij}$. Therefore, for a system containing ions or polarizable molecules such as water, the Coulomb potential must be taken into account for all atoms in the system and can be expressed by

$$v^{\mathrm{C}} = \frac{1}{2}\sum_{i\neq j}\frac{q_i q_j}{|\boldsymbol{r}_{ij}|} \tag{8}$$

where q_i and q_j are charges on atom i and j, respectively.

The trouble with long-range interaction potentials is not only the time-consuming calculation over all atom pairs in the simulation system, but also the fact that when simulating bulk liquids with a small system, periodic boundary

conditions must be used to avoid surface effects. The simulation box is replicated throughout the space to form an infinite lattice. During a simulation, when an atom moves in the central box, its periodic images in other replicated boxes move exactly in the same way. In this case, not only the long-range interactions among the atoms in the central box but also those between the atoms in the central box and the image atoms in all replicated boxes must be taken into account in the Coulomb potential calculation. Therefore, a lattice sum has to be calculated as

$$v^{\mathrm{C}} = \frac{1}{2}\sum_{\boldsymbol{n}}{}' \sum_{i,j=1}^{N} \frac{q_i q_j}{\left|\boldsymbol{r}_{ij} - \boldsymbol{n}L\right|} \tag{9}$$

where $\boldsymbol{n}$ is a lattice vector and L is the length of the simulation box which is assumed to be cubic here. The prime on the first summation means $i \neq j$ for $\boldsymbol{n} = 0$. It is known that the above lattice sum is only conditionally convergent and the result depends on the summation order. Different techniques have been developed in the literature to overcome this difficulty, which can be classified into three categories: the Ewald summation method, the particle-mesh method and the multipole method. For brevity, only the Ewald summation method will be briefly described here; the details of the particle-mesh method and multipole method can be found in a review paper [5].

The basic idea of Ewald summation is to break down the lattice sum in Eq. (9) into two parts: a short-range potential that can be treated with a simple cutoff scheme and a long-range potential that is periodic, slowly varying, which can be represented to an acceptable accuracy by a finite Fourier series. The strategy is to construct a cloud of screening charge of opposite polarity so that each charge in the system is screened by this charge cloud, which makes the electrostatic potential due to the charge at position $\boldsymbol{r}_i$ decay rapidly to nearly zero at a short prescribed distance. This approach makes the potential of this composite charge distribution a short-range interaction and can be calculated in real space. The screening charges are compensated using a smoothly varying periodic charge density that can be summed up in the reciprocal Fourier space. The final form of the Ewald summation can be written as [5]

$$v^{\mathrm{C}} = \frac{1}{2}\left[\sum_{\boldsymbol{n}}{}' \sum_{i,j=1}^{N} \frac{q_i q_j \operatorname{erfc}\left(\alpha \left|\boldsymbol{r}_{ij} - \boldsymbol{n}L\right|\right)}{\left|\boldsymbol{r}_{ij} - \boldsymbol{n}L\right|} + \frac{4\pi}{L^3}\sum_{\boldsymbol{k}\neq 0}\sum_{i,j=1}^{N} \frac{q_i q_j}{|\boldsymbol{k}|^2} \mathrm{e}^{-|\boldsymbol{k}|^2/4\alpha^2} \mathrm{e}^{i\boldsymbol{k}\boldsymbol{r}_{ij}} - \frac{2\alpha}{\sqrt{\pi}}\sum_{i=1}^{N} q_i^2\right] \tag{10}$$

Bonded Interaction Potentials within Molecules

For a system consisting of molecules composed of multiple atoms, in addition to the short-range and long-range interactions discussed above, the intramolecular bonded interactions between the atoms can also play an important role. These bonded interactions can have different contributions corresponding to the energy coming from bond vibrations (two covalently bonded atoms), angular vibrations (varying bond angle between three bonded atoms), improper dihedrals (four bonded atoms in the same plane) and proper dihedrals (torsional deformation of four bonded atoms). The typical form of the bonded interaction potentials is

$$\begin{aligned} v^{\mathrm{Bonded}} &= \sum_{\mathrm{Bonds}} k_r (r - r_{\mathrm{eq}})^2 \\ &+ \sum_{\mathrm{angles}} k_\theta (\theta - \theta_{\mathrm{eq}})^2 \\ &+ \sum_{\mathrm{improper}} k_\xi (\xi - \xi_0)^2 \\ &+ \sum_{\mathrm{proper}} k_n (1 + \cos(n\varphi - \varphi_0)) \,. \end{aligned} \tag{11}$$

At the beginning of the simulation, a fixed list can be established which contains all indices of atom pairs, atom triplets and atom quadruples that participate in the bonded interactions. The bonded interaction potentials can be calculated on the basis of this fixed list at each time step instead of checking all the atoms in the system.

Integration Algorithm

From the initial configuration and the given potential functions, the equations of motion can be integrated using finite difference methods. The integration algorithm, which is normally called the integrator, must be accurate since it determines the accuracy of the simulation results. However, no integration algorithm can provide an exact solution due to the roundoff of the finite number representation and the finite difference scheme. The integrator must be accurate in the sense of approximating the true trajectory of the system as closely as possible, which requires the use of a short time step. On the other hand, the integrator also has to pursue the use of a long time step δt for the computing efficiency. Therefore, there is a tradeoff between accuracy and efficiency when selecting the integration time step.

The most widely used integration algorithm for the equations of motion is the Verlet algorithm. Various versions of the Verlet algorithm exist in the literature, including

the original Verlet scheme, the leap-frog scheme and the velocity Verlet algorithm. They are essentially equivalent and we will briefly introduce the leap-frog and velocity Verlet algorithms here. The leap-frog scheme can be written as

$$\boldsymbol{v}\left(t+\tfrac{1}{2}\delta t\right)=\boldsymbol{v}\left(t-\tfrac{1}{2}\delta t\right)+\delta t\cdot\boldsymbol{a}(t) \tag{12a}$$

$$\boldsymbol{r}(t+\delta t)=\boldsymbol{r}(t)+\delta t\cdot\boldsymbol{v}\left(t+\tfrac{1}{2}\delta t\right) \tag{12b}$$

where $\boldsymbol{r}$, $\boldsymbol{v}$ and $\boldsymbol{a}$ are the position, velocity and acceleration vectors, respectively. In this scheme, the stored quantities are the current position $\boldsymbol{r}(t)$, acceleration $\boldsymbol{a}(t)$ and the half-step velocity $\boldsymbol{v}(t-1/2\,\delta t)$. In order to calculate the kinetic energy at time t, the current velocity may be calculated by

$$\boldsymbol{v}(t)=\frac{1}{2}\left[\boldsymbol{v}\left(t+\tfrac{1}{2}\delta t\right)+v\left(t-\tfrac{1}{2}\delta t\right)\right]. \tag{13}$$

The velocity Verlet algorithm takes the following form:

$$\boldsymbol{v}\left(t+\tfrac{1}{2}\delta t\right)=\boldsymbol{v}(t)+\tfrac{1}{2}\delta t\cdot\boldsymbol{a}(t) \tag{14a}$$

$$\boldsymbol{r}\,(t+\delta t)=\boldsymbol{r}(t)+\delta t\cdot\boldsymbol{v}\left(t+\tfrac{1}{2}\delta t\right) \tag{14b}$$

$$\boldsymbol{v}\,(t+\delta t)=\boldsymbol{v}\left(t+\tfrac{1}{2}\delta t\right)+\tfrac{1}{2}\delta t\cdot\boldsymbol{a}(t+\delta t)\,. \tag{14c}$$

This scheme stores the information of positions, velocities and accelerations all at the same time step.

Statistical Ensemble

If there is no time-dependent external force, the dynamics of a molecular system will evolve on a constant-energy surface. Therefore, a natural choice of the statistical ensemble in molecular dynamics simulation is the microcanonical ensemble (NVE). Other types of ensembles, such as the canonical ensemble (NVT) and the isothermal–isobaric ensemble (NPT), can also be realized by controlling corresponding thermodynamic variables. For the last two ensembles, the temperature of the ensemble needs to be controlled and four different control mechanisms, namely differential control, proportional control, integral control and stochastic control, have been developed in the literature. As an example, a proportional thermostat for the NVT ensemble will be briefly discussed as follows.

In order to correct the deviation of the actual system temperature from the prescribed T_0, Berendsen et al. introduced a proportional method in which the system is weakly coupled to an external heat bath, and at each time step the velocities of the atoms in the system are multiplied by a scaling factor

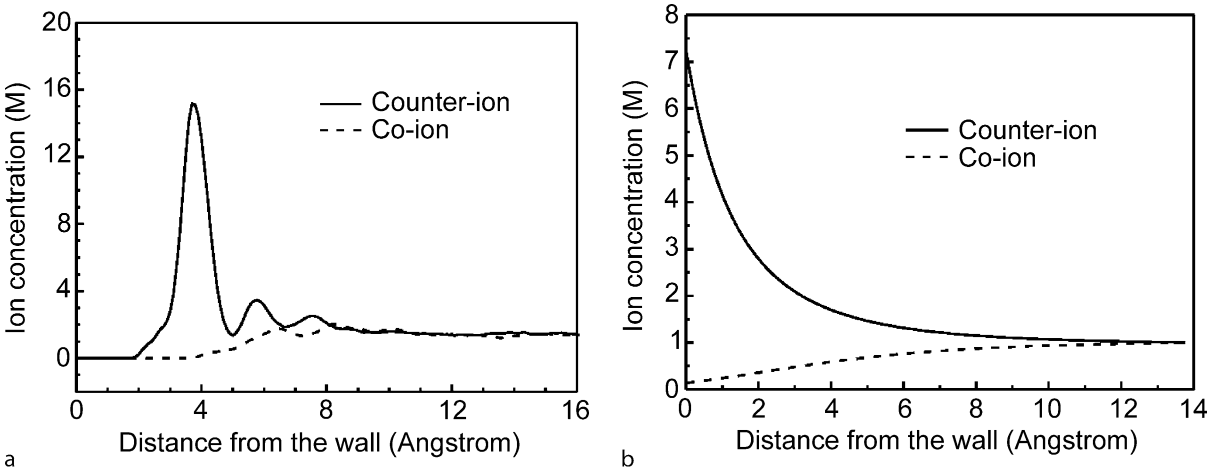
$$\lambda=\left[1+\frac{\delta t}{\tau}\left(\frac{T_0}{T}-1\right)\right]^{\frac{1}{2}}. \tag{15}$$

In this way, the kinetic energy of the system is scaled and the temperature of the system is forced to approach the prescribed temperature. The coupling time constant τ represents the time scale in which the system reaches the prescribed temperature. Using the Berendsen thermostat, the system temperature is allowed to fluctuate instead of being set as a constant. At each time step, the temperature is corrected to a value closer to T_0. For a larger time constant (τ), it takes longer time for a system to reach the prescribed temperature.

Key Research Findings

The molecular dynamics simulation method has seen a rapid development and been applied to model solids, liquids and gases. Applications of molecular dynamics simulations to micro- and nanofluidics have been an active research topic over the past decade including studies of the structure of water, ion distribution in the electric double layers, electroosmotic flow, etc. Because of the complex structure of water molecules, significant efforts have been made to develop models and potential functions to accurately represent the intermolecular interactions. Most of these studies tried to calculate water properties such as density, enthalpy of evaporation, diffusivity, critical point, etc., to verify the accuracy of the model. A large number of water models, such as SPC/E, TIP3P and TIP4P, have been developed and extensively examined against experimental results, which laid a solid foundation for studying micro- and nanofluidic phenomena with the molecular dynamics simulation method.

Using molecular dynamics to study the electric double layer structure started a little over a decade ago, with the hope of determining more accurate structures because the classical description of an electric double layer based on the Poisson–Boltzmann equation is accurate only for low surface potential and dilute electrolytes. The Poisson–Boltzmann equation only considers the electrostatic interactions between the charged surface and ions in the solution, but not the ion–ion interactions in the solution and the finite molecule size, which can be taken into account in molecular dynamics simulations. It was shown [6, 7] that the ion distribution in the near-wall region could be significantly different from the prediction of classical theory. Typical molecular dynamics simulation results of counter-ion and co-ion concentrations in a nanochannel are shown



Molecular Dynamics Simulation Method, Figure 2 Counter-ion and co-ion concentrations across a nanochannel obtained from the molecular dynamics simulation (**a**) and the Poisson–Boltzmann equation (**b**)

in Fig. 2a. The ion distribution obtained from the Poisson–Boltzmann equation is also shown in Fig. 2b for comparison. Different from the traditional Poisson–Boltzmann prediction, both counter-ions and co-ions are depleted in the near-wall region (2 Å from the channel wall) due to the finite sizes of wall atoms and ions. Also, the counter-ion and co-ion concentrations from the molecular dynamics simulation do not change monotonically to their values in the channel center, but fluctuate with peaks and valleys, resulting from the molecular stacking near the channel wall. Molecular dynamics was also used to simulate electroosmotic flow, and it was found that the viscosity near the wall could be much higher than the bulk viscosity [7] and the continuum theories had to be corrected to agree with the molecular dynamics results [8]. To date, molecular dynamics studies of micro- and nanofluidic phenomena have just started and many fundamental issues still need to be investigated.

Future Directions for Research

Future research efforts relating to molecular dynamics simulation in micro- and nanofluidics could be devoted to two areas, i. e., development of the simulation methodology itself and fundamental studies of the phenomena in micro- and nanofluidics. With the advent of massively parallel computers, it is possible to increase both the length scale and the time scale of molecular dynamics simulations to model larger and more complex systems. However, the current parallel molecular dynamics codes do not scale well enough to use thousands of processors provided by modern computer clusters. Therefore, parallel algorithms with better scalability are highly desirable.

Many issues in micro- and nanofluidics require a fundamental understanding of the interactions among ions, fluid, surface charges and biomolecules. For example, in recent experiments [9, 10] using nanopores or nanochannels as biosensors, both ion current enhancement and ion current blockade were observed when DNA molecules were translocated through the nanopore/nanochannel. This was explained by the competition of two effects: conductance decrease due to the volume occupied by the DNA molecule of lower mobility, and the increased ions adsorbed on the DNA to shield the charge on the DNA backbone. The crossover from current enhancement to current blockade occurred at different concentrations in different experiments. This indicates that the complex charge interactions inside the nanopore/nanochannel may not be fully reflected by the simple models developed in the literature. It can be imagined that molecular dynamics, as a powerful research tool for an assembly of molecules, could greatly contribute to fundamental issues such as the complex charge interactions among ions, fluid, surface charges and macromolecules such as DNAs and proteins.

Monoclonal

Definition

Monoclonal antibodies are antibodies which have been artificially produced against a specific antigen. They are extremely specific and bind to their target antigens.

Monostability

Definition

Capability to remain, without an external control action, in one of its two stable regimes.
This is a useful property in fluidic diverter valves with two outlets operated so that most of the time the fluid has to leave mainly through the preferred outlet and only exceptionally and for a short period of time the fluid has to leave through the other outlet. The regime with flow directed into the non-preferred outlet has to be maintained a the control input. In microfluidic valves operating at higher Reynolds numbers, more than ~ 1000, the monostability is usually obtained without by using the Coanda effect of attachment of a fluid jet to an attachment wall leading towards the preferred outlet. The monostable valves may be a very useful part of sampling units used in microfluidic systems for combinatorial chemistry testing.

Synonyms

Monte Carlo simulation method; Statistical sampling method; Random method

Definition

The Monte Carlo method generally refers to approaches that generate a simulated system with randomness introduced to the variables in the system. The integrated properties are built by sampling the field and the accuracy depends on the size of the sample subjecting to statistical scatter.

Overview

Monte Carlo methods belong to the category of probabilistic methods that can be used in problems of significant uncertainties in initial or input values. Early pioneers [1], with reference to the activities of similar processes in casinos for the repetitive occurrences of chances, or random-

ness, fronted the name Monte Carlo for the famous casinos in Monaco. As the method requires a large number of calculations, it was not widely used until the advent of modern computers.

The Monte Carlo method has been applied to problems in many different fields. It has been found useful in solving multidimensional differential–integral equations. Computational physicists often use it as an alternative to molecular dynamics approaches to examine nuclear and particle physics. Ray tracing in graphics uses a version of the Metropolis–Hastings Monte Carlo algorithm. Financial analysts use the method to generate data for investment portfolios and risk assessment. Engineering applications in reliability prediction, optimization, environmental impact studies, semiconductors behavior, and light transport modeling can also be found.

In microfluid mechanics, the direct simulation Monte Carlo (DSMC) method has been applied to study gas flows in microdevices [2]. DSMC is a simple form of the Monte Carlo method. Bird [3] first applied DSMC to simulate homogeneous gas relaxation problem. The fundamental idea is to track thousands or millions of randomly selected, statistically representative particles, and to use their motions and interactions to modify their positions and states appropriately in time. Each simulated particle represents a number of real molecules. Collision pairs of molecule in a small computational cell in physical space are randomly selected based on a probability distribution after each computation time step. In essence, particle motions are modeled deterministically while collisions are treated statistically. The backbone of DSMC follows directly classical kinetic theory, and hence the applications of this method are subject to the same limitations as kinetic theory. These limitations are associated with the fundamental assumption of molecular chaos and dilute gases. DSMC has been shown to be accurate at the Boltzmann equation level for monatomic gases undergoing binary collisions [4]. The statistical error of a DSMC solution is inversely proportional to the square root of the sample size N. A large sample size is needed to reduce the statistical error. The primary drawback of DSMC is the significant computer resources required for simulating a practical flow. A significant advantage of DSMC is that the total computation required is proportional to the number of molecules simulated N, in contrast to N^2 for molecular dynamics simulations.

Basic Methodology

The feature that separates Monte Carlo methodology from deterministic methods is mainly the use of random numbers, or pseudo-random number sequences in the algorithm. The use of random number differs in the various Monte Carlo methods. A simple Monte Carlo method can be programmed in a few lines of coding or by using existing software, while a general-purpose routine can be quite complicated.

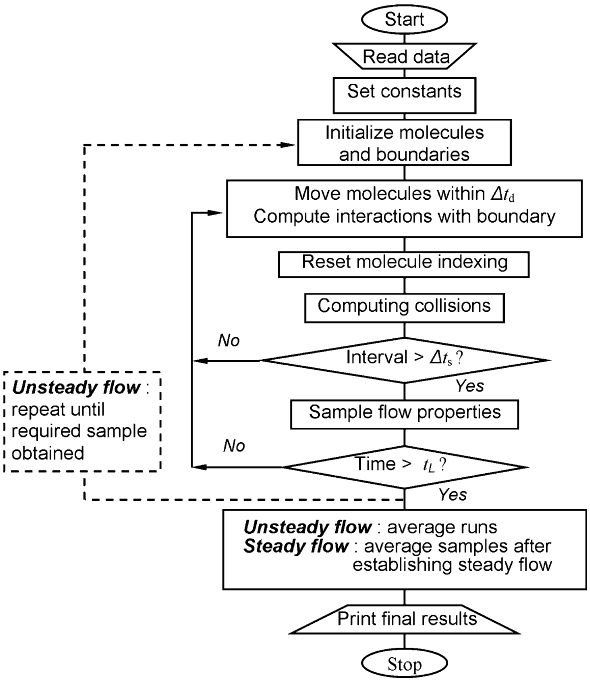
The most common use of Monte Carlo methods is Monte Carlo integration. This can be best illustrated by a simple integration $\int_\Omega f\,\mathrm{d}x$, where x represents multidimensional variable defined in the region Ω. The integration can be started by identifying a region V, of which Ω is a subset. The region V can be randomly sampled in x. For sample points that fall in Ω, f assumes its value. For sample points that are not in Ω, take f as zero. For a total of N samples, the basic Monte Carlo integration algorithm gives

$$\int_\Omega f\,\mathrm{d}x = \frac{\Omega}{N}\sum_{i=1}^{N} f(x_i)$$

The statistical error of such sampling is proportional to $1/\sqrt{N}$. Therefore, the accuracy of the method increases with the sample size. More advanced adaptive Monte Carlo methods use, for instance, importance sampling to enhance the convergence and the accuracy over that of the basic Monte Carlo integration.

The DSMC method often used in micro gas flow simulations was originally developed for high Knudsen number rarefied gas flow. The procedures involved in applying DSMC to steady and unsteady flow problems are presented in Fig. 1 [2, 5].

Execution of the method requires the physical domain to be divided into a distribution of computational cells. The cells provide geometric boundaries and volumes, which are used to sample macroscopic properties. Also, only molecules located within the same cell, at a given time, are allowed to collide. The DSMC simulation proceeds from a set of prescribed initial condition. The molecules randomly populate the computational domain. These simulated molecules are assigned random velocities, usually based on the equilibrium distribution. The simulated representative particles move for a certain time step. This molecule motion is modeled deterministically. This process enforces the boundary conditions. With the simulated particles being appropriately indexed, the molecular collision process can be performed. The collision process is modeled statistically, which is different from deterministic simulation methods such as the molecular dynamics methods. In general, only particles within the same computational cell are considered to be possible collision partners. Within each cell, collision pairs are selected randomly and a representative set of collisions is performed. The post-collision velocities are determined. There are several



Monte Carlo Method, Figure 1 DSMC flow chart [2]

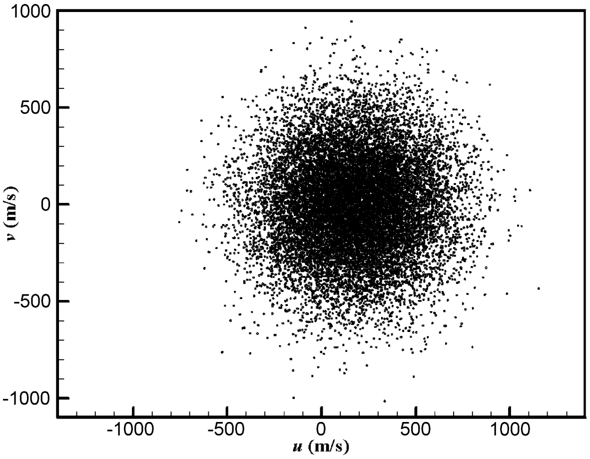
collision-sampling methods that have been used successfully. The currently preferred model is the *no-time-counter* (NTC) technique used in conjunction with the sub-cell method [6]. Figure 2 [2] shows the velocity phase plane in a cell for a typical microflow simulation. The sample size is 17,370.

Key Research Findings

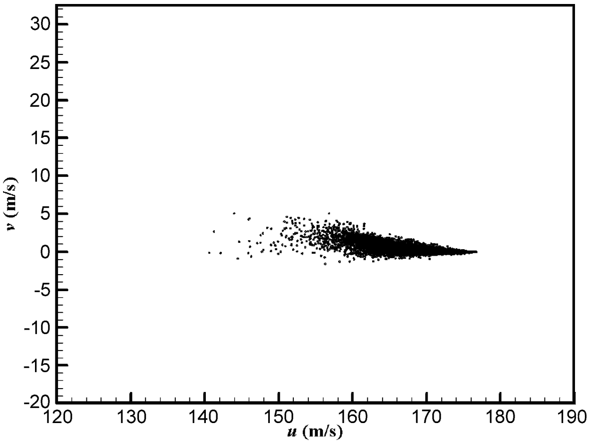
For microflow simulations, the statistical scatter associated with DSMC limits its applications to microflows with extremely low velocity. The information preservation (IP) method has been developed to address this issue. The method [7, 8] introduces preserved information velocities. It has been applied to low-speed Couette, Poiseuille and Rayleigh flows in the slip, transition and free-molecular flow regimes, and to low-speed microflows. For convergence, the computation time of an IP scheme can be several orders of magnitude smaller compared with a regular DSMC simulation. Figure 3 [2] shows the IP velocity phase plane results for the same microflow as shown in Fig. 2 obtained by DSMC. The reduction of the scattering is significant.

Future Directions for Research

Monte Carlo methods are inherently parallel and can be readily parallelized compared with deterministic



Monte Carlo Method, Figure 2 Velocity phase plane from a DSMC simulated microflow



Monte Carlo Method, Figure 3 Velocity phase plane from an IP simulated microflow

approaches. With the advent of low-cost, PC-based cluster computing, the parallel nature of Monte Carlo method should be further explored. Simulations of fluid behavior and properties at micro- and nanoscales may be facilitated with hybrid types of method employing both Monte Carlo and molecular dynamics techniques. This combination allows the simultaneous exploration of, for instance, thermal properties and local phase space.

Morphotropic Phase Boundary

Definition

The boundary in a composition diagram along which there are a maximum number of polarization states. With PZT, for example, the choice of x in the relative concentration of Pb_x versus Zr_{1-x} is typically set near 0.52, along the *morphotropic phase boundary*, to increase the ability of the material to be polarized in response to an externally applied electric field or stress. Usually the material is doped with either acceptor or donor ions to give either a low-loss *hard* material at the expense of polarization difficulty and reduced piezoelectric coupling or a lossy *soft* material with greater piezoelectric coupling.

Definition

Microfluidic and nanofluidic phenomena arising from Lab-on-a-Chip microdevices are characterized by hierarchal multiscale nature with respect not only to space but also to time. In the area of microfluidics and nanofluidics, multiscale modeling aims to develop a viable multiscale computational methodology to study fluid mechanics in spatial and temporal domains ranging from the molecular level to the continuum level.

Overview

Size generally means the physical dimensions, proportions, magnitude, or extent of an object. In the real world, length is one of the most important dimensions of measurement, spanning from 10^{25} m (our entire universe) down to 10^{-15} m (proton and neutron). Many fundamental processes of biology, however, do not cover quite as large a range of sizes as mentioned above. For instance, translation, gene regulation, and cell communication occur on the micrometer to nanometer scale. Table 1 lists the typical length scales of some of biological objects. In order to study the various biological phenomena and processes at the molecular level and at the cellular level, researchers must be able to access these relevant length scales. This requires the experimental devices to have characteristic sizes of a few nanometers up to several micrometers. During the past decade, micromachining and microfabrication technology has become available to make nano- and micron-sized devices, thus enabling studies of objects with these length scales.

Multiscale Modeling and Numerical Simulations, Table 1 Length scale of typical objects in biology

Objects	Length
Diameter of glucose molecule	1 nm
Diameter of DNA helix	2 nm
Diameter of insulin molecule	5 nm
Thickness of cell wall (gram negative bacteria)	10 nm
Size of typical virus	75 nm
Diameter of the smallest bacterium	200 nm
Diameter of red blood cell	8.4 μm
Diameter of average cell in human body	10 μm
Diameter of the largest bacterium	750 μm

Since the introduction of the concept of miniaturized total analysis system (μTAS) or Lab-on-a-Chip, the miniaturization of biological or chemical devices has attracted substantial attention and remarkable progress has been achieved. An integrated Lab-on-a-Chip device can incor-

porate many of the necessary components and functionality of a typical room-sized laboratory into a small chip that perform a specific biological or chemical analysis, including sample treatments, transport, reactions and detection. Originally it was thought that the most significant benefit of the miniaturization would be the analytical improvements associated with the scaling down of the size. Further development revealed other advantages such as minimized reagents, increased automation, and reduced manufacturing costs.

Lab-on-a-chip devices are not just a simple small version of the conventional instruments. Miniaturization raises many new challenges. Fluid and sample transport is a crucial issue in these Lab-on-a-Chip devices because many biological and chemical processes and experiments take place in aqueous environments. The fundamental properties of fluidics in micro/nanoscale may differ significantly from those in larger devices [1]. In microscale (100 nm $\sim$ 100 μm), the fluidic phenomena still can be described by continuum theory, but the decrease of length scale makes surface force and electrokinetic effects important and inertial force unimportant. One of the well-known examples is that mass transportation in microfluidic device is normally dominated by viscous force rather than inertial force. Dimensions of fluidic channels continue to be scaled down to below 100 nm, entering the region of nanofluidics. In these scales, the surface-to-volume ratio is very high, the non-slip boundary condition does not hold fully, and fluid constitutive relations are strongly affected by the existence of the boundary. The study of micro/nanoscale fluid mechanics is important for the understanding and development of the Lab-on-a-Chip devices at the corresponding scales.

Fluid flow in small devices acts differently from those in macroscopic scale. The Reynolds number (Re) is the most often mentioned dimensionless number in fluid mechanics. The Re number, defined by $\rho UL/\mu$, represents the ratio of inertial forces to viscous ones. In most circumstances involved in micro- and nanofluidics, the Re number is at least one order of magnitude smaller than unity, ruling out any turbulence flows in micro/nanochannels. Inertial force plays an insignificant role in microfluidics, and as systems continue to scale down, it will become even less important. For such small Re number flows, the convective term $(\rho \boldsymbol{u} \cdot \nabla \boldsymbol{u})$ of Navier–Stokes equations can be dropped. Without this nonlinear convection, simple micro/nanofluidic systems have laminar, deterministic flow patterns. They have parabolic velocity profile in pressure-driven flows, plug-like velocity profile in electroosmotic flows, or a superposition of both. One of the benefits from the low Re number flow is that genomic material can be transported easily without shearing in Lab-on-a-Chip devices. It is worth noting, however, that other mechanisms, such as capillary effects, viscoelasticity, and electrokinetic effects may complicate the flow phenomena since their nonlinearity increases in small scales [1].

Along with experimental and theoretical studies, numerical simulation has been an indispensable tool in almost every research and application field for many years. It also provides great help in the design of microfluidic and nanofluidic devices. Simulations allow researchers to rapidly determine how design change will affect chip performance, thereby reducing the number of prototyping iterations. However, there are several factors that complicate the numerical simulation of micro/nanoscale phenomena and thus distinguish it from the macroscale counterpart. The first and most important one is the large range of relevant length scales, which can vary up to seven orders (from Debye layer, nm, to channel length and substrate thickness, cm). Secondly, the downscaling of the size dramatically increases the relative importance of surface and interfacial phenomena. Rapid and localized changes of fluidic and material properties often occur in the miniature devices. Another challenge in numerical simulation is the intrinsic multi-physics phenomena that usually combine less or more fluid mechanics, heat transfer, electrokinetics, and chemical and biological thermodynamics and reaction kinetics. In general, one must consider all these aspects in order to provide a numerical picture for a true Lab-on-a-Chip device and therefore there is emerging need to develop multiscale modeling methods.

It is well known that the continuum theory in the Navier–Stokes equations only validates when the mean free path of the molecules is smaller than the characteristic length scale of the gas flow. Otherwise, the fluid will no longer be in thermodynamic equilibrium and the linear relationship between the shear stress and rate of shear strain cannot be applied. The commonly used no-slip boundary condition at the fluid-solid interface is not fully valid, and a slip length has to be introduced,

$$\Delta\, u|_w = u_{\text{fluid}} - u_{\text{wall}} = L_{\text{s}} \left.\frac{\partial u}{\partial y}\right|_w \tag{1}$$

where $\Delta\, u|_w$ is the tangential velocity at the solid wall, L_s is the constant slip length determining the degree of slip, and $\partial u/\partial y|_w$ is the strain rate computed at the wall. It should be noted that so far there is no well-established theory for treating slip boundary at liquid-solid interface in small scales.

Fortunately, for normal liquid flows with the characteristic scale above 10 nm, the continuum assumption still holds practically. For example, modeling and simulation of electrokinetic flow, based on the classical Poisson–

Boltzmann equations and the continuum Navier–Stokes equations, have explained many experimental results and guided the design of Lab-on-a-Chip systems. However, as the device scale shrinks further to several nanometers, or if the local effects such as surface roughness of molecular size and ion-surface interaction must be considered, one needs to resolve the atomistic details of the flow because these effects are neglected in the classical continuum. One example is the fluid density. Continuum theory assume that the density does not vary significantly over intermolecular distance, but fluctuations of density in the vicinity of the solid surface have been confirmed by molecular dynamics simulation and experiment. Therefore, molecular-based computer simulations, mainly Molecular Dynamics (MD) method and direct simulation Monte Carlo (DSMC) method, are necessary for improving our understanding of the flows at these scales.

Basic Methodology

There are two basic models of simulating a flow filed: the continuum model and the molecular model. The continuum model, in form of the Navier–Stokes equations or Euler equations, is able to describe the microfluidic phenomena where the channel sizes are in the micrometer range. It should be noted that many liquid flows in the nano regime can still be treated by continuum models (with appropriate boundary conditions), whereas this is no longer true for nanoscale gas flows. As the length scale decreases further to naonometer range, the continuum assumption begins to break down and molecular-based models, such as Molecular Dynamics method and direct simulation Monte Carlo, are needed to address the effects of the discrete particles: molecules, atoms, ions, and electrons.

Navier–Stokes/Stokes Simulation

The flow of incompressible liquids in continuum state can be described by the Navier–Stokes equations,

$$\begin{aligned} \rho(\partial_t \boldsymbol{u} + \boldsymbol{u}\cdot\nabla\boldsymbol{u}) &= -\nabla p + \mu\nabla^2\boldsymbol{u} + \boldsymbol{F} \\ \nabla\cdot\boldsymbol{u} &= 0 \end{aligned} \tag{2}$$

where $\boldsymbol{u}$ is the flow velocity vector, ρ is the fluid density, μ is the fluid viscosity, p is the pressure, and $\boldsymbol{F}$ is the body force acting on the liquid.

Computational Fluid Dynamics (CFD) based on the continuum Navier–Stokes equations Eq. (2) has long been successfully used in fundamental research and engineering design in different fluid related areas. Naturally, it becomes the first choice for the simulation of microfluidic phenomena in Lab-on-a-Chip devices and is still the most popular simulation model to date. Due to the nonlinearity arising from the convention term, Eq. (2) must be solved numerically by different discretization schemes, such as finite element method, finite difference method, finite volume method, or boundary element method. Besides, there are a variety of commercially available CFD packages that can be less or more adapted to model microfluidic processes (e. g., COMSOL (http://www.femlab.com), CFD-ACE+ (http://www.cfdrc.com), Coventor (http://www.coventor.com), Fluent (http://www.fluent.com), and Ansys CFX (http://www.ansys.com). For majority of the microfluidic flows, Re number is always very small and thus the flows are Stokes type. The full Navier–Stokes equations thus can be linearized as Stokes equations, which greatly reduces the computational cost. The Navier–Stokes/Stokes equations, coupled with other equations, have been applied in study of many kinds of phenomena in the microfluidic systems: electrokinetic flow with Poisson–Boltzmann equation, species transportation with species transport equation, chemical reaction with reaction equation, and thermal analysis with heat transfer equation.

Molecular Dynamics Simulation

Molecular Dynamics method was first used in thermodynamics, physical chemistry, and average thermochemical properties of gases, liquids, and solid. The basic idea of the MD method is straightforward: atoms or molecules are described as a system of interacting material points, whose motion is determined dynamically by a vector of instantaneous positions and velocities. The velocities $\boldsymbol{v}_i = (v_{x,i}, v_{y,i}, v_{z,i})$ and positions $\boldsymbol{r_i} = (x_i, y_i, z_i)$ of the single atoms evolve according to Newton's law of motion,

$$\begin{aligned} m_i \frac{\partial \boldsymbol{v}_i}{\partial t} &= \sum_{j\neq i} \nabla V(r_{ij}) \\ \frac{\partial \boldsymbol{r}_i}{\partial t} &= \boldsymbol{v}_i(t) \end{aligned} \tag{3}$$

where m_i is the mass and $V(r_{ij})$ is the interaction potential that models the physics of the system under consideration. Among a wide range of potentials employed in MD simulations, the Lennard–Jones $12-6$ potential is typically used to represent inter-atomic interactions,

$$V(r_{ij}) = 4\varepsilon\left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6}\right] \tag{4}$$

where $r_{ij}$is the distance between atoms i and j, ε is the energy scale, and σ is the Lennard–Jones diameter. The

set of Eq. (3) can be integrated in time, with initial conditions and specified boundary conditions. MD simulations are usually employed for homogeneous system where periodic boundary conditions are used. However, sometimes it is also necessary to impose arbitrary non-periodic boundary conditions. For example, interactions between the liquid and solid walls can be taken into account by adding different wall atoms, either fixed on a lattice or coupled to a lattice with large spring constant.

Direct Simulation Monte Carlo Method and Lattice–Boltzmann Method

MD simulations are highly inefficient for dilute fluid (gas) where the molecular interactions are infrequent. Alternative statistical approaches, such as direct simulation Monte Carlo method (DSMC) or Lattice–Boltzmann method (LBM), are more suitable for dealing with such a situation. DSMC is a direct particle simulation method based on kinetic theory and its basic idea is to track a large number of statistically representative particles. Unlike exactly calculating collisions in MD simulations, DSMC models collisions stochastically using scattering rates and postcollision velocity distributions based on kinetic theory. DSMC simulations are not correct at atomic scale, but they are accurate at scales smaller than mean free path. Most of DSMC methods are based on the following Boltzmann equation,

$$\frac{\partial nf}{\partial t} + \boldsymbol{c} \cdot \frac{\partial nf}{\partial \boldsymbol{r}} + \boldsymbol{F} \cdot \frac{\partial nf}{\partial \boldsymbol{c}} = \int_{-\infty}^{\infty} \int_{0}^{4\pi} n^2 (f^* f_1^* - ff_1) c_r \sigma \, \mathrm{d}\Omega \, \mathrm{d}\boldsymbol{c}_1 \quad (5)$$

where nf is the product of the number density n and the velocity distribution function f, $\boldsymbol{c}$ is the molecular velocity vector, $c_r$is the relative molecular speed, $\boldsymbol{F}$ is an external force, the superscript * denotes postcollision values, f and f_1 represent two different kinds of molecules, σ is the collision cross section, and Ω is the solid angel. The right hand side term of Eq. (5) represents the collision of molecules. In the DSMC simulations, the physical flow domain is discretized into a grid of cells, structured or unstructured. The size of the cells should be sufficiently fine so that the change of flow properties across the cell is small. The time step is chosen so that the molecules do not move across more than one cell during a time step. With initial conditions and imposed boundary conditions, Eq. (5) can be numerically solved. The macroscopic flow parameters, such as density, velocity, and temperature, are obtained by averaging the corresponding velocity functions over all particles in a single cell.

LBM has been developed to simulate flows in microchannels based on kinetics equations and statistical physics. In LBM, the motion of the fluid is modeled by a lattice Boltzmann equation for the distribution function of the fluid molecules. The discrete velocity Boltzmann equation corresponding to the Navier–Stokes equations can be written as,

$$\frac{\partial f}{\partial t} + \boldsymbol{c} \cdot \nabla f = \Omega + \boldsymbol{F} \quad (6)$$

where f is the single-particle distribution function for particles moving at velocity $\boldsymbol{c}$, $\boldsymbol{F}$ is the external force term, and Ω is collision operator representing the change rate resulting from collisions in f. The most commonly used collision operator is the BGK (Bhatnagar–Gross–Krook) model which uses a single relaxation time approximation,

$$\Omega(f(\boldsymbol{x}, t)) = -\frac{f(\boldsymbol{x}, t) - f^{\mathrm{eq}}(\boldsymbol{x}, t)}{\tau} \quad (7)$$

The appropriately chosen equilibrium distribution, denoted by f^{eq}, depends on the local fluid variables, and $1/\tau$ is the rate of approach to this equilibrium.

Originated from the lattice gas automata (LGA), the LBM has been widely applied in simulating the rarefied gaseous flow in microchannel. Recently the LBM has also found success in applications to the liquid microflows, particularly the electrokinetic flows. For the continuous liquid, the Navier–Stokes equations can be recovered from the Boltzmann equation by Chapman–Enskog expansion or multiscale analysis, in which the Boltzmann equation is split into different scales for space and time variables. The lattice that an LBM operates is usually designated by an identifier of DdQq where d is the number of dimensions and q is the number of velocity vectors. The geometry of the lattice should be symmetrical to satisfy the isotropic requirement of fluid properties. To correctly recover the Navier–Stokes equations, it also requires sufficient lattice symmetry. For a 2D LBM, there are three lattice models: D2Q5, D2Q7, and D2Q9. For a 3D LBM, there are three lattice models: D3Q15, D3Q19, and D3Q27. Although not a real mesoscale method, the LBM for the incompressible flow has comparable computing efficiency to a Navier–Stokes solver yet has the potential of providing accurate results beyond the slip-flow regime. Moreover, external force field (e. g., applied electric field) can be more easily added to the lattice Boltzmann equation than to the Navier–Stokes equations.

Multiscale Simulation

Molecular-based simulations have already become a powerful tool for studying nanoscale physical phenomena.

However, the length and time scales that molecular-based simulations can probe are still very limited (tens of nanosecond and a few nanometers), due to computer memory and CPU power limitations. On the other hand, nanoscale flows are often a part of larger scale devices that could contain both nanochannels and microfluidic domains. The dynamics of these systems depends on the intimate connection of different scales from nanoscale to microscale and beyond. MD simulation cannot simulate the whole systems due to its prohibitive computational cost, whereas continuum Navier–Stokes simulation cannot elucidate the details in the small scales. These limitations and the practical needs arising from the study of multiscale problems have motivated research on multiscale (or hybrid) simulation techniques that bridge a wider range of time and length scales with the minimum loss of information. A hybrid molecular-continuum scheme can make such multiscale computation feasible. A molecular-based method, such as MD for liquid or DSMC for gas, is used to describe the molecular details within the desired, localized subdomain of the large system. A continuum method, such as finite element or finite volume based Navier–Stokes/Stokes simulation, is used to describe the continuum flow in the remainder of the system. Such hybrid method can be applied to solve the multiscale phenomena in gas, liquid, or solid.

The key issue of the multiscale simulations is the coupling (exchanging information) between the molecular scale and the continuum scale. There are two classes of coupling schemes for liquids: direct flux exchange [2] and the domain decomposition method (Schwartz alternating method) [3]. O'Connell and Thompson's scheme [2] implemented a finite overlap region between the molecular domain and continuum domain to avoid sharp density oscillation and therefore allow two solutions to relax before coupled together. Hadjiconstantinou and Patera [3] proposed a Maxwell demon method for simulating incompressible flow. They introduced a particle reservoir to conserve mass flux across the MD-continuum interface. Several extensions of the model have been made but without much improvements on outputs. The most critical problem with the model is how to determine the empirically coupling parameter. Recently, a dynamic coupling model was proposed to simultaneously calculate the free parameter without any a priori input in computation, which yielded satisfactory results for the Couette flow and the Stokes flow. Various multiscale simulations have been used in studying the fluid flow with localized molecular characteristics. Qiao and Aluru [4] presented embedding multiscale simulation techniques for analysis of electroosmotic flow in nanochannels. The multiscale results were compared to direct MD simulations and found good agreement in ion distribution and velocity profile. Their simulations also indicated that the classical continuum theory significantly overestimates the average velocity at a high-bulk concentration. Werder et al. [5] developed an MD simulation coupled to a continuum Navier–Stokes solver based on finite volume discretization. The two regions were combined through Schwarz alternating method to exchange information. They used this hybrid method to study the flow of liquid argon past a carbon nanotube, and found that the resulting flow field agreed with a fully molecular reference solution.

Key Research Findings

While experimental evidence indicates that fluid flow in microdevices differs from flow in macroscale, existing experimental results are often inconsistent and contradictory because of the difficulties associated with such experiments and the lack of a guiding rational theory. Koo and Kleinstreuer [6] summarized experimental observations of liquid microchannel flows and computational results concerning channel entrance, wall slip, non-Newtonian fluid, surface roughness, and other effects. Those contradictory results suggest the need for applying molecular-based models to help establish a theoretical frame for the fluid mechanics in microscale and nanoscale.

Thompson and Troian [7] presented results from MD simulations of Newtonian liquids under shear and found a general nonlinear relationship between the slip boundary condition and the local shear rate at a solid surface. Werder et al. [8] conducted parallel MD simulations to investigate the wetting behavior of water droplets confined in carbon nanotubes and found that pure water showed a nonwetting behavior in nanotubes. Kalra et al. [9] used MD to study osmotically driven transport of water molecules through hexagonally packed carbon nanotube membranes and revealed several distinct features of the nanoflows. The thermal fluctuations become significant at the nanoscale and the flow is stochastic in nature. The flow also appears frictionless and is limited mainly by the barrier at the inlet and outlet of the nanotube. Yeh and Hummer [10] studied the electrophoresis of single-stranded RNA molecule through 1.5 nm-wide pore of carbon nanotube membranes using MD simulations. They found that translocation kinetics of RNA through nanotube membranes is sequence-dependent, which suggests the possibility of extracting sequence information from synthetic-pore translocation data.

Future Directions for Research

As advancements in microfabrication techniques allow for further shrinking Lab-on-a-Chip devices from the micron

regime to the nanometer regime, much nontraditional physics is still to be discovered and many exciting applications of Lab-on-a-Chip devices are yet to be exploited. For example, fast sequencing of DNA strands with a nanopore device need the knowledge of the conformations of DNA inside the pore in atomic detail. Due to difficulties associated with the nanoscale experiments, molecular-based simulation, as well as multiscale modeling, will play a more and more important role in development and optimization of such devices. The computer models must be able to cover length scale from nanometer to micron, and time scale from femtosecond to microsecond. Therefore considerable research effort should be put to construct the foundations for the multiscale methodology and to develop computational capability to realize such multiscale simulation. Meanwhile, it is also essential to develop novel experimental techniques for direct measurement and visualization of flow fields and molecular transport in the nanoscale. Such techniques will not only generate first-hand observation in nanometer regime, but also provide validation and improvement for the molecular-based models and multiscale simulations.

Definition

A nanochannel is a hollow channel with at least one dimension of its cross-section in the 1 – 100 nm range. Depending on the cross sectional configuration, a nanochannel can be classified as a twodimensional (2D) nanochannel or a nano-slit with one side of its cross-section in the nanometer regime, or a onedimensional (1D) nanochannel or a nanotube with its diameter (or both width and depth) in the nanometer regime. Short nanochannels are usually denoted as nanopores.

It is worth noting that some confusion exists at present in classifying nanochannels as 1D or 2D. Nano-slits are also referred to by some researchers as 1D confined nanochannels, and sometimes simplified as 1D nanochannels, while nanotubes are called 2D confined nanochannels. This is exactly opposite to the above classification so caution must be used to find out what a researcher means by 1D and 2D nanochannels in his writing. Here the definition follows the common practice in naming low dimensional structures, for example, thin films are usually denoted as two dimensional and nanowires are usually denoted as one-dimensional.

Overview

Nanochannels or nanopores are interesting nanostructures due to the fact that their sizes are comparable to either the size of DNAs or proteins or the Debye screening length of electric double layers. Current interest in nanochannels or nanopores in nanofluidic research was largely inspired by the pioneering work of single molecule sensing with a naturally occurring protein nanopore, α-hemolysin, which is a nanopore of about 10 nm long and has an smallest inner diameter of about 1.4 nm. The nanopore was embedded in a lipid bilayer membrane separating two fluid cells and a baseline ion current was set up under an electric bias across the nanopore. When single stranded DNA or RNA molecules were translocated through the nanopore, the ion current was partially blocked, making an extremely sensitive single molecule detector. These promising results motivated the development of robust and size-tunable inorganic nanopores as single molecule sensors with solid-state microfabrication techniques. Nanopores of about 2 nm in diameter have been fabricated and ion current modulation was observed when DNA molecules translocated through these solid-state inorganic nanopores.

Long nanochannels can be used as single molecule sensors in a similar way as nanopores, as has been demonstrated in several recent studies. In addition to the application as single molecule sensors, long nanochannels and their arrays can be used as filters for molecule separation, membranes for electroosmotic pumping, templates for nanowire synthesis, electrodes for supercapacitors, and

proton exchange membranes in fuel cells. Novel and complex transport phenomena can occur in nanochannels, leading to improved performance or new functions for devices made of nanochannels.

The promising applications of nanochannels in nanofluidics have excited great interest in fabrication of various kinds of nanochannels. In general, nanochannels can be made by either top down approach based on micro- and nanofabrication techniques, or the bottom up approach based on chemical self-assembly to build up nanostructures with chemical reactions [1]. The top down approach takes advantage of the rapid development of micromachining techniques, and can make nanopores or nanochannels as small as one to two nanometers. The fabrication process is usually based on lithography and etching on a silicon or glass substrate, making it possible to directly integrate the nanochannel with microfluidic components to make integrated nanofluidic devices. The disadvantage of the top down approach is that it could be very expensive, especially for nanochannels of ultra small size such as ~ 2 nm. The bottom up technique is based on chemical synthesis, which is usually cost-effective and can make very small pores. However, chemical synthesis usually makes an array of nanochannels either by anodization through a membrane, or by growing an array of nanochannels on a substrate. It may be difficult to separate a single nanochannel for certain applications. Integration with other components to make integrated nanofluidic devices may also pose challenges.

Many techniques have been developed to fabricate nanochannels or nanochannel arrays. Several general approaches of nanochannel fabrication relevant to nanofluidics are summarized in the following sections.

Basic Methodology

Nanochannel Fabrication with Solid-State Fabrication Techniques

Top down nanochannel fabrication techniques are developed mainly over the last decade with state-of-the-art micromachining facilities. Various kinds of nanochannels, such as short nanopores, 2D nanoslits, and 1D nanotubes have been fabricated and tested for different applications. Small nanopores are made based on the reflow of surface atoms under the irradiation of focused ion or electron beams. 2D nanoslits can be easily batch-fabricated with either etching of enclosed sacrificial lines or bonding of two chips with one having etched nanometer deep open channels on it. 1D nanochannels need advanced lithography capability and many techniques are not suitable for batch fabrication. Some more details of making these three types of nanochannels are as follows.

Fabrication of Inorganic Nanopores

Inorganic nanopores of about 2 nm pore size for single molecule sensing are fabricated with advanced microfabrication techniques and further processed by either focused ion beams or focused electron beams. To date, two processes have been developed to make either SiN_x nanopores with focused ion beams or SiO_2 nanopores with focused electron beams.

To make ~ 2 nm diameter SiN_x nanopores, a layer of nitride film is first deposited on top of a silicon wafer and the silicon wafer is then etched from the backside with KOH to leave a small region of free standing SiN_x membrane. Either an electron beam lithography or ion milling step will create a nanopore of tens of nanometers. Further exposure of the nanopore to focused ion beam will gradually shrink the pore to $1-2$ nm in diameter.

To make the ~ 2 nm SiO_2 nanopores, the typical process starts with a silicon-on-insulator (SOI) wafer. The silicon substrate is anisotropically etched by KOH to leave a small region of free-standing silicon film. E-beam lithography is then performed to create a hole in the device silicon layer, and the size of the hole is further reduced by thermal oxidation to grow a layer of SiO_2 from the device layer silicon. This process will lead to a nanopore of less than 20 nm diameter, which is subsequently shrunk to $2-3$ nm in a transmission electron microscope by focus electron beam mediated reflow of the SiO_2.

The size of these SiN_x or SiO_2 nanopores is comparable to the naturally occurring protein nanopores and ion current modulations through these solid-state nanopores have been observed when single DNA molecules are translocated through these pores. The single molecule detection experiments are performed by embedding the membrane with the nanopore between two bulk fluid cells and applying an electric bias on the order of hundreds millivolts with Ag/AgCl electrodes. The concentration of the electrolyte used is on the order of 0.1 M to 1 M and a baseline ion current on the order of 100 pA to 1 nA is observed. Single DNA molecule translocation through these nanopores will cause a current modulation of the baseline ion current that is significant enough to observe.

Fabrication of 2D Nanochannels

Fabrication of 2D nanochannels can be easily done with state-of-the-art microfabrication facilities based on either sacrificial lines or bonding of a flat chip with a chip with etched grooves of nanometer depth. These nanochannels can be batch-fabricated and easily integrated with other components to make integrated nanofluidic devices. While other techniques may be available to make 2D nanochannels, we will only briefly introduce the two most com-

mon techniques, namely those based on sacrificial lines and bonding because they can be readily made with easily accessible microfabrication facilities.

The sacrificial line method starts with deposition of the sacrificial thin film on selected substrates. Standard photolithography can then be used to pattern the sacrificial thin film into lines of different widths, depending on the available lithography tool and requirement. Another thin film will be subsequently deposited to cover the sacrificial lines and form closed channels with the substrate. Finally the sacrificial lines can be selectively etched away while the wall materials of the nanochannel are intact. In the design of the fabrication process with the sacrificial line technique, attention needs to be paid on selecting the sacrificial materials. The sacrificial material must be able to be deposited uniformly to a height of tens of nanometers and must be able to be selectively etched by some chemicals that do not attack the material that forms the channel wall. If the fabrication of the nanochannel is only part of a process to make integrated nanofluidic devices, then the sacrificial material must be compatible with other process steps. One example of this method is fabricating SiO_2 nanochannels with poly-silicon as the sacrificial material, which can be uniformly deposited by low pressure chemical vapor deposition (LPCVD) at a slow rate.

The bonding technique makes 2D nanochannels by bonding a flat chip with another chip with open nanochannels, usually made by lithography and etching. The bonding will produce a nanochannel enclosed by the two chips. Microchannels connected to the nanochannel and open holes through one of the chip are usually pre-made before the bonding process to provide access to the nanochannel. Different bonding processes are available to bond two different chips together, but anodic bonding and fusion bonding are usually the techniques adopted to make nanochannels. Anodic bonding is a bonding technique to bond silicon and sodium-rich glass with the assistance of high electric field. The advantage of anodic bonding is that the process can be carried out at relatively low temperatures (as low as about 180 °C). Fusion bonding can be used to bond silicon and silicon, and glass and glass at relatively high temperature to achieve desired bonding strength.

Fabrication of 1D Nanochannels

2D nanochannels provide the platform to study novel effects such as those due to overlapped electric double layers. However, the large lateral dimension (usually over 1 μm) could render the 2D nanochannel incapable of manipulating single macromolecules, so fabrication of 1D nanochannels is necessary for some single molecule sensing and manipulation purpose. Because 1D nanochannels need to control the size in both lateral and vertical directions, more advanced lithography techniques are needed to shrink the width of the nanochannel to be comparable to the height of the nanochannel. Much less efforts have been carried out to make 1D nanochannels, so only a couple of examples and some possible approaches are summarized as follows.

In principle, 1D nanochannels should be able to be made in the same ways as those for 2D nanochannels as long as advanced lithography tools are accessible to make sacrificial lines or open channels of tens of nanometers or even smaller in width. This can be done by state-of-the-art e-beam lithography to pattern sacrificial lines or by focused ion beam to dig open nanochannels on one chip for binding.

Making 1D nanochannels with nanoimprint lithography has been demonstrated and shown great promise for batch fabrication of integrated nanofluidic devices. Nanoimprint lithography makes a rigid mold with e-beam lithography and press the mold into a thin resist film and the shape of the film is subsequently solidified by being either exposed to UV light or cooled down below the glass transition temperature of the resist film. The ultra-fine resolution of nanoimprint lithography, as small as 10 nm, provides great potential of making 1D dimensional nanochannels for single molecule sensing and manipulation.

Since advanced lithography tools with resolution down to sub 100 nm may not be readily available, some novel techniques to fabricate 1D nanochannels have been developed and reported. One of these techniques uses standard microfabrication process and has the potential to make integrated nanofluidic devices [2]. This technique is similar to the *spacer technique* developed in solid-state electronic device fabrication. A spacer is the thin side wall achieved by conformal deposition of selected thin film on the side wall of a sacrificial structure. With the fine control of the LPCVD deposition process, a spacer as thin as 10 nm can be made. After removing the sacrificial structure, a spacer as thin as 10 nm is left on the substrate, which can be subsequently used as a mask to pattern nanometer lines or used as a sacrificial line to make a nanochannel. Other novel techniques involve shrinking a larger channel made by standard micromachining to smaller sizes by methods such as filling the channel with other materials [3].

One point that is worth noting is that the solid-state fabrication technique can be integrated with soft-lithography to make poly-dimethylsiloxane (PDMS) nanochannels, as commonly referred to as mold-machining. This method can be used to make both 1D and 2D nannochannels, depending on the mold fabricated. The mold is fabricated either with optical lithography or e-beam lithography to make the inverse shape of the desired chan-

nel. Then PDMS films with desired nanochannel structures can be made by pouring a liquid precursor over the mold and cured into the solid form, which can then be peeled off the mold and bonded to glass substrate to form enclosed nanochannels. The nature of soft lithography technique makes PDMS nanochannels cost effective; however, the polymer nature of PDMS renders weak mechanical strength to PDMS nanochannels, which limits the smallest feature size of PDMS nanochannels to about 200 nm. Even smaller PDMS nanochannels tend to collapse, which is the reason that most small nanochannels are made of inorganic materials such as SiO_2 or SiN_x.

Nanochannel Fabrication by Chemical Self-Assembly

Nanochannel fabrication with microfabrication techniques takes advantage of the rapid development of semiconductor industry and provides the opportunities of fabricating nanochannels of various configurations. In addition, it is relatively easy to integrate the nanochannel with other microscale components to make integrated nanofluidic devices. However, this approach is usually expensive and needs access to advanced fabrication facilities in a cleanroom. In contrast, chemical synthesis of nanochannels is much cheaper and can be realized with relatively simple set-up. The drawback of chemical synthesis is that usually only arrays of nanochannels can be made in a certain pattern and the nanochannels are of certain cross-sectional configuration determined by the synthesis mechanism. In addition, the integration of chemically synthesized nanochannels into a Lab-on-a-Chip device might pose significant challenges. Numerous kinds of nanochannels can be made by chemical synthesis and it is difficult to exhaust every nanochannel structure made by chemical synthesis. Here the fabrication of three kinds of nanochannels, i. e., carbon nanotubes, SiO_2 nanotubes, and anodic porous alumina, all have been used for nanofluidic studies, will be briefly described as follows.

Synthesis of Carbon Nanotubes

Carbon nanotubes have attracted huge attention ever since they were discovered because of their unique structures. The studies are mainly focused on the mechanical, electrical, and thermal properties of carbon nanotubes and the applications of their novel properties. Fluid behavior inside carbon nanotubes and fluid transport through carbon nanotubes have been investigated only recently and novel fluidic phenomena, such as abnormally low flow resistance, have been observed. Carbon nanotubes are usually synthesized by arc-discharge, laser ablation, and Chemical Vapor Deposition (CVD) [4]. The arc-discharge and laser ablation methods involve the condensation of carbon atoms generated from evaporation of solid carbon sources. The temperatures involved in these methods are close to the melting temperature of graphite, 3000 – 4000 °C. In arc-discharge, carbon atoms are evaporated by plasma of helium gas ignited by passing high currents through opposing carbon anode and cathode. By controlling the growth conditions such as the chamber pressure and arc current, high quality multi-wall carbon nanotubes (MWCNTs) can be obtained. To grow single wall carbon nanotubes (SWCNTs), a metal catalyst is added to the arc-discharge system by using a carbon anode with a small percentage of cobalt catalyst. In laser ablation, intense laser pulses are used to ablate a carbon target containing a small percentage of nickel or cobalt catalysts. Usually the target is placed in a tube-furnace heated to 1200 °C. During laser ablation, a flow of inert gas is passed through the growth chamber to carry the grown nanotubes downstream to be collected. The CVD growth involves heating a catalyst material to high temperatures in a tube furnace and flowing a hydrocarbon gas through the tube reactor for a period of time. Nanotubes grown over the catalyst are collected after cooling the system to room temperature. By carefully selecting the hydrocarbon, catalysts, and tuning the growth temperature, both SWCNTs and MWCNTs can be synthesized by the CVD method.

SiO_2 Nanochannels Made From Silicon Nanowires

SiO_2 capillaries have been extensively used in microfluidic and nanofluidic devices so an efficient and cost-effective approach of fabricating SiO_2 nanochannels can greatly facilitate the development of nanofluidic devices. A fabrication process of SiO_2 nanochannels based on partial oxidation of silicon nanowires have been developed recently. The process starts with synthesis of single crystalline silicon nanowires with the vapor-liquid-solid (VLS) method. Once the silicon nanowires are synthesized, a timed dry oxidation process is applied to partially oxidize the silicon nanowires into silicon-core/SiO_2-sheath nanowires. Finally the core/sheath nanowires are exposed to XeF_2 gas to etch away the silicon cores and SiO_2 nanotubes are formed. The diameter of these SiO_2 nanotubes can be as small as 10 nm and the length can be more than 20 μm.

Alumina Nanochannels by Anodization

Alumina nanochannel array has been made for long time and has been used as filters in various applications. More recently, alumina nanochannels have been used as template to synthesize various kinds of nanostructures such as different nanowires. In addition, the nanochannel array has been used to provide nano-environment for biological related studies. The alumina nanochannel membrane pro-

vides a great flexibility because it has easily tunable pore diameter (from 7 – 300 nm), easily tunable pore length (from ~100 nm to more than 100 μm), and high pore densities (up to 7×10^{10} /cm^2).

Fabrication of the alumina nanochannel array is a straightforward process involving anodization of aluminum sheets. To achieve high quality, the aluminum is usually mechanically and electrochemically polished to produce as smooth a surface as possible. The anodization can be done with different acid solutions such as oxalic acid, sulfuric acid, or phosphoric acid. The anodization of aluminum involves the initial formation of oxide layer on the surface, and the oxygen will then transport through the oxide only preferentially at sites that provides low resistance conduction path. The oxide at those sites will start to dissolve, leading to the nucleation of pores, which then grow perpendicular to the surface of the aluminum because of equilibrium between the field-enhanced oxide dissolution at the interface of the electrolyte/oxide, and the oxide growth at the aluminum/alumina interface until the pore grows deep into the aluminum.

To make highly ordered alumina nanochannel array, modifications of the standard anodization process have been made. Successful techniques include pre-pattern to make small dimples on the surface of aluminum to initiate anodization only at specified sites, and a two step anodization process in which the first step serves as an initiation of the regular pattern of tiny dimples on the surface. With these modifications, highly ordered parallel alumina nanochannel arrays have been fabricated.

Key Research Findings

Fabrication of ~1.8 nm diameter nanopores in a SiN_x membrane by ion-beam sculpting was invented rather accidentally around the year 2001 when Jiali Li et al. [5] attempted to dig nanometer holes with focused ion beam but failed with no nanopore open even after excessively long ion beam exposure. They later found that by exposing a 60 nm diameter pore to the focused ion beam, the pore size could be shrunk from 60 nm to ~1.8 nm under the irradiation of energetic Ar^+ ion, which helped the flow of SiN_x molecules along the surface. SiO_2 nanopores of around 3 nm have been fabricated also rather accidentally when Storm et al. [6] used a 300 kV transmission electron microscope to observe a ~20 nm diameter pore made of SiO_2. They found that the pore shrunk under the irradiation of the focused electron beam and the shrinking process can be controlled very precisely since the shrinking rate is at 0.3 nm per minute. The pore shrinking mechanism is believed to be the viscous flow of the amorphous SiO_2 under the irradiation of energetic electrons.

Making nanochannels by combined sacrificial layer and e-beam lithography was reported by Harnett et al. [7], and later nanochannel arrays of 10 nm by 50 nm cross-sectional dimensions were fabricated with nanoimprint lithography by Cao et al. [8]. Mao and Pan reported a thorough investigation of using bonding techniques to make nanochannels of different aspect ratios with glass–glass and glass–silicon [9]. They showed if the nanochannels survived or collapsed under different aspect ratios. Fabricating SiO_2 nanotubes based on partial dry oxidation of silicon nanowires and etching of the intact silicon core was realized in the year of 2003 by Fan et al. [10].

Future Directions for Research

Nanochannel fabrication is an important step to make integrated nanofluidic devices. Solid-state nanochannel fabrication technique can easily integrate the nanochannel with other components to make integrated nanofluidic devices because the channel is made with lithography at specified position. However, the cost of solid state fabrication is usually high so methods to reduce the cost and to remove the requirement of advanced nanolithography tools can greatly lower the barrier of making integrated nanofluidic devices. The cost of chemical synthesis is usually low but it can be a big challenge to separate one nanochannel from the massively synthesized nanochannels by chemical methods to make integrated nanofluidic devices, so approaches to realize this is highly desirable. On the other hand, the array of nanochannels prepared by chemical synthesis could be of great advantage for applications that need massively parallel nanochannels.

Definition

This entry describes recent advances in understanding of fluid (gas & liquid) flow through graphitized carbon nanotubes. We discuss both simulation and experimental results.

Overview

Carbon nanotubes are tubules that consist of a graphene sheet rolled up into a seamless cylinder with diameters of the order of a few nanometers. Carbon nanotubes have unique properties such as extraordinary strength and unique electrical properties, and are efficient conductors of heat. Carbon naotubes also act as extraordinary pipes in the true nanofluidic regime.

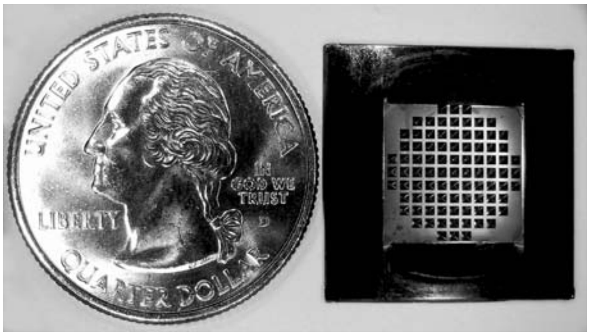
When studying molecular properties inside carbon nanotubes we need to consider the applicability of the continuum physics. A liquid fluid particle is defined as a volume containing a relatively large number of molecules. Since less than 1% statistical fluctuation (1% statistical resolution in other words) of a physical property can be obtained for more than 10,000 particles, we may regard this number of liquid as a continuum limit of fluid particle. A sphere containing 10,000 equidistant molecules would have a diameter corresponding to about 25 molecules. Since a water molecule has a diameter of ~ 0.24 nm, the diameter of the 10,000-molecule sphere will have diameter of 6 nm. A system with spatial size of its domain much larger than 6 nm can thus allow the fundamental hypothesis of hydrodynamics to work. In the range of sizes of carbon nanotubes, continuum theories start to break apart. Molecular dynamics simulations have first predicted and, more recently, a growing body of experimental evidence has started to verify the unique molecular structure and

unique transport mechanisms of molecules confined in the interior of graphitic carbon nanotubes. Water and gas transport in nanometer-size nanotube pores is orders of magnitude faster than predicted by classical theories that do not take in account unique surface properties and the scale of carbon nanotubes. The novel transport phenomena have important implications for technological developments such as the energy efficient filtration membranes and drug delivery platforms. Understanding of molecular structure and transport in carbon nanotubes directly enhances our understanding of the fundamentals of transport at the nanoscale and of the way the biological channels function.

Basic Methodology

The developments in this field have been motivated by a large number of simulations. A central question in nanofluidics concerns the extent to which the classical equations describing the way fluids interact with nanomaterials hold at the nanoscale. Molecular simulation is ideally suited to shed light on this problem. They provide a way of probing static and dynamic behavior of molecules by taking in account both intermolecular and molecule–nanotube interactions in a carbon nanotube environment that is commensurable with molecular size. In the first simulation of fluid flow in a simple nanotube using a realistic model for the solid, Sokhan et al. [1] in 2001 showed that fluids flowing through carbon nanotubes experience very low surface friction, that is very small Maxwell coefficients (~ 0.01) or equivalently large slip boundary conditions, whereas pores made from other materials show higher values and stick boundary conditions. Multiple other simulations have since then revealed interesting phenomena related to flow of gases, water, ions, and polymers (such as DNA and proteins) through carbon nanotubes.

Experimental work can be divided into work that examines structure of fluids inside of the carbon nanotubes using



Nanofluidics in Carbon Nanotubes, Figure 1 Sub-2 nm carbon nanotube membrane chip, from [16]

techniques such as neutron diffraction, NMR and in situ TEM, and the studies that examine transport properties using specially fabricated devices in which carbon nanotubes serve as pores (Fig. 1). Two experimental groups have so far demonstrated devices that allow studies of transport through graphitic carbon nanotubes. As synthesized carbon nanotube mats have considerable spacing between individual carbon nanotubes. Researchers have, therefore developed methods to fill those spaces with a dense material and confine transport through carbon nanotubes. B. Hinds group at U. of Kentucky has fabricated carbon nanotube membranes utilizing multiwall carbon nanotubes with ID $\sim 6-7$ nm and a polystyrene as the matrix material. O. Bakajin's group at Lawrence Livermore National Laboratory is using membranes that have both sub-2 nm ID double wall carbon nanotubes and multiwall ones as pores and use silicon nitride to fill interstitial spaces between the nanotubes.

Key Research Findings

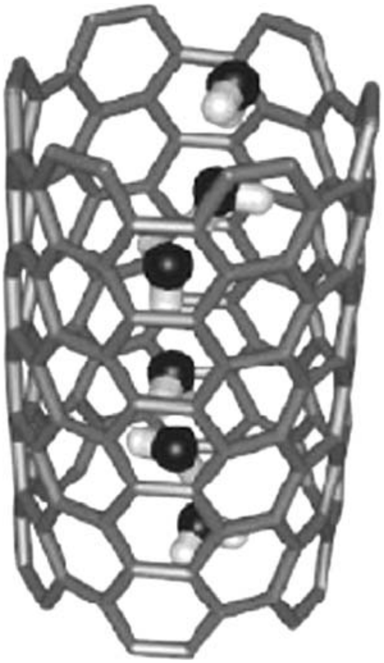
Simulations of Gas Transport

MD simulations showed that the transport rates in nanotubes are orders of magnitude faster than in other materials, attributing the exceptionally high transport rates in nanotubes to the inherent smoothness of the nanotube walls.

As an example, see Skoulidas et al. [2]. They reported atomistic simulations for both self- and transport diffusivities of light gases in carbon nanotubes and compared them with transport rates in zeolites with comparable pore sizes.

Simulations of Water and Ions

There have been numerous reports of the simulations of water and ions through carbon nanotubes. This entry does not intend to present a comprehensive review of the field, but rather give examples of major research developments. Koga et al. [3, 4] studied solid and liquid phases of water confined in narrow arm chair carbon nanotubes ($1.1-1.7$ nm in diameter) and the phase transition at various fixed temperatures ($240-320$ K) and pressures ($50-500$ MPa). They found that solid phases of confined water are different from those of any known bulk ice structure and determined by the confining geometry. Hummer et al. [5] reported the first report of molecular dynamics simulations showing spontaneous and continuous filling of a nonpolar carbon nanotube with a 1D ordered chain of water molecules (Fig. 2). The simulation suggest fast water transport through a single-walled nanotube 13.4 Å long with a small diameter of 8.1 Å. In another study, Kalra et al. [6] reported a through carbon nanotube comparable



Nanofluidics in Carbon Nanotubes, Figure 2 Structure of the hydrogenbonded water chain inside the nanotube [5]

to the flow rate measured for the transmembrane protein aquaporin-1, and are practically independent of the length of the nanotube, in contrast to predictions of macroscopic hydrodynamics. A study by N. Aluru's group [7] examined ionic flow in carbon nanotubes with the goal of using carbon nanotubes as artificial protein channels found in cell membranes. They suggest that cationic or anionic selectivity could be obtained by symmetrical placement of the functional groups.

Simulations of Polymers

Wei, C. and D. Srivastava [8] reported diffusion of polymers to be several orders of magnitude faster than through the zeolite channels (of comparable size). Also report that translocation time through the nanotube scales as N^2, where N is the number of monomers in a polymer. Gao et al. [9] calculated that a single stranded DNA will spontaneously insert into the nanotubes from water solutions provided that the nanotube is big enough, attributing the mechanism to Van der Waals attraction. Yeh and Hummer studied electrophoretic transport of nucleic acids through 1.5 nm carbon nanotubes. Their simulation showed that without electric field RNA would remain trapped in the hydrophobic pores. Sorin & Pande [10] recently also demonstrated that confinement inside a nanotube denatures protein helices.

Experimental Observations of Structure of Fluids

Y. Gogotsi's group [11, 12] has reported in situ TEM observations of water inside carbon nanotubes filled using autoclave treatment at different temperatures and pressures. The TEM observations of the 2 – 5 nm-diameter nanotubes confirm the successful filling of and reveal disordered gas/liquid interfaces contrasting the smooth curved menisci visualized previously in MWNT with diameter above 10 nm. They demonstrated a wet/dry transition on the nanometer scale by means of external heating. Their TEM results suggest that when ultrathin channels such as carbon nanotubes contain water, fluid mobility is greatly retarded compared to that on the macroscale. This observation does not agree with the measurements of flow through carbon nanotube membranes.

Argonne National Laboratory group [13] used neutron diffraction and scattering methods to observe confined water molecules in a 1.4 nm diameter carbon nanotube. The water structure inside the tube is observed. They observed a single-file of water within an ice-tube-layer inside the internal nanotube wall at a temperature more than a hundred degrees lower than the room temperature.

Experimental Observations of Fluid Transport

Hinds et al. [14] published the first account of experiments involving fluid flow through a membrane composed of graphitic carbon nanotubes. The paper claimed that the gas flow through these MWNT membranes with pore sizes in the 6 – 7 nm range followed Knudsen theory. Later revision of the density of the open pores revealed enhancement of flow rates over the predictions of the Knudsen model. Hinds et al. also studied diffusion of aqueous ionic species ($Ru(NH_3)_6^{3+}$ diameter $= 0.55$ nm) and noted that the diffusion coefficient was near the bulk aqueous-solution diffusion for the Ru cation, inferring only limited interaction between the ion and the nanotube tip and walls. More recently the same group reported measurements of flow rates of water, ethanol, and alkanes [15]. The results demonstrate dramatically enhanced flow through ~ 7 nm-diameter nanotube cores compared with conventional fluid flow theory. Observed flow rates were four to five orders of magnitude greater than predicted by hydrodynamics based on macroscale behavior. The implied slip lengths (3 to 70 μm), which are much greater than the tube diameter, are consistent with a nearly frictionless interface.

Holt et al. [16] measured water and gas flow through the pores of double walled carbon nanotubes. These tubes had inner diameters less than 2 nm with nearly defect-free graphitic walls. Five hydrocarbon and eight non-hydrocarbon gases were tested to determine flow rates and to demonstrate molecular weight selectivity compared

with helium. Water flow was pressure-driven at 0.82 atm and measured by following the level of the meniscus in a feed tube. The results for both gas and liquid show dramatic enhancements over flux rates predicted with continuum flow models. Gas flow rates were between 16 and 120 times that expected according to the Knudsen diffusion model in which fluid molecule–wall collisions dominate the flow. Water flow rates were 560 to 8400 times greater than those calculated according to the Hagen–Poiseuille equation. Minimum slip lengths are estimated in the range of 140 to 1400 nm. To express these findings in a practical context, the nanotube membranes showed flow rates several orders of magnitude greater than those of conventional membranes, despite having pore sizes an order of magnitude smaller.

Future Directions for Research

The field of carbon nanotube nanofluidics is very young. Fundamental question about physical principles that govern fast flow of gases and liquids in carbon nanotubes are still not fully answered. There will be more simulation and experimental work on this topic.

Definition

Nanofluidic systems are integrated microdevices with at least one component in the devices having length scales in the range of one to hundreds of nanometers. The critical dimension of nanofluidic systems is comparable to relevant length scales such as diffusion lengths of molecules, sizes of molecules and Debye screening lengths of electric double layers. Nanofluidic systems are ideally suitable for single molecule detection because the systems have the capability of either constraining an individual molecule in a nanochannel for optical detection or providing electrical signals reflecting the presence of an individual molecule inside a nanochannel of the system.

It is worth noting that there is still debate on whether nanofluidic systems should be strictly used for systems with channels of tens of nanometers or smaller in all cross-sectional dimensions, or they can include systems with micro-sized channels that contain nanoliter volumes. The definition here emphasizes the comparable sizes of channels with nanoscale physical length scales, which may lead to interesting phenomena and applications.

Overview

Microfluidic Lab-on-a-Chip technology has been a focus of research over the past two decades and is now making a great impact with the commercial applications of various novel devices in rapid diagnosis, drug discovery and drug delivery. Microfluidics uses microfabricated fluid channels with dimensions of the order of tens to hundreds of micrometers to deliver liquids of nanoliters and work with a small ensemble of molecules. Introducing nanoscale channels into microfluidic Lab-on-a-Chip devices, to make nanofluidic systems, leads to a new breakthrough in creating new functions such as single molecule detection and manipulation. Nanofluidic systems for single molecule detection emerged in the mid-1990s with the demonstration of detecting single DNA molecules with a nanofluidic system composed of a naturally occurring protein nanopore, α-hemolysin, embedded in a lipid bilayer. Since then, nanofluidic single molecule detection has seen great progress as advanced nanofabrication techniques allow the fabrication of small nanochannels or nanopores with dimensions of the order of one to hundreds of nanometers, providing human-made nanofluidic systems.

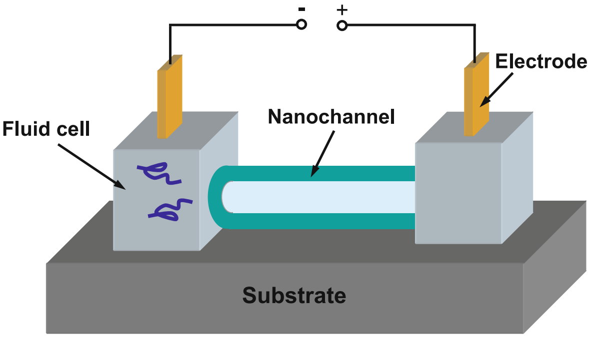
Fabrication of nanofluidic systems usually involves fabrication of nanochannels and integration of the nanochannels with microfluidic components to make functional nanofluidic systems. Microfluidic component fabrication is usually done with either solid-state fabrication on silicon or glass substrates, or soft-lithography fabrication with polymers such as polydimethylsiloxane (PDMS), which is a transparent, biologically compatible, elastomeric polymer. Nanochannel fabrication is more challenging and usually involves advanced microfabrication techniques such as e-beam lithography or nanoimprint lithography. Top-down nanofluidic system fabrication based on solid-state fabrication techniques can readily integrate the fabricated nanochannel with microchannels by alignment in the lithography step during device fabrication process. Integration of nanochannels synthesized massively via bottom-up chemical reactions with microfluidic components for single molecule detection can be a significant challenge in device fabrication.

To date, nanofluidic single molecule detection has been done in two ways. One takes the advantage of the comparable size of nanochannels and macromolecules, and detects the modulation of ion current through a nanochannel or a nanopore when an individual macromolecule enters the nanochannel/nanopore. This method ist well-known as resistive-pulse sensing or the Coulter principle. The other uses a nanochannel as a confined region to limit the number of molecules inside the nanochannel and uses other methods such as optical microscopy to sense a single molecule inside the nanochannel. Both approaches have demonstrated successful detection of single molecules inside nanofluidic channels. However, to date, only a few examples for each approach have been reported since nanofluidic systems have been developed only within the last decade.

Basic Methodology

Nanofluidic Single Molecule Detection Based on the Comparable Size of the Nanochannel and the Molecule

Nanofluidic single molecule detection based on the comparable size of the nanochannel and the molecule is based on the measurement of the electrical current through a nanochannel. In this approach, a nanochannel connects two fluid cells at each side of the nanochannel and an ion current is set up by applying an electric bias across the nanochannel. When a macromolecule of comparable size to the nanochannel enters the nanochannel, it will alter the electrical resistance of the nanochannel, and hence results in a modulation of the electrical current through the nanochannel. Therefore, a nanofluidic system can detect single molecules as long as there is a nanoscale channel in the system with comparable size to the molecules of interest. Figure 1 shows a schematic diagram of nanofluidic



Nanofluidic Systems for Single Molecule Detection, Figure 1
A schematic diagram of nanofluidic system for single molecule detection based on electrical current modulation when macromolecules are translocated through the nanochannel

systems that detect single molecules based on this sensing mechanism.

This simple concept was first implemented in pioneering work [1] on single DNA molecule sensing with a naturally occurring protein nanopore, α-hemolysin, which is a nanopore of about 10 nm in length and has a smallest inner diameter of about 1.4 nm. The detection is based on the ion current blockade when DNA molecules transport through the nanopore. The nanopore was embedded in a lipid bilayer membrane separating two fluid cells and a baseline ion current was set up under an electrical bias across the nanopore. When single stranded DNA or RNA molecules were translocated through the nanopore, the ion current was partially blocked, making an extremely sensitive single molecule detector.

The promising results and simple concept motivated development of robust and size-tunable inorganic nanopores as single molecule detectors and two types of nanopores of $\sim 2-3$ nm in diameter have been made based on the reflow of amorphous SiN_x or SiO_2 under the irradiation of focused ion or electron beams. It was found that the molecules of SiN_x or SiO_2 amorphous films could undergoes viscous flow under the bombardment of energetic ions or electrons and a $2-3$ nm pore could be made on a SiN_x or SiO_2 film by exposing the film with an initial pore of tens of nanometers to focused ion or electron beams. Successful single molecule detection with nanofluidic systems composed of a nanopore embedded between two fluid cells was demonstrated by measuring the ion current modulations from the translocation of DNA molecules through the nanopore [2].

These nanopores were not fabricated in batches but made individually in expensive tools and the fluid cells at each side of the nanopore are bulk fluid cells, which may consume a significant amount of sample. Efforts of making on-chip nanofluidic systems for single molecule detection based on the same principle started with a 3 μm long, 200 nm in diameter PDMS nanochannel on a glass substrate [3]. The channel size (200 nm) is much larger than a typical nanopore (< 10 nm) due to the limitation of the mechanical strength of PDMS. Instead of two terminal measurements, four electrodes were patterned with two on each side of the nanochannel, enabling four probe electrical measurements to detect the small current change. Current blockade of the order of 30 pA induced by single DNA molecules ($\sim$ 16 μm long) was observed in a baseline ion current of 15 nA. The volume occupied by the DNA is estimated to be about 0.16% of the volume of the channel and the nanofluidic system is not suitable for the detection of even smaller molecules since the current modulation will be too weak to be distinguished from the noise of the baseline current. Even smaller nanochannels can be made with inorganic materials such as SiO_2 or SiN_x, which has been demonstrated in a nanofluidic system that has SiO_2 nanochannels of 20 μm in length with inner diameters of $40-60$ nm [4]. The nanofluidic system has been used to detect the presence of single DNA molecules inside the nanochannel.

The detection mechanism looks straightforward: macromolecules will block the ion current through nanochannels, which indicates the presence of macromolecules in the nanochannel. However, it turns out that the phenomena can be much more complex. It was found [5] that when DNA molecules moved through a $4-5$ nm diameter, $50-60$ nm long nanopore in 0.1 M buffer solutions, current enhancement instead of current blockade was observed. Later, Fan et al. [4] observed that when λ-DNA molecules passed through ~ 50 nm SiO_2 nanochannels, ion current enhancement occurred in low-concentration (0.5 M) buffer solutions, but ion current blockade occurred in high-concentration (2 M) solutions. The reason is believed to be that the current blockade in 2 M solutions is due to the geometrical exclusion of high concentration ions by the DNA molecules, while the current enhancement in 0.5 M solutions can be attributed to the increased counter-ions in the nanochannel to shield the DNA backbone. This is the first observation of current crossover as the solution concentration changes, which has been confirmed by other more recent experiments with nanopores. Simple models have been proposed to explain the current modulation but a thorough understanding of the complex interactions between the surface charge, the ions in the solution and the charged DNA molecules has not been achieved yet. For example, the crossover from current enhancement to current blockade occurred at different concentrations for different experiments. More interestingly, in the experiment with the 200 nm PDMS channel [3], current blockade instead of current enhancement

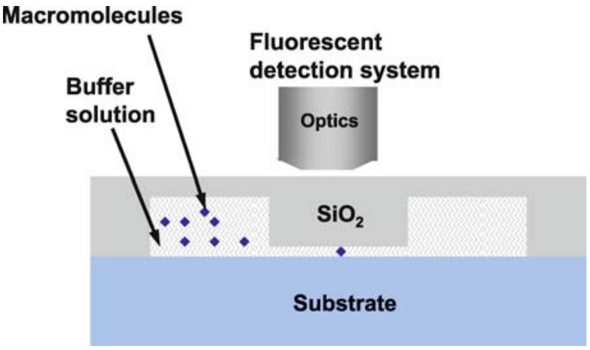
N

occurred even though the concentration of the buffer used (0.1 M) is lower than the crossover concentration in other experiments, which means a current enhancement should have been observed for a 0.1 M buffer solution, as shown in the experiment [5] using 0.1 M buffer solutions. This indicates that the complex charge interactions inside the nanochannel may not be fully reflected with the simple models developed in the literature.

The more ambitious goal of single molecule detection with nanofluidic systems is the detection of not only the presence of single molecules but also the structure, morphology and dynamics of the molecules, such as DNA sequencing or protein structure sensing. Therefore, sensing of more subtle details of the molecules than just the presence of the molecules is being actively pursued. Soon after the detection of single molecules with α-hemolysin, an attempt [6] at DNA sequencing was made by tethering an oligonucleotide inside the α-hemolysin, and single base pair mismatch between DNA strands of up to 30 nucleotides was discriminated. In fact, the idea was proposed back in 1989 by David Deamer, who conceived that the DNA sequence can be read out by passing a single stranded DNA through a nanopore with built-in sensors to detect the DNA sequence through the changing electrical pattern. Similar ideas should also be applicable to the detection of protein structures under different conditions. The rapid development of more powerful nanofluidic systems in recent years has certainly made the technique closer to the detection of the structure, morphology and dynamics of single molecules. However, many challenging problems still need to be solved by research breakthroughs. For example, the sensitivity is still not good enough to distinguish signals from different DNA bases for DNA sequencing. This is especially true considering the fact that the length of the nanopore is usually much larger than the length of each DNA base and tens or even hundreds of DNA bases may present in the nanopore. Breakthroughs in novel and more sensitive detection techniques other than simple ion current modulation and better control of the translocation of DNA molecules must be achieved before DNA sequencing can be realized. Similar challenges also exist for the detection, structural study and spectroscopy of protein molecules with nanofluidic systems.

Nanofluidic Single Molecule Detection Based on the Confinement of Nanochannels on Molecules

Nanofluidic systems could also combine with other single molecule detection techniques to provide unprecedented opportunities to achieve high resolution and acquire information that is not easily accessible in bulk solutions. Single molecule detection with scanning probe microscopy and optical microscopy has been an active research field for about three decades. Many interesting and powerful techniques have been developed to explore the structure, composition, and other properties of single molecules. To date, nanofluidic systems have been mainly combined with fluorescent single molecule detection techniques to sense the presence and properties of single molecules, as schematically shown in Fig. 2.



Nanofluidic Systems for Single Molecule Detection, Figure 2
A schematic diagram of nanofluidic systems for single molecule detection based on fluorescent microscopy. The nanochannel isolates single molecules for detection and helps to increase the signal to noise ratio

Nanofluidic systems constructed for fluorescent single molecule detection are relatively simple with nanochannels connected to microchannels at each side of the nanochannels and molecules of interest are usually introduced into the nanochannels through electrophoresis for fluorescent detection. Various kinds of nanochannel fabrication techniques such as focused ion beam milling and nanoimprint lithography have been used to fabricate the nanofluidic channels. The fabricated nanofluidic system is usually positioned on a fluorescent microscope for fluorescent single molecule detection.

The nanoscale dimension of a nanofluidic system can provide several advantages for fluorescent single molecule detection. One is the capability of nanochannels to hold tiny volumes of solutions, which can contain only one molecule for detection. Optical single molecule detection observes volumes of femtoliters so in bulk systems, pico- to nanomolar concentrations of molecules are required in order to isolate individual molecules in the volume under observation. The low concentration requires patience when introducing the molecules of interest into the detection range and limits the study of properties only to those that are not sensitive to the concentration. Nanofluidic systems allow single molecule detection in solutions of much higher concentrations since nanochannels confine the liquid from two dimensions and provide the possibility of having only one molecule in the focal

volume even in a high concentration solution. In addition, molecules in nanochannels have a slow diffusion coefficient up to 50 – 100 times smaller than that in bulk [7], which helps the molecule to reside in the focal volume for an observation of much longer time.

Single molecule detection in nanofluidic systems also provides the possibility of achieving detection with higher resolution. Nanofluidic systems can help to reduce the background noise from other molecules and impurities in the solution to achieve higher signal-to-noise ratio. The fluorescent signal of a single molecule is independent of the detection volume, while the noise in the detection generated from impurities of the sample, Rayleigh straylight and Raman scattering scales linearly with the size of detection volume. Therefore, single molecule detection in nanoscale channels, which contain a tiny volume of the solution, can help to achieve a high signal-to-noise ratio.

Nanofluidic systems are also ideally suitable for certain single molecule detection techniques such as total internal reflection fluorescence (TIRF) microscopy. TIRF utilizes evanescent waves, which are generated by total internal reflection of a laser beam, to excite the fluorescence signal, and since evanescent waves decay exponentially, the molecule of interest must locate to the close proximity of the interface of the glass and liquid. Nanofluidic systems confine molecules of interest in nanochannels, which is well in the evanescent field of TIRF microscopy.

Another advantage of nanofluidic systems for single molecule detection is due to the fact that the small dimension of nanochannels can force DNA molecules to stretch, enabling analysis that is not possible for DNA molecules in a random coil configuration in a free solution. For example, through fluorescent molecule detection, the lengths of single DNA molecules in different size nanochannels have been measured [8], which helps to infer the statics and dynamics of DNA molecules in highly confined nanoenvironments. Investigation of protein–DNA interactions can also benefit from the nano-confinement provided in nanofluidic systems. For example, the numbers of proteins bound to DNA molecules have been counted by introducing DNA molecules into nanochannels [9], which stretch the DNA molecules and allow the count of the number of proteins bound to the DNA molecules. It is difficult to do this in bulk solutions since the random coil configuration of DNA molecules will prevent the count of proteins attached to a DNA molecule. The above mentioned advantages are just some that have been recognized in the past. More advantages of nanofluidic systems for single molecule detection may be found in the near future since using nanofluidic systems for single molecule detection is attracting more attention as advanced nanofabrication techniques are making nanofluidic systems more readily available.

Given all the advantages of using nanofluidic systems to confine single molecules for further detection and investigation, it is worth noting that this comes with the efforts of fabricating nanofluidic systems. Nanochannel fabrication usually requires advanced solid-state fabrication techniques in a cleanroom, which can be expensive if the required nanofluidic systems contain nanochannels of tens of nanometers or even smaller in all cross-section dimensions. In addition, the fundamental physics of fluid flow in nanochannels of around ten nanometers or even smaller in diameter is still not fully understood, which may add more complexity to the study of single molecules in nanochannels.

Key Research Findings

Using α-hemolysin embedded in lipid bilayer to sense single DNA molecules was reported by Kasianowicz et al. in 1996 [1]. Later, sequence-specific DNA molecule detection was demonstrated with an individual oligonucleotide tethered inside the α-hemolysin [6], in which single base pair mismatch between DNA strands of up to 30 nucleotides was discriminated.

Single DNA molecule detection with nanofabricated inorganic SiN_x nanopores was first demonstrated by Li et al. [2] and the ion current blockade resulting from DNA molecule translocation through nanopores was demonstrated. Chang et al. [5] later observed ion current enhancement induced by DNA molecules through a SiO_2 nanopore in 0.1 M buffer solutions, which indicates that complex charge interactions can happen inside nanochannels.

Single DNA molecule detection with long nanochannels was first demonstrated by Saleh and Sohn [3] with a PDMS nanochannel of 200 nm in diameter. They observed current blockade in 0.1 M buffer solutions. Later, Fan et al. [4] first reported the crossover of ion current modulation from current enhancement in low-concentration solutions to current blockade in high-concentration solutions.

Lyon and Nie [7] confined single molecules in a pulled silica capillary of submicrometer dimension (500 – 600 nm inner diameter) and detected single molecules with a confocal fluorescence microscope. They found that the diffusion of molecules in the silica capillary was much slower than that in bulk solution, allowing 50 – 100 times longer observation period. Foquet et al. [10] reported a nanofluidic system made by microfabrication for fluorescent single molecule detection in 2004 and demonstrated that nanochannels could be used to isolate a single molecule for fluorescent detection. Tegenfeldt et al. [8] measured the

lengths of genomic-length DNA molecules in nanochannel arrays and examined the dynamics of DNA molecules in confined nanochannels. Later, Wang et al. [9] counted the number of proteins bound to DNA molecules by stretching DNA molecules in nanochannels. The low occupancy level they found indicates that the proteins on the DNA may have some long-range interactions.

Future Directions for Research

Nanofluidic systems were developed only recently and their potentials for single molecule detection have not been fully explored. Single molecule detection based on the comparable size of nanochannels and molecules has been very successful in sensing the presence of single molecules. However, using this technique to acquire more information of the molecules, such as the sequence of DNA molecules and the structure and morphology of protein molecules, is still at very early stage. So investigation is urgently needed to further develop this technique, enabling acquisition of information beyond the presence of single molecules.

Nanofluidic systems made for fluorescent single molecule detection have shown several advantages such as isolating single molecules for detection and manipulating single molecules to detect desirable information. The research is still in the early stage and the potential of using nanofluidic systems to manipulate single molecules to extract useful information is still far from being fully explored. Therefore, it is time to perform research to design novel nanofluidic systems to manipulate single molecules and obtain information beyond the presence of single molecules.

For both detection approaches, it is of great interest to study the complex interactions between the molecules of interest and the nano-environment. The high surface area to volume ratio in nanochannels can change the behavior of molecules significantly from that in bulk solutions. The complex interactions between the molecules of interest and the ions and surface charges are still not fully understood yet. These effects must be clarified before extensive applications of nanofluidic systems for single molecule detection.

Aggregation of nanoparticles; Assembly of nanoparticles into controlled nanostructures

Definition

Nanoparticle controllable assembly refers to the assembly of nanoparticles into controlled nanostructures (wires, rods, belts, rings, tubes, thin films, superlattices, and sophisticated 3D nanostructures) via interactions like electrostatic interaction, covalent-interaction, metal–ligand interaction, etc.

Overview

Nanoparticle (NP) controllable assemblies are of considerable interest for both fundamental research and applications, since they provide direct bridges between nanometer-scale objects and the macroscale world. Generally speaking, nanoparticle (NP) controllable assemblies can be classified into three categories: one-dimensional (1D), two-dimensional (2D) and three-dimensional (3D) NP assemblies. These controllable assemblies are likely to play critical roles in the improvement of the efficiencies of various electronic, optoelectronic, magnetic, and other devices, and also nanostructure based micro-nano fluidic systems.

In this context, we present a systemic review of current research on NP controllable assemblies. Their basic methodologies are classified and key research findings of novel characteristics of NP assemblies, such as novel properties in electronics, optics, magnetics, etc., are elucidated. Problems and promise of NP controllable assembly are also indicated.

Basic Methodology

One-Dimensional Assemblies of Nanoparticles

1D assemblies of nanoparticles refers to the controlled assembly of nanoparticles into wires, rods, belts, rings and tubes, which have become the focus of intensive research owing to their unique application in mesoscopic physics and fabrication of nanoscale devices. The basic method for 1D assemblies can be divided into template-directed method and template-free method which will be introduced in the following text.

Template-Directed Methods

Template-directed synthesis represents a straightforward route to 1D NP assemblies. In this approach, the template simply serves as a scaffold with (or around) which a different material is generated in situ and shaped into a nanostructure with its morphology complementary to that of the template. A wealth of templates including organic polyelectrolytes and biomolecules (so-called *soft templates*), inorganic wires and tubes (so-called *hard templates*), pores, and step edges, have been employed successfully to produce 1D NP assemblies. It is generally accepted that template-directed synthesis provides a simple, high-throughput, and cost-effective procedure that also allows the complex topology present on the surfaces of a template to be duplicated in a single step. Here we review the results for 1D NP assemblies using the most common linear templates.

Polyelectrolytes Linear polyelectrolytes in solution can provide a scaffold for the adsorption of metal ions with opposite charges. Thereafter, the ion-absorbed polyelectrolyte templates can transform to 1D metal or semiconductor-NP assemblies either by a reduction reaction or by chemical combination of ion pairs. Minko and co-workers explored this strategy to prepare 1D Pd NP assemblies. Colfen and co-workers adopted double-hydrophilic block copolymers (DHBCs) with more complex structures, in which one hydrophilic block interacted strongly with appropriate inorganic materials and the other hydrophilic block mainly promoted solubility in water, to synthesize 1D NP assemblies of materials such as $CaCO_3$, $CdWO_4$.

Biomolecules Biomolecules, including DNA, proteins, and microorganisms, are superior templates for the synthesis of 1D NP assemblies. Among biotemplates, DNA is probably the most frequently used molecule owing to its strong electrostatic and coordation interactions with NPs. Different kinds of NPs, such as Ag, Pd, Au, and Pt have been organized using this technique. Taking advantage of electrostatic interactions between metal or semiconductor NPs with DNA, 3 nm wide chains from CdS have been prepared while ribbon-like and even branched Au NP assemblies could also be prepared on DNA templates. Well-defined silver nanorings (100 nm in diameter) dispersed in water, have been simply synthesized based on the use of dilute solutions of DNA condensates as nanostructured templates.

Besides DNA, linear fibrous biomacromolecules like fibrin, dextran, and collagen are excellent candidates for producing 1D NP arrays. Double helical arrays by assembling Au and Pd NP on peptide nanofibrils under different PH conditions were obtained. Using dextran as a template a variety of metal and metal–oxide NP chains have been synthesized. TiO_2 and SnO_2 NPs can self-assemble onto linear collagen peptides to form 1D aggregares.

N

Linear microorganisms have also been employed. Dujardin et al. and Mann and co-workers used the tobacco mosaic virus, which has the shape of a linear tube, for assembly of various kinds of NPs inside and outside the tubes. Belcher and co-workers utilized bacteriophage to obtain oriented CdS, ZnS, CoPt, and FePt nanowires (NWs). Au and Ag NWs were also obtained by depositing Au and Ag solutions onto the surface of the yeast *Saccharomyces cerevisiae*.

Bacteria can form minerals intra-, inter- and extracellularly, nanoparticles formed in the bacteria cell can be assembled by manipulating the bacteria. External fields can be utilized to direct the assembly of the particles. Chains and rings from magnetic particles formed by controlling motion of the magnetotactic bacteria (MS-1) in external magnetic field, using microelectromagnets. Cellular membranes of the bacteria were removed by cell lysis, leaving the assemblies of magnetic nanocrystals.

Inorganic Nanowires and Nanotubes Carbon nanotubes (CNTs) and inorganic nanowires (NWs) are probably the most logical nanostructures to use as structure-directing matrices for the preparation of 1D NP assemblies.

Both the inner cavities and outer surfaces of hollow CNTs can serve as templates for 1D NP assemblies. Almost a decade ago, Ajayan, and Iijima reported encapsulating 1D Pd NP arrays in CNTs made via capillary induced filling. Afterwards, various types of 1D metal and metal–oxide NP arrays were prepared inside CNT cavities, and an appropriate review can be found in the publication of Ugarte et al. [1]. In general, the preparation methods can be classified into three types: the first is direct chemical or physical vapor deposition of metal or semiconductor NPs onto the surfaces of the CNTs and NWs, the second is sol-gel decoration of metal complexes onto the surfaces of CNTs and NWs and the last one is the modification of the surface properties of CNTs and NWs followed by specific adsorption of NPs. Using the above strategies, many 1D arrays of varying types of metal and semiconductor NPs such as Au, Ag, Pt, SnO_2, TiO_2, have been formed.

Other Templates Linear pores and channels inside polymers, alumina, and silica templates are also used to make linear agglomerates of NPs.

Template-Free Self-Assembly Methods

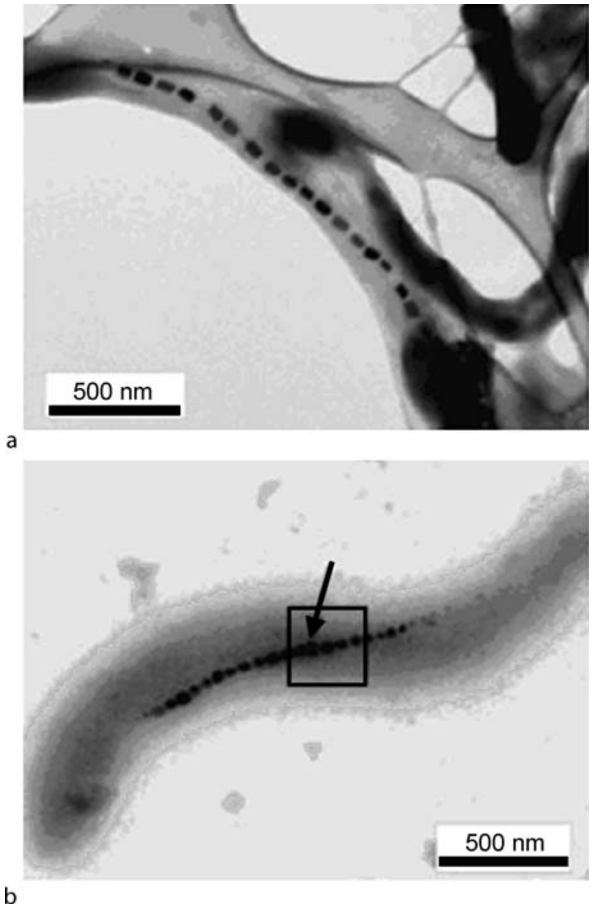
Template methods for the preparation of 1D NP assemblies have several intrinsic disadvantages. For instance, linear templates may have a considerable effect on both the photonic and electronic properties of the resulting 1D NP assemblies. Although post-synthetic physical or chemical treatment can help remove the templates, it is possible that they also cause morphological and structural alterations to the NP chains, which are detrimental to their application. There has been a growing realization in the research community that templates may not at all be necessary for the formation of 1D NP structures because, under certain conditions, they may self-assemble due to the inherent anisotropy of NP–NP interactions. Self-assembly has been extensively explored as a bottom-up approach for generating complex nanostructures on various scales. In particular, monodispersed colloids have been pursued as building blocks for the formation of wire-like structures through self- or externally manipulated assembly.

Magnetic Dipole Moments Chain formation and anisotropy of magnetic NPs have been well-known in nature for a long time. For instance, an anisotropic chain-like structure of maghemite NPs has been observed in terrestrial magnetotactic bacteria as shown in Fig. 1. These chain structures within the bacterium, which give rise to the formation of permanent magnetic dipoles, act as a critical orientation system. Moreover, a similar biomineralization process also occurs in the human brain, which might provide a theory for the mechanism of interaction of environmental magnetic fields with the human central nervous system. For references on the preparation of 1D NP chains by utilizing magnetic moments, one may refer to the review of Prof. M. P. Pileni [2].

Electric-Dipole Moments Electric-dipole moments are prevalent in semiconductor NPs due to either the presence of an anisotropic crystal lattice or surface defects. However, strong electrostatic or steric repulsion from stabilizers overcompensates electric-dipole attractions between NPs. Semiconductor NPs, silver and gold NPs were discovered to spontaneously form 1D chains. However, the origin of the dipole interaction and the driving forces of chain formation in metallic colloids remain unknown.

Oriented Aggregation The crystallographically specific orientation among primary nanocrystals also results in the formation of self-assembled NP chains, which was first explored by Banfield and co-workers. Some concrete examples can be referred to the review on oriented aggragation of NPs [3].

Langmuir–Blodgett Assembly The Langmuir–Blodgett (LB) technique has been used to assemble 1D nanoscale building scale. Various superstructures can be obtained as a result of different interactions between the

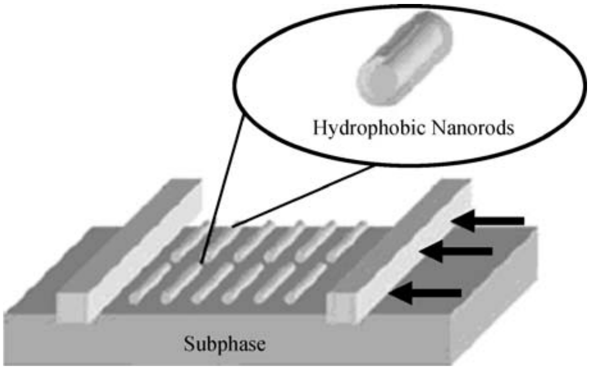


Nano-Particle Controllable Assembly, Figure 1 TEM images of the (**a**) MV-1 strain, and (**b**) MS-1 strain of terrestrial magnetotactic bacteria. Reproduced with permission from [11]

individual nanostructures and different surface pressure applied.

Previously, Langmuir–Blodgett films of various nanoparticles such as Ag, Au, and CdS have been prepared. Typically, the surface of the nanocrystals are functionalized by organic molecules (usually long alkyl chains) in order to prevent particle aggregation and also to ensure the nanoparticles float on the subphase surface (usually water). The nanoparticles are dispersed in organic solvents such as toluene, and this solution is spread dropwise onto the subphase surface. The nanoparticles form a monolayer on the water–air interface, which is slowly compressed. This monolayer can be transferred during the compression process using either horizontal or vertical liftoff to substrates such as transmission electron microscopy (TEM) grids or silicon wafers in order to be inspected with electron and optical microscopy.

Applying Langmuir–Blodgett technique, the assembly of one-dimensional nanostructures such as nanorods and



Nano-Particle Controllable Assembly, Figure 2 Schematic illustration of the Langmuir–Blodgett apparatus for nanorod assembly. Nanorods are generally rendered hydrophobic through surface functionalization. Reproduced with permission from [12]

nanowires have been synthesized successfully. These 1D nanostructures are rendered hydrophobic by surfactant surface functionalization before the LB experiments. Figure 2 schematically shows the experimental apparatus.

2D and 3D Assemblies of Nanoparticles

2D and 3D assemblies have been made by using a large variety of techniques, such as template-directed assembly, solvent evaporation, Langmuir–Blodgett (LB) transfer, producing self-assembled monolayers and multilayers, and layer-by layer assembly, etc.

Template-Directed Assembly

Template-directed assembly refers to the use of some templates (including synthetic templates and natural templates) to assembly preformed nanoparticle building blocks, forming sophisticated and complex architectures. Various methods are used including sol–gel, chemical vapor deposition, chemical vapor infiltration, atomic layer deposition, dip-coating, evaporation and deposition, LBL, sonochemical assembly and biological-assisted assembly.

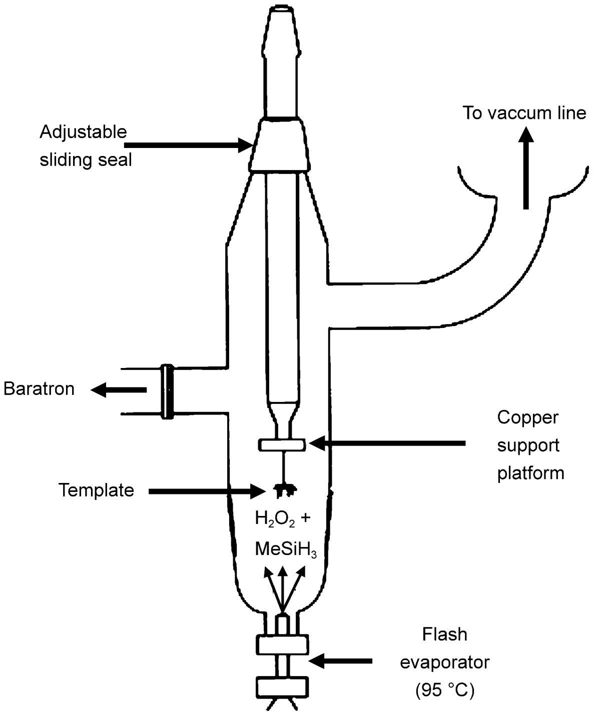
Sol–Gel The sol–gel process involves the transition of a system from a liquid (the colloidal *sol*) into a solid (the *gel*) phase. The sol is made of solid particles of a diameter of few hundred nm, usually inorganic metal salts, suspended in a liquid phase. In a typical sol–gel process, the precursor is subjected to a series of hydrolysis and polymerization reactions to form a colloidal suspension, then the particles condense in a new phase, the gel, in which a solid macromolecule is immersed in a solvent. Various materials have been synthesized applying sol–gel method

by using different templates. For example, metal oxides can be formed by oxidation of the sol containing metal in the form of metal salts, metal alkoxides, etc. Sulfides can be formed by introducing S (aqueous or gaseous), into a sol containing ions like Cd(II), Zn(II), Fe(II), ect. Metals can be formed by reducing metal-containing sol covering the template. Still more materials, like nitride, zeolite, phosphor are also synthesized using sol–gel.

Chemical Vapor Deposition (CVD) and Chemical Vapor Infiltration (CVI) Chemical vapor deposition (CVD) is a chemical process used to produce high-purity, high-performance solid materials. The process is often used in the semiconductor industry to produce thin films. In a typical CVD process, the wafer (substrate) is exposed to one or more volatile precursors, which react and/or decompose on the substrate surface to produce the desired deposit. Frequently, volatile byproducts are also produced, which are removed by gas flow through the reaction chamber. Microfabrication processes widely use CVD to deposit materials in various forms, including: monocrystalline, polycrystalline, amorphous, and epitaxial. These materials include: silicon, carbon fiber, carbon nanofibers, filaments, carbon nanotubes, SiO_2, silicon-germanium, tungsten, silicon carbide, silicon nitride, silicon oxynitride, titanium nitride, and various high-k dielectrics.

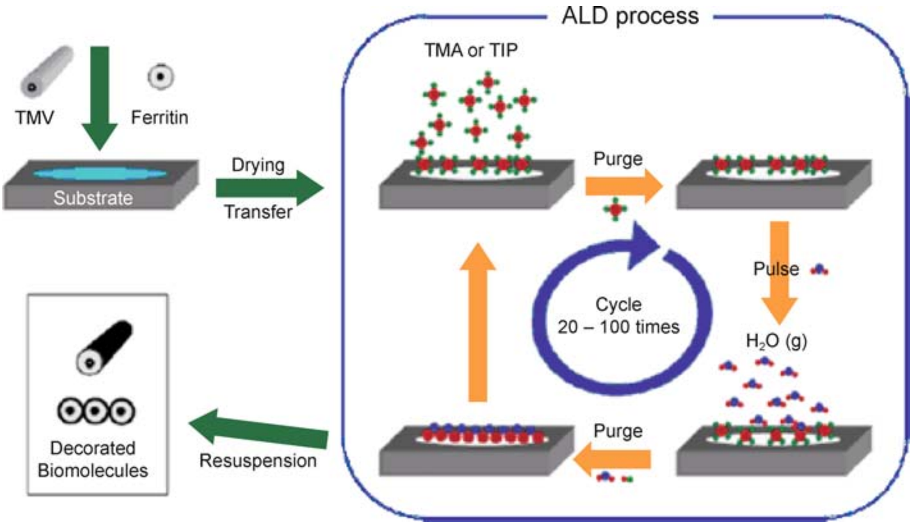
Templates with complex structures can be used to controllable assembly of nanoparticles using gaseous reactants of good flowing properties, and near net-shaping is possible. G. Cook et al. have demonstrated the controlled vapor-phase oxidation of silanes on the surface of butterfly wings, producing an exact, inorganic oxide replica of natural form. The experimental apparatus for the chemical vapor deposition of silica is shown in Fig. 3. While CVD deposits materials onto a surface, chemical vapors in CVI can penetrate porous structures and deposit materials within the "body". Most materials that can be deposited by CVD can also be deposited by CVI. Here CVI has the edge when it comes to bulky templates like wood tissues, eg. Thickness of the coatings can be controlled by the number of deposition or infiltration cycles, and there is no background deposition which commonly occurs in sol–gel. Despite the many advantages of CVD and CVI, they are relatively expensive.

Evaporation and deposition is a straightforward method to assembly nanoparticles as a thin coat by replicating surface features of templates. Evaporation and deposition can produce fine structures from bio-templates. Au microshells showing diatom frustule morphologies and complex structures at the nanoscale; continuous Au nanowires as thin as 10nm can be formed on DNA by evaporation, while those grown from solution are no thinner than 30nm due to the stochastic metal deposition in solution. Metals of various kinds can be used for evaporation and deposition as long as they are suitable for evaporation. Compound coatings can be formed by surface reactions of synthetic vapors, eg. ultra-thin and compact TiO_2 coatings formed on diatom frustules via surface reactions of volatilized $TiCl_4$ and H_2O alternatively flown onto the template surface.



Nano-Particle Controllable Assembly, Figure 3 Experimental apparatus for the chemical vapor deposition of silica. Reproduced with permission from [13]

Atomic Layer Deposition (ALD) Atomic Layer Deposition (ALD) is a self-limiting, sequential surface chemistry that deposits conformal thin-films of materials onto substrates of varying compositions. ALD is similar in chemistry to chemical vapor deposition (CVD), except that the ALD reaction breaks the CVD reaction into two half-reactions, keeping the precursor materials separate during the reaction. ALD film growth is self-limited and based on surface reactions, which makes achieving atomic scale deposition control possible. By keeping the precursors separate throughout the coating process, atomic layer control of film grown can be obtained as fine as ~ 0.1 angstroms per monolayer. ALD has unique advantages over other thin film deposition techniques, as ALD grown



Nano-Particle Controllable Assembly, Figure 4 Schematic illustration of the ALD process. Reproduced with permission from [14]

films are conformal, pin-hole free, and chemically bonded to the substrate. With ALD it is possible to deposit coatings perfectly uniform in thickness inside deep trenches, porous media and around particles. The film thickness range is usually 1 – 500 nm. ALD can be used to deposit several types of thin films, including various ceramics, from conductors to insulators.

M. Knez et al. showed the application of atomic layer deposition, a gas-phase thin film deposition process, to biological macromolecules (Tobacco Mosaic Virus and Ferritin), which are frequently used as templates in nanoscale science, and the possibility to fabricate metal oxide nanotubes and thin films with embedded biomolecules, the experimental process is shown in Fig. 4.

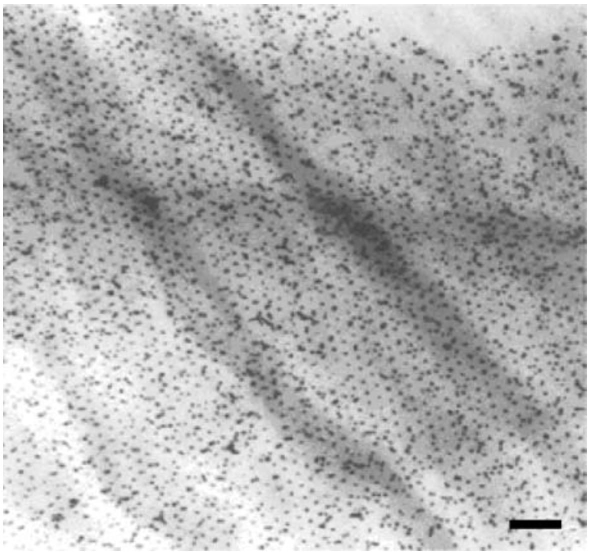
Dip-Coating Dip coating refers to the immersing of a substrate into a tank containing coating material, removing the piece from the tank, and allowing it to drain. The coated piece can then be dried by force-drying or baking. It is a popular way of creating thin film coated materials along with the spin coating procedure. The dip coating process can be, generally, separated into 3 stages:

1. Immersion: the substrate is immersed in the solution of the coating material at a constant speed preferably judder free – sometimes cheese is applied to help fluid stick to material.
2. Dwell time: the substrate remains fully immersed and motionless to allow for the coating material to apply itself to the substrate.
3. Withdrawal: the substrate is withdrawn, again at a constant speed to avoid any judders. The faster the substrate is withdrawn from the tank the thicker the coating material that will be applied to the board.

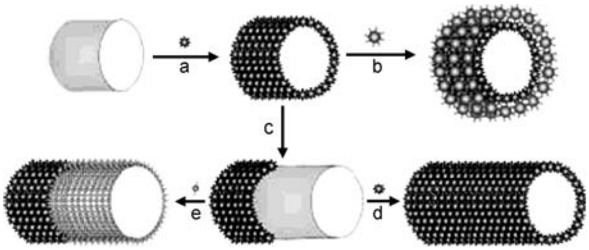
The dipping is slow and the substrate is withdrawn from the tank at a uniform velocity to obtain a uniform coating. In template-directed synthesis, the template is used as the substrate, e. g. hollow mesoporous silica fibers with hierarchical order were fabricated by dip-coating a single strand of spider silk in liquid crystalline silica-surfactant mesophase. A high degree of alignment of the mesochannels was observed, which was created along the fiber due to the shear flow along the silk direction when dip-coated under gravity.

Biological-Assisted Assembly The aggregation of NPs induced by specific biological interactions has attracted huge interest in the assembly of nanoscale components into controlled and sophisticated nanostructures. Biological systems possess inherent functional groups with material specificity or polarity, which greatly facilitate assembly onto these templates. Biomolecules, bacteria, fungus, virus, diatom, etc. are widely used as templates to assemble NPs into controlled nanostructures. Interactions like electrostatic interaction, metal–ligand interaction, streptavidin-biotin (antigen–antibody) interaction, DNA-intercalator interaction, etc. are utilized.

For example, two-dimensional iron-oxide nanoparticle array can be prepared using ordered ferritin molecules as the template. Au and CdSe – ZnS quantum dots can assemble into ordered arrays using a chaperonin protein template, which was modified with thiol groups to bind the nanoparticles via metal–ligand interactions. Au nano-



Nano-Particle Controllable Assembly, Figure 5 TEM image showing S-layer templated periodic array of 5 nm sized gold nanoparticles. Scale bar is 100 nm. Reproduced with permission from [15]



Nano-Particle Controllable Assembly, Figure 6 Schematic illustration of the use of a living hypha of a filamentous fungus as the template for the assembly of oligonucleotide-funtionalized Au nanoparticles into ordered microscopic structures. (**a**) As the living fungal hypha grows, the Au nanoparticles (functionalized with single-stranded DNA) bind to its cell walls and a microscopic tube-shaped nanoparticle assembly is formed. (**b**) Additional layers of nanoparticles functionalized with complementary oligonucleotide strands can be assembled onto the surface of the microscopic nanoparticle tube through DNA hybridization. (**c**) The fungal hypha will continue to grow in a favorable environment and generate unmodified hyphae ends. (**d**) and (**e**) These fresh ends can be modified with new particles, thus providing control of the architecture along the growth axis. Reproduced with permission from [16]

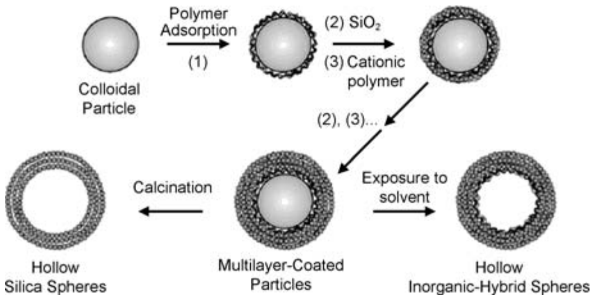
clusters can be formed using IgGs (immuno-globulin Gs) aggregates as the template.

Viruses are similar to biomolecular templates because the viral capsid is in fact a complex composed of protein subunits. Viruses coupled with nanoparticles can be used as building blocks to form nanoparticle assemblies, or virus assemblies of two- and three-dimension can be used as templates. Virus is advantageous as a building block because identical viruses can be produced in large amounts at low cost, and nanoparticles templated by viruses generally have a high monodispersity. Viruses may have inherent self-assembly, for example, nanowires mineralized using TMV templates are often found to be longer than individual TMV particle, indicating a higher-order assembly of the TMV particles. It is a reversible head-to-tail assembly of TMV, attributable to the complementary hydrophobic interactions between the dipolar ends of the helical structure, and the trend of the head-to-tail assembly may be favored in acidic environments.

Self-assembled 2D crystals of a bacterial surface layer protein (S-layer) were used to fabricate highly ordered superlattice arrays of gold nanoparticles by deposition from pre-formed colloids [4]. The S-layer template consisted of hexameric units arranged in a periodic (P6) hexagonal structure with lattice constant, 18 nm. Each hexamer was in the form of a hollow cone with a 2 nm wide positively charged central channel, and this site-specific surface periodicity was used to control the periodic assembly of negatively charged gold nanoparticles by electrostatic binding as shown in Fig. 5. Besides 2D nanostructures, bacteria can also used as templates for the assembly of nanoparticles into 3D nanostructures. For example, preformed ceramic (SiO_2), magnetic (Fe_3O_4), and semiconducting (CdS) inorganic nanoparticles were incorporated into macroscopic threads of *Bacillus subtilis* by reversible swelling of the superstructure in colloidal sols [5].

Nanoparticle assembly on living fungi can lead to structures of interesting forms. Z. Li et al. used the living hypha of a filamentous fungus, *Asprgillus niger*, for Au nanoparticle assembly. The schematic illustration is shown in Fig. 6. The Au particles are modified with oligonucleotides which bind to the hypha surface. As the hypha keep growing, the fresh uncovered ends continue to bind Au particles, forming a continuous Au coating. Nanoparticles (not necessarily Au) modified with complementary-oligonucleotides can be assembled onto the first layer of particles via DNA complementary coupling, thus multilayered coatings can be formed.

Layer-by-Layer (LBL) Assembly LBL assembly, largely developed by Decher, Lvov, and Mohwald in the 1990s, is a popular technique for the fabrication of organized, multilayer organic–inorganic films based on the alternating adsorption of oppositely charged materials as shown in Fig. 7. LbL assembly, which was initially based on alternating electrostatic absorption, has successfully been extended to encompass different kinds of driving forces, such as hydrogen bonding, covalent bonding, and other weak intermolecular interactions. It is now widely



Nano-Particle Controllable Assembly, Figure 7 Illustration of procedures for preparing hollow inorganic silica and inorganic-hybrid spheres through colloid-templated electrostatic LBL assembly of silica NP polymer multilayers, followed by the removal of the templating core and, optionally, the polymer. Reproduced with permission from [17]

accepted that LbL assembly can be a powerful approach for assembling functional building blocks into ultrathin films with controlled internal organization, thickness, and molecular structure on planar solid substrates.

LBL assembly also been extended to construct freestanding nanostructures by controllable assembling nanoparticles. Freely suspended flexible LbL structures with different shapes, compositions, and properties can be fabricated by using sacrificial substrates (planar, spherical, and cylindrical). Depending upon the fabrication procedure, freestanding LbL microcapsules, microtubules, microcubes, microcantilevers, and planar films can be obtained as shown in Fig. 8.

These structures can be classified into three broad groups according to the media surrounding them:

- LbL structures in air,
- LbL structures at the air/liquid interface, and
- LbL structures at the liquid/liquid interface.

Since the first report by Möhwald and co-workers in 1998, the fabrication of LbL microcapsules has become one of the hottest areas in this field. LbL assembly, nanocapsules, nanoreactors, responsive films and capsules, biomimetic microcapsules, the mechanical properties of the microcapsules, and the permeability of these capsules are also hot research areas.

Sonochemical Assembly Sonochemistry is emerging as a promising approach for the controllable assembly of nanoparticles due to the application of powerful ultrasound radiation ($20\,\text{kHz} - 10\,\text{MHz}$) which can break chemical bonds. The chemical effects of ultrasound arise from acoustic cavitation: the formation, growth, and implosive collapse of bubbles in liquid. The implosive collapse of the bubble generates localized hot spots through adiabatic compression or shock wave formation within the gas phase of the collapsing bubble. The conditions formed in these hot spots have been experimentally determined, with transient temperatures of 5000 K, pressures of 1800 atm, and cooling rates in excess of $1010\,\text{K/s}$. These extreme conditions attained during bubble collapse have been exploited to prepare nanoparticles of metals, metal carbides, metal oxides, and metal sulfides and to the further surface assembly of nanoparticles on the templates by forming chemical bonds or chemical interactions with the substrate and cannot be removed by washing.

A variety of templates have been used for the sonochemical assembly of nanoparticles including silica and PS spheres, wool, microorganisms etc. Controllable assembly of ZnS, CdS, CdSe, metals (Ag, Au, Pd, Pt), etc. onto silica or PS spheres have been demonstrated.

H. Zhou et al. [6] developed a novel bacteria-templated sonochemical route for the controllable assembly of ZnS nanoparticles into desired hollow nanostructures. It is based on artificial mineralization and cell disruption under ultrasound. Two shapes of bacteria cocci and bacillus were used as templates to direct the formation of corresponding ZnS hollow spheres and hollow nanotubes, respectively. The inorganic replicas retain the original morphologies of the templates faithfully. This bacteria-templated sonochemical method can be extended to the synthesis of various ZnS hollow assemblies by templating other shapes of bacterium such as vibrios, spirillum, square bacteria, etc. Meanwhile, this method is expected to be a generic means to the simple synthesis of hollow assemblies of various materials.

Template-Free Self-Assembly

Self-assembled nanocrystals have attracted an increasing interest over the last ten years. The level of research activity is growing seemingly exponentially, fueled in part by the observation of physical properties that are unique to the nanoscale domain. The first two-dimensional (2D) and three-dimensional (3D) superlattices were observed with Ag_2S and CdSe nanocrystals. Since then, various self-organized lattices of silver, gold, cobalt, and cobalt oxide have been prepared successfully. It has been demonstrated that three-dimensional superlattices of nanocrystals are often organized in a face-centered cubic (FCC) structure. In other cases, the particles pack in a hexagonal lattice. The template-free self-assembly is simple and straightforward compared with template-directed assembly. Here, we focus on the fabrication modes of self-assemblies in 2D and 3D superlattices.

Solvent Evaporation M. P. Pileni reported the solvent evaporation method for the self-assembly of nanoparticles. With silver and silver sulfide, the nanocrystals are able to self organize in 2D and 3D super lattices to form "supra"

N

crystals. The process is as follows: Immediately after the solution containing the nanocrystals is deposited on the substrate, the solvent begins to evaporate and droplets form. The Ag_2S nanocrystals themselves are fully solvated by the heptane, which prevents their assembly into dense structures. As the droplets grow and begin to merge, some of the Ag_2S nanocrystals (which are still mobile because of the thin solvent layer present on the HOPG surface) are expelled away from the merge center as shown in Fig. 9. These dressed particles form compact monolayer islands, whose density increases after all of the solvent evaporates and interdigitation of the alkyl chains on the Ag_2S nanocrystal occurs. Other particles are caught in the center of the droplet merge point. The pressure exerted on these particles by the droplet menisci is large, and while a monolayer initially forms, continued droplet coalescence engenders the formation of a 3D structure.

Field-Directed Self-Assembly By applying an external field (including electric-field, thermal-field, magnetic-field, fringing-field, etc.) during the deposition process of nanocrystals, the particles can be oriented along the direction of the applied field.

A new gas-phase integration process has been developed to assemble nanomaterials into desired areas using localized fringing fields. This process is expected to work with any material that can be charged, including organic and inorganic, metallic, semiconducting, and insulating materials.

Electric-field-directed self-assembly of higher-order structures with more than 50 layers of nanoparticles can be carried out in a rapid and highly parallel format using a CMOS electronic microarray device. Control of the current, voltage, and activation time of each of the 400-microarray electrodes allows a combinatorial approach to optimize nanoparticle binding. Under optimal conditions, nanoparticle layers form within 15 s of microelectrode activation, and the directed assembly of more than 50 alternate layers of nanoparticles is complete within an hour. The final multilayered structures are removed from the support by a relatively simple lift-off process. The electric-field process allows the parallel patterned assembly of multilayer structures using extremely low concentrations of nanoparticles and produces minimal nonspecific binding to unactivated sites. These results are significant for the development of rapid, maskless nanofabrication and hierarchical integration of biomolecular-derivatized nanocomponents into higher-order materials and devices.

By applying a magnetic field during the deposition process of nanocrystals, the easy axes of the particles are oriented along the direction of the applied field, inducing again the

collective magnetic properties. Enhancement of the SEM grid shows that these dots are organized in a well-defined hexagonal network (Fig. 10).

Langmuir–Blodgett (LB) Transfer Langmuir–Blodgett (LB) films have been investigated, extensively, over the past 70 years. In the 1930s, Irving Langmuir and Katherine Blodgett introduced a method for fabricating monolayer and multilayer arrays of surfactants. Since that time, this Langmuir–Blodgett (LB) technique has been used, extensively, to construct a wide variety of organized thin films. Typically, LB films are fabricated by dipping a solid support, vertically, through a surfactant monolayer at an air–water interface. For example, a single "down-trip" of a hydrophobic support from air into water results in the monolayer being transferred, such that the hydrocarbon tails are in intimate contact with the support and the polar head groups extend outward towards the bulk aqueous phase (Fig. 11). A subsequent "up-trip" generally deposits a second monolayer with a head-to-head orientation with the first deposited monolayer. Further dipping can then lead to multilayers of the surfactant.

In recent years, there has been a steady shift away from the LB technique towards self-assembly methods for the fabrication of monolayer and multilayer arrays (Fig. 12). In contrast to the LB method, which requires a film balance and careful control over surface pressures during dipping and transfer, self-assembly is carried out by simple immersion of a suitable support into a solution containing an excess of monomer. The formation of multilayer arrays via self-assembly has also become popular. Most commonly, a charged surface is dipped into a solution containing a polyionic species, followed by dipping into a second solution that contains a polymeric counterion. Repeti-

tion of such dipping then produces the desired material in a layer-by-layer manner.

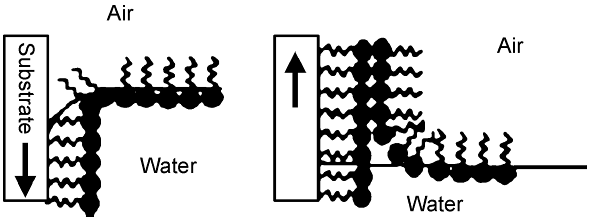
Micro Force Driven Self-assembly of nanoparticles into 2D and 3D nanostructures can also be achieved by virtue of micro forces like capillary force, dielectrophoretic force, hydrophobic force, etc.

N. Bowden et al. realized self-assembly of topologically complex, millimeter-scale objects into ordered two-dimensional arrays driven by capillary forces, with the shapes of the assembling objects and the wettability of their surfaces determining the structure of the arrays. The system was composed of solid objects floating at the interface between perfluorodecalin and water and interacting by lateral capillary forces; patterning of the wettability of the surfaces of the objects directs these forces. Self-assembly results from minimization of the interfacial free energy of the liquid–liquid interface. Calculations suggest that this strategy for self-assembly can be applied to objects on a micrometer scale.

A new class of microwires can be assembled by dielectrophoresis from suspensions of metallic nanoparticles. The wires are formed in the gaps between planar electrodes and can grow faster than 50 μm per second to lengths exceeding 5 mm. They have good ohmic conductance and automatically form electrical connections to conductive islands or particles. The thickness and the fractal dimension of the wires can be controlled, and composite wires with a metallic core surrounded by a latex shell can be assembled. The simple assembly process and their high surface-to-volume ratio make these structures promising for wet electronic and bioelectronic circuits.

Key Research Findings

In the former section we have introduced the basic methods for controllable assembly of nanoparticles systematically, some typical examples have been given as well. The preparation of NP assemblies should serve the exploration of their novel properties and applications. So, in this section we will list some key research findings focusing on their novel properties and potential applications.



Nano-Particle Controllable Assembly, Figure 11 A stylized illustration showing a single surfactant monolayer being transferred to a hydrophobic support on a down-trip, followed by the transfer of a second monolayer on the up-trip, to form a bilayer. Reproduced with permission from [20]

Indeed, 1D NP assemblies exhibit many collective properties in optics, magnetics, electronics, and so forth. For instance, 1D magnetic NP arrays showed anisotropic and collective magnetic properties. Pileni and co-workers obtained 1D chains of 8 nm Co NPs by applying a magnetic field (1 T) parallel to a highly oriented pyrolytic graphite (HOPG) substrate during the evaporation process. Magnetic measurement results demonstrated that, with respect to partially disordered NP aggregates, the reduced remnant magnetization and coercivity of the 1D Co chains increased from 0.52 and 0.13 T to 0.60 and 0.14 T, respectively. The increase of both remnant magnetization and coercivity of the 1D Co NP chains were attributed to the enhanced orientation of their magnetic moments along the direction of the applied magnetic field.

1D NP arrays have been utilized as gas sensors. Favier et al. [7] fabricated parallel 1D Pd NP arrays using the electrochemical reduction method (Fig. 13a). adsorption of H_2 gas caused a reversible expansion of the crystalline lattice of Pd. As a result, the gaps between the Pd NPs in the linear arrays decreased, thus improving electron transport along the chains (Fig. 13b). The gaps opened up again when hydrogen was vented from the sensors, and such reversible responses make 1D Pd NP arrays good prototypes of reproducible gas sensors.

2D and 3D assemblies of nanoparticles also show some novel and unique properties in optics, electronics, magnetics, etc. For instance, Recently, Z. L. Wang and coworkers [8] demonstrated the fine structure of the wing scale of a Morpho Peleides butterfly was completely replicated by a uniform Al_2O_3 coating through a low-temperature ALD process. An inverted structure was achieved by removing the butterfly wing template at high temperature, forming a polycrystalline Al_2O_3 shell structure with precisely controlled thickness. Other than the copy of the morphology of the structure, the optical property, such as the existence of PBG, was also inherited by the alumina replica. Reflection peaks at the violet/blue range were detected on both original wings and their replica, while a simple alumina coating shifted the reflection peak to longer wavelength because of the change of periodicity and refraction index. The alumina replicas also exhibited similar functional structures as waveguide and beam splitter, which may be used as the building blocks for photonic ICs with high reproducibility and lower fabrication cost compared to traditional lithography techniques. The "waveguide" properties of the alumina replicas is shown in Fig. 14.

Rod-shaped viruses can form liquid crystalline phases, which can be controlled by factors like virus suspension concentration, ionic strength of solution, external fields, etc. For example, M13 phages are found to randomly orientated in an isotropic concentration range, but transform to nematic, cholesteric, and smetic phases with increased concentrations, solid-phase films and 1D fibers can be obtained at much higher concentrations. Belcher et al. [9] utilized liquid crystal system of M13 to arranged ZnS nanocrystals into ordered domains at the nano- and micrometer scale under an external magnetic field, forming a self-supporting biological-semiconducting hybrid film. The schematic illustration of the process is shown in Fig. 15. The films were typically $\sim 15\,\mu$m thick and several centimeters in extent. Optical characterization revealed that the films were composed of $\sim 72\,\mu$m periodic dark and bright band patterns which corresponded to the chiral smectic C structure. The films showed smectic-like lamellar morphologies between the ZnS nanocrystals and M13 viral layers when imaged by SEM. A periodic length of 895 nm was observed, corresponding to the combination of virus length (860 – 880 nm) and nanocrystal aggregates (~ 20 nm). Surface morphology of the viral film exhibited zig-zag chiral smectic O patterns due to the long rod shape of the viruses conjugated to an inorganic head group composed of ZnS nanocrystals. The viral film cast on an ITO substrate showed smectic B morphologies when imaged by atomic force miscroscopy (AFM) (Fig. 16). TEM images of microtomed cross sections of the viral film revealed 2 – 3 nm nanocrystals that were aligned and were extended to more than $2\,\mu$m in length. The $2\,\mu$m bands formed in parallel were separated by ~ 700 nm, corresponding to the length scale imposed by the virus in a tilted smectic alignment. Based on the similar mechanism, other forms of assemblies can also be obtained as shown in Fig. 17.

Fibrous assemblies like nanofibers, nanopipes, nanotubes may have applications in micro/nano-fluidic systems. Vertically aligned carbon nanofibers grown by plasma-enhanced chemical vapor deposition are used as sacrificial templates for nanopipes with internal diameters as small as 30 nm and lengths up to several micrometers that are oriented perpendicular to the substrate. Such nanopipes can be implemented as functional elements in gas- and liquid-phase micro/nano-fluidic devices. The functionality of nanopipes has been demonstrated by observing fluidic transport between two fluid regions that were physically separated by a membrane containing the nanopipe pores.

(**d**) Height and (**e**) phase AFM images of a viral film cast on an ITO substrate. Inset in (**d**) illustrates the viral packing. Reproduced with permission from [23]

Several applications of nanopipes can be envisioned, including highthroughput sensing, analysis of molecular species, drug delivery systems, and fluidic interfaces to live cells.

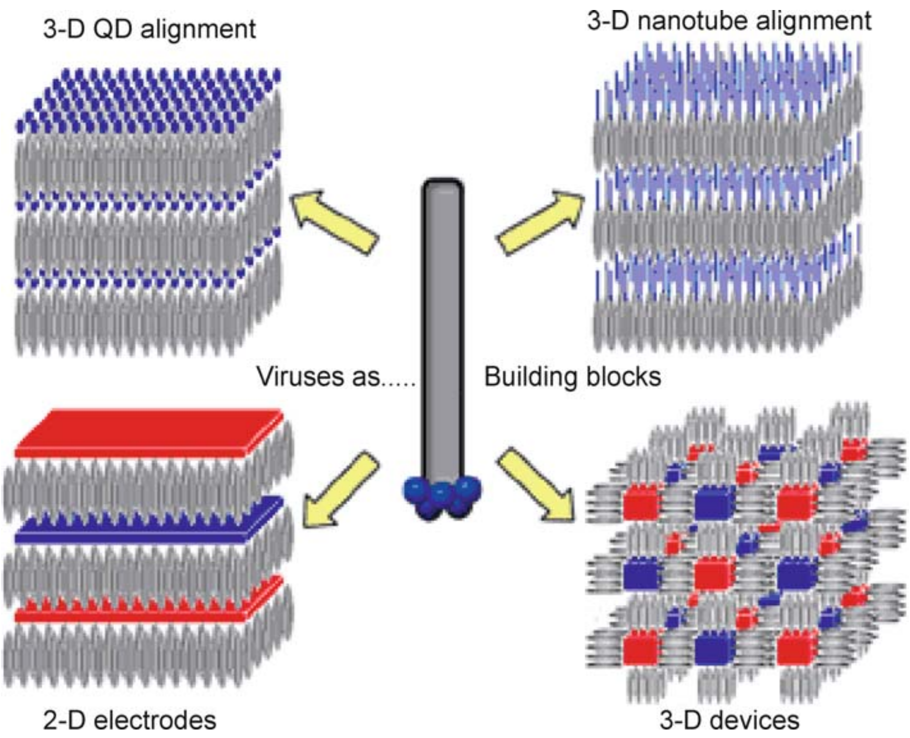
Future Directions for Research

As described in this text, significant developments have been made in nanoparticle controllable assembly during the last year. The field continues to grow internationally and contribute to new interdisciplinary areas concerned with the synthesis, properties and applications.

Although 1D NP chains are ubiquitous in nature, research into their preparation and properties are still in their early stages. There are plenty of unknown phenomena awaiting exploration and there are also many problems requiring resolution. Practical application of devices based on 1D NP requires large-scale production as well as precise positioning of 1D NP arrays. Although numerous methods have been developed to prepare 1D NP chains, attaining precise arrangement of these chains remains highly desirable. Recent research has demonstrated that 1D NP chains could be accurately positioned and assembled into complex patterns by DNA templates on solid substrates [10] which also can be utilized in the practical fabrication of NP devices. The exploration of new properties and applications of 1D NP assemblies is strongly dependent on their preparation methods. We believe that, in the future, two issues should be addressed in order to understand the properties of 1D NP chains. One important issue is to control the interparticle distances in NP chains, so that distance-dependent photonic and electronic transfer along the NP chains could be realized, which will have applications in electronic and photonic devices, telecommunications, and sensors. Another critical issue is to produce NP chains consisting of multiple components, which are of considerable interest for both the fundamental-research and application communities.

As for 2D and 3D NP assemblies, prospects for the future include the development of novel transcription methodologies, as well as the creation of new transcribable templates which present a greater degree of structural complexity or can give rise to extended, patterned architectures. One of the principal challenges remaining consists of finding novel methodologies for obtaining transcribed structures with a high degree of order at the 2D or 3D level. Particularly, biological assemblies of nanoparticles may play an important role in the preparation of NPs assemblies due to the opportunities that are opening up with regard to biological coding of the assembly process. Besides, the exploration of the relationship between the sophisticated structures and the corresponding specific functionality is highly appealing and urgent. Complex assemblies of nanoparticles by using sophisticated biological systems would probably provide great opportunities and potentials for the extensive study of the relationship between the sophisticated structures and the corresponding specific functionality. This area is still in an early phase of development and many fantastic phenomena remain unknown and awaiting exploration.

Assembling and design of nanostructures for micro- and nano-fluidics systems has led to a wide range of microchemical applications. Material properties are crucial in the fabrication, assembly, and operation of micro- and



Nano-Particle Controllable Assembly, Figure 17 Schematic diagram of various self-assemble structures using one dimensional viruses with zere dimensional quantum dots (QD), one dimensional nanowires/nanotubes, two dimensional plate-shaped devices and three dimensional components. Reproduced with permission from [24]

nanofluidic systems. Thus, development of new methods for manufacturing nanoparticles assemblies with good properties for micro and nanofluidic devices is highly important. Choice-of-material considerations range from an assessment of whether a desired channel design can be microfabricated in a certain material to whether the material is compatible with the operating conditions (i. e., pressure, temperature) and the chemical composition (solvent, solutes) of the fluid used. Moreover, in certain cases, specific surface can be used to the benefit of the application of the device. For example, these materials can be equipped with functional nanofeatures such as nanogrooved surfaces, patchy hydrophobic-hydrophilic nanopatterns, and stimuli-responsive nanocoatings. Therefore, these materials are expected to form a new economically-viable nanofluidic platform. This platform provides novel capabilities that could not be realized with the existing or improved photo-lithographically manufactured platforms.
There are almost unlimited research opportunities that are being, and will be explored by many labs around the world in this general area of NPs controllable assembly. However, one should also realize that some potential environmental and health issues might arise. In this regard, a systematical evaluation on how these nanostructures will impact our environment and health is urgently needed!

Definition

A ►nanoparticle is generally defined as a particle whose diameter is between 1 and 100 nm. No distinction is made according to the material: nanoparticles can be metals, metal compounds, organic compounds, and polymers. A ►composite nanoparticle is a nanoparticle which has a composite structure, including core-shell structure, onion-like structure, or gladiate composition.

Overview

Nanoparticle Properties and Applications

►Nanoparticles are generally defined as particles with diameters ranging from 1 to 100 nm. Recently, synthesis methods for nanoparticles have been rapidly developed. Nanoparticles are expected to find applications in various fields, i. e., biology, electronics, optics, informatics, and environmental engineering, as tags for biomolecules, quantum transistors, LEDs, super mass storage media, and

electrodes for wet-type solar cells [1]. Nanoparticles often exhibit unique properties, such as superparamagnetism in magnetic particles, surface plasmon shift in metallic particles, and quantum size effects in semiconductor particles. In particular, the quantum size effect for *semiconductor nanoparticles* with a particle radius of less than the Bohr radius (in most cases, less than 5 nm), contributes to the ability to control their band gap energy, and this is expected to be relevant for many of the unique applications listed above.

Most of the features listed above are affected by particle size. Therefore, in many cases, it is necessary to control a homogeneous particle size to fully utilize particles' unique and pre-eminent properties. Moreover, tuning particle size often enables tuning of particle properties. Some efforts have been made to classify nanoparticles of wide particle size distribution; however, it is still difficult to achieve high efficiency together with high yield. Furthermore, other properties such as shape and crystallinity can often affect nanoparticle properties and direct control of these properties is also required. Therefore, much effort has been made to control these nanoparticle properties.

As will be described in the following sections, property (size and size distribution, morphology, crystallinity, and so on) control implies precise process control, i. e., control of reaction conditions. Here, a microreactor is a useful tool that can control reaction conditions flexibly and accurately. Furthermore, a microreactor can be an easy setup on-line reaction analyzer, in particular allowing in situ observation of article properties, for example optical spectroscopy.

This article introduces some applications of microreactors for nanoparticle preparation and growth analysis.

Nanoparticle Synthesis Method

The methodology of particle synthesis can be categorized into three phases: gas-, liquid-, and solid-phase methods. In order to control the properties of nanoparticles, it is necessary to precisely control the synthesis process. The *colloidal process*, in which solvents and surfactants are of great help in preventing particle aggregation and deposition on the wall, is the most reported for nanoparticle synthesis in a microreactor. This method is also one of the most utilized methods for nanoparticle synthesis that allows control of particle size, shape, and even crystal structure and crystallinity by controlling particle ► nucleation and growth.

Generally, particle size control by the colloidal method requires nucleation and growth control. Furthermore, aggregation control is also important. Nucleation is considered to be affected by the free energies of nuclei (affected by properties of nuclei, such as size, structure, morphology, chemical bonding strength, surface properties, etc.), and nucleation kinetics (which is also affected by attachment and collision frequency of reaction species, dissolution rate of embryos (clusters), etc.). However, in the current state of understanding, the mechanism of nucleation is still in a "black box" and is hardly well controlled.

Even so, there is a classic but still often utilized model that explains nucleation with a balance between surface free energy and volume free energy. When a small particle is generated from solution, its total free energy change (ΔG) can be expressed as the sum of surface free energy change (ΔG_s) and volume free energy change (ΔGv):

$$\Delta G = \Delta G_s + \Delta G_v = 4\pi r^2 \gamma + \frac{4}{3}\pi r^3 \Delta g_v \qquad (1)$$

Here, r is the particle radius, γ is the surface energy of particles, and Δg_v is specific volume energy change. From this formula, it can be understood that the solubility of nuclei depends on particle size and they cannot exist stably in a solution when their size is less than the critical size, whereas they are stable when their size exceeds it. The particles of critical size are generally called critical nuclei. Nucleation rate (J) can be determined by saturation ratio as shown in the following formula:

$$J = J_0 \exp\left[-16\gamma^3 {V_s}^2 / 3k^3 T^3 (\ln S)^2\right] \qquad (2)$$

where J_0 is the nucleation constant, γ is the surface energy, V_s is the volume of a monomer (precursor), k is the Boltzmann constant, T is absolute temperature, and S is the degree of supersaturation, i. e., $(C - C_s)/C_s$ (where C is the concentration of monomer and C_s the saturating concentration of monomer).

Particle growth is more studied than nucleation and some growth kinetic models such as the surface reaction-limited model, diffusion-limited model, and Ostwald ripening model have been proposed, and their growth kinetics can often be well explained solely or by a combination of some kinetic models. Shape and size distribution of the particles are often influenced by kinetics. For example, diffusion-limited growth kinetics gives a larger growth rate for smaller particles and can reduce the coefficient of variation (CV) of particle size distribution while particles are growing (when diffusion layer thickness $> 2D$ (where D is particle diameter)). In contrast, Ostwald ripening usually increases the CV of *monodispersed* particles because smaller particles dissolve while larger particles grow.

Various processes are proposed for particle synthesis. Among them, for nanoparticle synthesis by the colloidal process, the nucleation-growth process (where one nuclei of particle grows into one particle), aggregation growth process, and confined growth process (e. g., particle growth in microemulsions) are often taken. The aggregation growth model is a rather new model proposed by Zukoski which explains the growth of monodispersed particles by a sol–gel method (such as SiO_2 and TiO_2), by balance of aggregation and repulsion of large and small particles. In the aggregation growth model, monodispersed particles can be obtained under diffusion-limited growth by attachment of small particles to a large particle. In this case, surface properties of small particles largely affect the growth kinetics. In addition, controlled aggregation gives anisotropic shaped particles similar to those reported for ZnO nano-rods. The confined space growth process has a rather long history. This process makes particles in a confined space such as a microemulsion. In this case, the collision frequency, stability, and shape of the emulsions affect the particle size distribution and shapes.

For the nucleation-growth model, narrow particle size distribution cannot be obtained solely by growth kinetics control: nucleation timing control is also very important. An ideal model for monodispersed particles using this process was proposed in the 1950s known as the La Mer model (shown schematically in Fig. 1). Under an assumption that particle aggregation can be ignored, shorter nucleation time can reduce fluctuation of particle growth duration, and thus reduce particle size distribution. In this case, during growth, it is very important to control the monomer concentration at a level not exceeding the critical nucleation concentration. On the other hand, under the same reaction yield, a larger number of particles can produce smaller particle size. Therefore, following this model, a rapid increase in the concentration of the nucleation stage is necessary to obtain a larger number of nuclei as can be deduced from Eq. (2). Considering this, in order to obtain monodispersed nanoparticles (especially of small size) a rapid and precise chemical reaction control is required, in addition to prevention of particle aggregation. As a matter of fact, despite the reported large number of nanoparticle syntheses, many of them set the solution volume to a few tens of milliliters. This is because a larger solution volume makes it more difficult to uniformly control the reaction condition (Fig. 2). Even though the La Mer model has been considered as "ideal" for monodispersed particle synthesis, only a few materials including silver halide were said to follow this model for microparticles. Recently, however, fairly stable nanoparticles are reported to follow this model. In addition to efficient surfactant employment, possibly the high

numeric concentration of particles was helpful in preventing free particle generation (second nucleation) during the reaction.

As such, for nanoparticle preparation, homogeneous and precise control of reaction conditions are important to obtain well-defined nanoparticles with controlled properties. To achieve this, appropriate choice of reaction process is important as well as appropriate choice of reaction systems including solvents and capping agents.

Nanoparticle Synthesis Using a Microreactor

The small channel size of a microreactor is of particular advantage for ►reaction condition control. The high sur-

face/volume ratio and small heat capacity of a microchannel can make rapid control of temperature possible in order to control the reaction. For example, a thermo-conductive simulation showed that 0.3 s was enough to raise the solution temperature from 20 to 300 °C, when the reactor was placed in a 300 °C heating media [2]. Additionally, another important unit operation, mixing, is also reported to be enhanced by a properly designed micromixer because the fine flow pattern control makes it possible to reduce the mutual diffusion length of the flows to be mixed rapidly. These rapid and prompt controls of the reaction can lead to the control of nucleation and growth kinetics in nanoparticle preparation as shown in the following.

Basic Methodology

Nanoparticle Synthesis Method Using a Microreactor

As mentioned above, microreactors are expected as small-size industrial reactors for nanoparticle synthesis. A number of reports on nanoparticle synthesis in a microreactor have been published following the reports of De Mello's group and Maeda's group in 2002. Among them, the most dominant and currently being employed in nanoparticle synthesis using a microreactor is the nucleation-growth model. Therefore, this section mainly focuses on this process.

Nanoparticle synthesis by a colloidal process has four steps which include nucleation, growth, ripening, and aggregation. To control the properties of particles, a precise control of these four processes is necessary. The nucleation process is often triggered by mixing raw material solution and precipitant, or by heating the mixed solution especially when the room temperature reaction rate is negligible. To control the nucleation state by this method it is necessary to control concentration and temperature of reactants within a short period of time (i. e., sufficiently shorter than nucleation time), preferably in a controlled fashion. However, nanoparticles of high crystallinity often require high temperature [1] where reaction rate is high. Therefore, for most batch reactions, scaling up makes control of the process difficult, because fluctuations easily arise due to high reaction rate. To effectively utilize this model, high reaction controllability is required which in turn can be provided by microreactors.

Taking into account the above discussions, several groups, including us, have studied nanoparticle synthesis in a microreactor, and the following three methods were reported in 2002 (Fig. 3a–c):

(a) Mixing-triggered reaction by applying rapid mixing provided by a micromixer [3].
(b) Interface reaction between two liquid phases that were stably generated in a microchannel [4].
(c) Temperature-triggered reaction by applying rapid heating in a microchannel [5].

Method (a) was reported by Edel et al. They rapidly mixed aqueous solutions of Na_2S and $Cd(NO_3)_2$ by a micromixer to obtain CdS nanoparticles, and showed that CdS nanoparticles with a similar quality to that of a batch reaction could be continuously produced. They also showed that the particle size distribution got wider when the flow rate was low, because of poor mixing quality which led to inhomogeneous concentration of reactant causing inhomogeneous nucleation and growth condition. This report is the first for a controlled nanoparticle synthesis showing the importance of mixing state for the mixing-triggered reaction.

Method (b) was reported by Wang et al. They used titanium isopropoxide cyclohexane solution (oil phase) and aqueous solution of alkali (water phase) as raw material solutions. These two solutions flowed from different inlets and were made to meet in a microreactor to react at the interface between these solutions. Here, the microreactor
